Jack L. Michael

*"One might ask why it is of any value to be able to recognize and correctly name these various effects. I would answer that I have found, for myself at least, that I cannot understand some things unless I can talk about them clearly."**

*From "What Every Student of Behavior Analysis Ought to Learn: A System for Classifying the Multiple Effects of Behavioral Variables," by J. Michael, 1995, *The Behavior Analyst, 18*, p. 284.

ABOUT THE AUTHORS

Photo credit: Jill C. Dardig.

Tim Heron (left), John Cooper (center), and Bill Heward (right)

John Cooper, Tim Heron, and Bill Heward were faculty members at The Ohio State University for a combined 90 years. Together they trained special education classroom teachers and leadership personnel guided by the philosophical, scientific, and technological principles of applied behavior analysis. The Ph.D. program in special education and applied behavior analysis that they and their colleagues developed at OSU was the first doctoral program accredited by the Association for Behavior Analysis International. John, Tim, and Bill each received the Alumni Award for Distinguished Teaching, OSU's highest honor for teaching excellence. They are joint recipients of the Ellen P. Reese Award for Communication of Behavioral Concepts from the Cambridge Center for Behavioral Studies.

John O. Cooper, Ed.D., is Professor Emeritus in the College of Education and Human Ecology at The Ohio State University. His research and teaching interests include precision teaching, inner behavior, fluency building, and verbal behavior. He is a past president of the Standard Celeration Society, past member of the Board of Directors for the Society for the Advancement of Behavior Analysis, and Applied Representative to the Executive Council and as Chairperson, Graduate Program Accreditation Committee of the Association for Behavior Analysis International.

Timothy E. Heron, Ed.D., is Professor Emeritus in the College of Education and Human Ecology at The Ohio State University. Tim's research interests include tutoring systems, inclusion of students with disabilities in general education classrooms, consultation, and self-correction instructional approaches. Tim is co-author of *The Educational Consultant: Helping Professionals, Parents, and Students in Inclusive Classrooms*, Fourth Edition (with Kathleen Harris, 2001). Since 2000, Tim has been an active Federal Aviation Administration, Gold Seal Certified Flight Instructor; has authored the text *Instrument Flying: 10 Indispensable Principles to Know and Remember*; and continues to apply the principles and procedures of applied behavior analysis to the next generation of aviators.

William L. Heward, Ed.D., BCBA-D, is Professor Emeritus in the College of Education and Human Ecology at The Ohio State University. Bill's interests include "low-tech" methods for increasing the effectiveness of group instruction and promoting the generalization and maintenance of newly learned skills. He has authored or co-authored five other books, including *Exceptional Children: An Introduction to Special Education,* Eleventh Edition (with Sheila Alber-Morgan and Moira Konrad, 2017), and *Sign Here: A Contracting Book for Children and Their Parents* (with Jill C. Dardig, 2016). A Fellow and Past President of the Association for Behavior Analysis International, Bill is a recipient of the Fred S. Keller Behavioral Education Award from Division 25 of the American Psychological Association and the Distinguished Psychology Department Alumnus Award from Western Michigan University.

CHAPTER CONTRIBUTORS

Thomas S. Critchfield, Ph.D., is Professor of Psychology at Illinois State University. He earned his doctorate in Behavior Analysis from West Virginia University and completed a post-doctoral fellowship at the Johns Hopkins University School of Medicine. A Fellow and Past President of the Association for Behavior Analysis International and of Division 25 of the American Psychological Association, Tom has served as Associate Editor for the *Journal of the Experimental Analysis of Behavior*, *Perspectives on Behavior Science*, *Mexican Journal of Behavior Analysis*, and *Conch Republic Archives of Psychology*. His interests include derived stimulus relations, punishment and negative reinforcement, effective instruction, and the process of bench-to-bedside scientific translation.

Thomas R. Freeman, M.S., BCBA, is Senior Vice President of ABA Technologies, Inc., where he focuses on the dissemination of behavioral science, in part by helping create curricula and instructional materials for the Florida Institute of Technology ABA Online program. With nearly 40 years of experience in ABA, Tom has held various clinical, supervisory, and administrative positions in Massachusetts and Florida. He has also participated in animal behavior studies with orangutans in Borneo and Hawaiian spinner dolphins, and was Field Director of the University of Hawaii's Humpback Whale Project. Tom is dedicated to applying behavior analysis to mainstream social needs (e.g., general education, environmental issues) and common individual challenges (e.g., anxiety, depression, and grief), and is particularly interested in coordinating ABA and psychiatric services, identifying practices as evidence-based (or not), and studying the evolution of ethics.

Brian A. Iwata, Ph.D., is Distinguished Professor of Psychology and Psychiatry at the University of Florida. He and his students have published over 250 articles and chapters on disorders of learning and behavior and on functional analysis methodology. Brian is a former editor of the *Journal of Applied Behavior Analysis* and past president of the Association for Behavior Analysis International, Division 33 of the American Psychological Association, the Society for the Advancement of Behavior Analysis, the Society for the Experimental Analysis of Behavior, and the Florida Association for Behavior Analysis. He has chaired study sections for both NIH and NIMH and is a fellow of the American Association on Intellectual and Developmental Disabilities, the American Psychological Association, the Association for Behavior Analysis International, and the Association for Psychological Scien ce. In 2015, he received the Gold Medal for Lifetime Achievement in the Application of Psychology from the American Psychological Association.

Linda A. LeBlanc, Ph.D., BCBA-D, Licensed Psychologist, is President of LeBlanc Behavioral Consulting. She received her Ph.D. in 1996 from Louisiana State University. She previously taught at Claremont McKenna College, Western Michigan University, and Auburn University, and was Executive Director of Trumpet Behavioral Health. Her research interests focus on behavioral treatment of autism, technology-based behavioral interventions, behavioral gerontology, supervision and mentorship, and systems development in human services. Dr. LeBlanc has been an associate editor for *Behavior Analysis in Practice, The Analysis of Verbal Behavior,* and the *Journal of Applied Behavior Analysis.* She has been a senior editor for *Education and Treatment of Children* and will serve as the editor of the *Journal of Applied Behavior Analysis* from 2020 to 2022. Linda is the 2016 recipient of the American Psychological Association Nathan H. Azrin Award for Distinguished Contribution in Applied Behavior Analysis, and a fellow of the Association of Behavior Analysis International.

Jose Martinez-Diaz, Ph.D., BCBA-D, is Professor and Director of the School of Behavior Analysis at the Florida Institute of Technology, and CEO of ABA Technologies, Inc., an instructional design and technology company. He earned his doctorate in clinical psychology with an emphasis in behavior analysis and therapy from West Virginia University. Jose's principal areas of interest are practitioner training, professional and ethical issues, instructional design and technology, organizational behavior management, and the conceptual analysis of behavior. A past president of the Florida Association of Behavior Analysis (FABA), Jose has served on the board of directors for the Behavior Analyst Certification Board, the Association of Professional Behavior Analysts (APBA), and the Cambridge Center for Behavioral Studies. Awards recognizing Jose's contributions to effective and ethical practice of behavior analysis include the APBA's Jerry Shook Award and FABA's Charles H. Cox Award for Outstanding Service and Advancement of Behavior Analysis in Florida.

Jack Michael, Ph.D., is Professor Emeritus in the Department of Psychology at Western Michigan University, where he taught for 36 years. His primary scholarly interests are verbal behavior, basic theory regarding motivation, and the technical terminology of behavior analysis. Jack contributed to the founding of the Association for Behavior Analysis International and served as its third president. His publications include the highly acclaimed text *Concepts and Principles of Behavior Analysis* (2004). A Fellow of the Association for Behavior Analysis International and the American Psychological Association, Dr. Michael has received many honors and recognitions, including the Distinguished Service to Behavior Analysis Award from the Association for Behavior Analysis, the 2002 Don Hake Award for Translational Research from Division 25 of the American Psychological Association, the 2012 Victor Laties Lifetime of Service Award from the Society for the Experimental Analysis of Behavior, and Western Michigan University's top two faculty honors: Distinguished Faculty Scholar Award and Distinguished Teaching Award. In 2012, Jack was the first recipient of an award named in his honor by the Verbal Behavior Special Interest Group affiliated with ABAI.

Caio F. Miguel, Ph.D., BCBA-D, is Professor of Psychology at California State University, Sacramento. His research interests span basic, applied, and conceptual issues in the study of motivation, verbal behavior, covert mediation, and derived stimulus relations. Caio has served as editor of *The Analysis of Verbal Behavior* and associate editor for the *Journal of Applied Behavior Analysis*. His publications have appeared in English, Portuguese, and Spanish language journals, and he has given hundreds of professional presentations throughout North America, South America, and Europe. Caio received the 2013–2014 Award for Outstanding Scholarly Work from the College of Social Sciences and Interdisciplinary Studies at CSU Sacramento, and the 2014 Outstanding Mentor Award by the Student Committee of the Association for Behavior Analysis International.

Nancy A. Neef, Ph.D., is Professor Emeritus in the College of Education and Human Ecology at The Ohio State University. She has served as editor of the *Journal of Applied Behavior Analysis,* as president of the Society for the Experimental Analysis of Behavior, and on the Executive Council and as chair of the publication board for the Association of Behavior Analysis International. Nancy has published more than 60 articles and chapters in the areas of developmental disabilities, research methodology, and instructional technology. Much of her research has focused on extensions and applications of basic research in the assessment and treatment of attention-deficit hyperactivity disorder. Nancy was the recipient of the first Distinguished Alumnus Achievement Award in Psychology from Western Michigan University and the 2006 Award for Outstanding Research in Applied Behavior Analysis from Division 25 of the American Psychological Association.

Stephanie M. Peterson, Ph.D., BCBA-D, is Professor and Chair of the Department of Psychology at Western Michigan University. Her primary research interests are choice and concurrent schedules of reinforcement in the treatment of severe problem behavior and in the functional analysis of problem behavior. Stephanie also has interests in applications of behavior analysis to educational interventions and teacher training. She has served on the editorial boards of the *Journal of Applied Behavior Analysis* and *The Behavior Analyst* and currently serves as a consulting senior editor for *Education and Treatment of Children*. She is a former member of the Board of Directors for the Behavior Analyst Certification Board.

Carol Pilgrim, Ph.D., is Professor of Psychology at the University of North Carolina, Wilmington. Her primary research interests are in the analysis, application, and conceptual treatment of relational stimulus control, particularly stimulus equivalence. Carol is a former editor of *The Behavior Analyst* and associate editor of the *Journal of the Experimental Analysis of Behavior* and *The Behavior Analyst.* She has served as President of the Association for Behavior Analysis International (ABAI), the Society for the Advancement of Behavior Analysis, Division 25 of the American Psychological Association (APA), and the Southeastern Association for Behavior Analysis. Carol is a fellow of ABAI and Division 25 of APA, and she has been honored with the North Carolina Board of Governors Teaching Excellence Award (2003), the UNCW Faculty Scholarship Award (2000) and Graduate Mentor Award (2008), and the ABAI Student Committee Outstanding Mentor Award (2006) and Distinguished Service to Behavior Analysis Award (2017).

Ruth Anne Rehfeldt, Ph.D., BCBA-D, is Professor of Behavior Analysis and Therapy at Southern Illinois University. She completed her Ph.D. at the University of Nevada. Dr. Rehfeldt has published over 100 articles and book chapters in behavior analysis, primarily on basic and applied investigations of verbal behavior and derived relational responding, relational frame theory, and acceptance and commitment therapy. Ruth Anne served as the editor and business manager for *The Psychological Record* for 12 years. She is or has been an editorial board member for a number of behavior analytic journals, including *Journal of Applied Behavior Analysis, Journal of the Experimental Analysis of Behavior,* and *The Analysis of Verbal Behavior*. She has held a number of leadership positions within the Association for Behavior Analysis International. Dr. Rehfeldt has won a number of teaching and research awards during her tenure at Southern Illinois University.

Richard G. Smith, Ph.D., BCBA-D, LBA-TX, is Associate Professor in the Department of Behavior Analysis at the University of North Texas, where he served as Department Chair for 13 years. Rick received his master's and doctoral degrees at the University of Florida. His primary research interest is in the assessment and treatment of behavior disorders in persons with developmental disabilities, with specific areas of focus in motivational variables and advances in functional analysis procedures. A former associate editor for the *Journal of Applied Behavior Analysis,* Rick's work has been recognized with the American Psychological Association's Division 25 B. F. Skinner Award for Innovative and Important Research by a New Researcher (1997), the Texas Chapter of the American Association on Intellectual and Developmental Disabilities' Research Award (2000), the Texas Association for Behavior Analysis' Career Contributions to Behavior Analysis in Texas Award (2014), and the University of North Texas President's Special Faculty Recognition Award (2017).

Mark L. Sundberg, Ph.D., BCBA-D, is a Licensed Psychologist in private practice. He specializes in language research and the development of language assessment and intervention programs for children and adults with language delays. Mark is founder and past editor of the journal *The Analysis of Verbal Behavior,* a past president of The Northern California Association for Behavior Analysis, and a past chair of the Publication Board of the Association for Behavior Analysis International, and has served on the Board of Directors of the B. F. Skinner Foundation. Mark is the author of *The Verbal Behavior Milestones Assessment and Placement Program (VB-MAPP),* and co-author (with James W. Partington) of the books *Teaching Language to Children with Autism or Other Developmental Disabilities* and the original *Assessment of Basic Language and Learning Skills: The ABLLS.* Mark has received several awards, including the 2001 Distinguished Psychology Department Alumnus Award from Western Michigan University and the 2013 Jack Michael Outstanding Contributions in Verbal Behavior Award from ABAI's Verbal Behavior Special Interest Group.

PREFACE

As it was 17 years ago, when we began writing the previous edition of this book, our overriding goal for the third edition was to produce an accurate, comprehensive, and contemporary description of applied behavior analysis. The result is a text that demands concentrated and serious study.

Despite its size, scope, and in-depth treatment of concepts, principles, procedures, and issues, *Applied Behavior Analysis, Third Edition*, should be viewed as an introductory text for two reasons. First, the reader need not possess any specialized prerequisite knowledge to understand the content. Second, attaining a full understanding of applied behavior analysis requires considerable study and guided experience beyond this text. There is no topic presented within these pages that has not been treated in greater depth elsewhere. Students of applied behavior analysis should build upon what they learn from this book by reading other sources. How much reading is needed to fully grasp and appreciate applied behavior analysis? Don Baer (2005), one of the co-founders of applied behavior analysis, estimated that

> [T]he cost of knowing well the basic principles and paradigms of the theoretical and experimental aspects of behavior analysis would require about 2,000 pages and some laboratory experience. ABA shares the same basic principles with the theoretical and experimental branches of behavior analysis and adds to them an even larger number of secondary principles, strategies, and tactics for making those basic principles work in the real world as they do in the laboratory. ABA also adds a set of principles about ethical and humane practice, prominent among which is the need to be certain, through constant and extensive measurement and experimentation, that the particular case in hand is going well and will continue to go well—because it will change as it progresses. The cost of knowing all that is, I estimate, about 3,000 pages of reading and several years of supervised practical experience. (pp. 27–28)

The field has grown markedly since its formal inception in 1968, so much so that Baer's 3000-page reading assignment might now exceed 4000 pages, or more. We trust that this book's 800-plus pages will contribute to Baer's reading assignment for many future behavior analysts. Specific suggestions for additional readings in applied behavior analysis and in the conceptual and basic research branches of behavior analysis are cited throughout this text.

Again, while our objective is to provide a complete description of the principles and procedures for changing and analyzing socially important behavior, mastery of this book's content represents the beginning, not the end, of one's study of applied behavior analysis. If our efforts as textbook writers and chapter contributors, combined with those of instructors who assign this book, are successful, the dedicated student will come away with a sound repertoire of fundamental knowledge about applied behavior analysis. In turn, this knowledge will serve as the foundation for more advanced study and supervised practica that ultimately will lead to independent efforts to change and understand behavior that are scientifically sound, socially significant, and ethically appropriate.

TERMINOLOGY

Meaningful description of any scientific activity necessitates a standard set of technical terms. Effectively communicating the design, implementation, outcomes, and/or theoretical bases of an applied behavior analysis requires the accurate use of the discipline's terminology. Throughout this text, we have made every effort to define and use behavior analytic terminology in a conceptually systematic and consistent manner. Mastering the specialized vocabulary of applied behavior analysis is an important initial step in embracing the science and participating effectively as a researcher, practitioner, or consumer. We encourage students to study the field's terminology with diligence. Toward that end, the third edition includes a glossary of more than 500 technical terms and concepts.

REFERENCES, EXTRACTS, NOTES, AND GRAPHS

An important function of any introductory text to a scientific discipline is to expose students to the empirical and conceptual literature of that field. This edition contains more than 2700 citations to primary-source publications, including historically important experiments (e.g., the first graph presented by B. F. Skinner in his 1938 book *The Behavior of Organisms*), and classic and contemporary examples of applied behavior analysis research—most of which were published in the field's flagship journal, the *Journal of Applied Behavior Analysis.* We also make extensive use of quotations and extracts from key publications representing the conceptual literature. We have done this not only for the historical and/or technical authority these authors provide, but also because their inclusion increases students' exposure to and appreciation for the field's rich primary-source literature.

The third edition includes more than 150 graphs of data from peer-reviewed research, many of which are accompanied by detailed descriptions of the study's methodology. We have a fourfold purpose for providing many procedures, graphs, and references. First, we want to illustrate behavior analysis principles and procedures with actual applications and real data, not hypothetical examples. Second, reading the procedural descriptions will help students appreciate the high degree of technical precision and control of complex environments that researchers and practitioners must achieve to solve problems and show functional relations between variables. Third, the references provide students whose interests are piqued by the descriptions or graphs with directions to the original studies for more in-depth study. Finally, the graphs provide multiple opportunities for students to develop and refine—through practice and discussion with their instructors, mentors, and fellow students—higher-level visual analysis skills.

THIRD EDITION CONTENT ENHANCEMENTS AND FEATURES

Applied behavior analysis has become more mature and sophisticated since the second edition was published. Although the basic principles of behavior remain unchanged, advances in all three interrelated domains of the science of behavior—theoretical, basic research, and applied research—have improved our understanding of those principles and led to increased effectiveness in developing and applying effective and humane behavior change interventions. These developments are reflected in the more than 1,000 new references to the conceptual, basic, and applied literatures of behavior analysis added to this edition.

Chapters by Outstanding Authors

The third edition includes seven chapters authored by prominent scholars in applied behavior analysis. This group of contributors includes the current and two former editors of the *Journal of Applied Behavior Analysis,* two previous editors of *The Analysis of Verbal Behavior,* and associate editors of the *Journal of the Experimental Analysis of Behavior*. Members of this well-known and prolific group of behavior analysts first reported some of the most significant advances in behavior analysis in publications.

Negative Reinforcement

In Chapter 12, Negative Reinforcement, Rick Smith and Brian Iwata present an authoritative account of this commonly misunderstood and misapplied form of reinforcement. In addition to precisely defining this principle, dispelling misconceptions about it, and illustrating applications across a broad spectrum of cases, Smith and Iwata provide specific guidelines for incorporating negative reinforcement into behavior change interventions.

Motivation

Until recently, motivation, a major topic in psychological theories and everyday explanations of behavior, has been an assumed, but inadequately understood, topic in behavior analysis. Due largely to the work of Jack Michael, behavior analysts now have a much better understanding of motivation and its role within applied behavior analysis. In Chapter 16, Motivating Operations, Jack Michael and Caio Miguel explain how certain antecedent events have dual motivating effects: a behavior-altering effect, which makes certain behaviors more (or less) likely; and a value-altering effect, which makes certain events more (or less) effective as reinforcement.

Verbal Behavior

In Chapter 18, Verbal Behavior, Mark Sundberg contrasts B. F. Skinner's functional analysis of verbal behavior with traditional approaches to language, defines and gives examples of basic types of elementary verbal operants (e.g., mands, tacts, intraverbals), and describes implications and applications for these concepts in designing and implementing language intervention programs.

Equivalence-based Instruction

In Chapter 19, Equivalence-based Instruction, Carol Pilgrim builds upon Sidman's groundbreaking research on stimulus equivalence to explain the conditions in which learners acquire new skills and verbal relations without direct instruction on those skills. Pilgrim defines equivalence-based instruction, describes its key outcomes—class formation, delayed emergence, class expansion and class merger, transfer of function, and contextual control—and shows how lessons can be designed to promote those outcomes.

Nonequivalence Relations

In Chapter 20, Engineering Emergent Learning with Nonequivalence Relations, Tom Critchfield and Ruth Anne Rehfeldt explain how people make sense of and function effectively in a world of arbitrary relations in which stimuli "go together," not because they share physical properties, but rather because social-verbal reinforcement contingencies teach people to relate them in a certain way. Relational frame theory (RFT) and acceptance and commitment therapy (ACT), a therapeutic approach grounded in RFT, are described.

Functional Behavior Assessment

In Chapter 27, Functional Behavior Assessment, Stephanie Peterson and Nancy Neef describe one of the more significant developments in applied behavior analysis. Functional behavior assessment has become a well-established method for discovering the function that a problem behavior serves for a person (e.g., to obtain social attention, to avoid an assigned task, to provide sensory stimulation), information that enables practitioners to design interventions that teach adaptive replacement behaviors that serve the same function.

Ethics

In Chapter 31, Ethical and Professional Responsibilities of Applied Behavior Analysts, Tom Freeman, Linda LeBlanc, and Jose Martinez-Diaz clarify what ethical behavior is, explain why ethical behavior is a necessary part of the applied behavior analyst's repertoire, review ethical codes of conduct for behavior analysts, and describe specific procedures for ensuring and assessing ethical practice. New content regarding client services (e.g., informed consent, conflict of interest) and, importantly, ethical implications of new technologies, social media, and professional networking to support ethical behavior is presented.

TEXT ORGANIZATION AND STRUCTURE

The book's 31 chapters are organized into 13 parts. The two chapters in Part 1 describe some tenets that are fundamental to all scientific endeavors, outline a history of behavior analysis as a natural science approach to understanding behavior, define applied behavior analysis, and describe principles and concepts of that science. Parts 2 and 3 examine the elements necessary for an applied behavior analysis. Part 2 presents considerations, criteria, and procedures for selecting, defining, and measuring *applied behavior.* The five chapters in Part 3 examine the logic

and operation of specific tactics for the experimental *analysis* of behavior–environment relations, and some issues in planning, replicating, and evaluating analyses of behavior.

The seven chapters in Parts 4 through 6 explore the two most significant principles of behavior—reinforcement and punishment; how antecedent events alter one's motivation to respond; and how behavior comes under the discriminative control of environmental conditions. Part 7 is a detailed examination of B. F. Skinner's analysis of verbal behavior and its implications and applications for language development. The five chapters in Part 8 describe how applied behavior analysts use equivalence-based instruction, nonequivalence relations, imitation, modeling, observational learning, shaping, and chaining to develop new skills and patterns of behavior from simple to complex.

Part 9 details how problem behaviors can be decreased with nonpunishment interventions: extinction, differential reinforcement, and antecedent interventions. Part 10 describes functional behavioral assessment, sophisticated methods for determining the purpose that problem behavior serves for a person, and important information that leads to the design of treatments that replace the problem behavior with adaptive alternative behavior serving the same function.

Part 11 describes four special applications of behavior change technology: token economy, contingency contracting, group contingencies, and self-management. Part 12 outlines strategies and tactics for increasing the likelihood that efforts to change behavior yield generalized outcomes: behavior changes that maintain across time, occur in appropriate settings and situations beyond the training setting, and spread to other useful behaviors. The book's final part describes ethical and professional responsibilities of behavior analysts, ethical implications of new technologies, social media, and professional networking.

SUPPLEMENTS AND RESOURCES FOR STUDENTS AND INSTRUCTORS

Instructor's Resource Manual and Test Bank (ISBN 1-292-32464-3)

An Instructor's Resource Manual includes suggestions for learning activities, additional Experiencing Firsthand exercises, supplementary lectures, case study analyses, discussion topics, group activities, additional media resources, and answers to all multiple-choice questions and essay-type questions. The *Test Bank* that accompanies this text contains more multiple-choice and essay-type questions. Some items (lower-level questions) simply ask students to identify or explain concepts and principles they have learned. But many others (higher-level questions) ask students to apply those same concepts and principles to specific classroom situations—that is, to actual student behaviors and teaching strategies.

Powerpoint® Slides (ISBN 1-292-32466-X)

The PowerPoint slides include key concept summarizations, diagrams, and other graphic aids to enhance learning. They are designed to help students understand, organize, and remember core concepts and theories.

Companion Website

Text Content Related to the Behavior Analyst Certification Board® BCBA® & BCABA® Behavior Analyst Task List© Fifth Edition

The Behavior Analyst Certification Board® (BACB®) is a nonprofit corporation established in 1998 to meet professional credentialing needs identified by behavior analysts, governments, and consumers of behavior analysis services. To be certified as a Board Certified Behavior Analyst® (BCBA®) or a Board Certified Assistant Behavior Analyst® (BCaBA®), a person must meet academic-degree, educational, and practical-experience eligibility requirements and then pass a psychometrically sound examination. The BCBA and BCaBA examinations are based on the *BCBA/BCaBA Task List* (5th ed.; BACB, 2017a), which was developed by 16 subject matter experts and subsequently content validated through a survey of more than 6000 BACB certificants (BACB, 2017b). The complete *BCBA/BCaBA Task List* (5th ed.) is available on the companion website (www.pearsonglobaleditions.com).

We have connected the content of this text to the tasks that the BACB determined are necessary to function as an entry-level behavior analyst. A chart identifying which Task List items are covered in each chapter is also provided on the companion website. Due to the complex nature of applied behavior analysis, in which the concepts and principles and their application are interrelated and not easily or effectively presented in a linear fashion, some Task List items are covered in more than one chapter. Students studying for BCBA and BCaBA examinations can look up key words from Task List items in the Subject Index to identify the page numbers where relevant information about each item in the *BCBA/BCaBA Task List* (5th ed.) can be found.

This text presents the basic knowledge that a qualified behavior analyst must possess. Although mastering this content will help you obtain a passing score on the BCBA or BCaBA examinations, two important qualifiers must be recognized. First, the BCBA and BCaBA examinations require knowledge beyond that included in this, or any, single textbook. Therefore, to further prepare for the examinations we encourage students to study original sources, engage in supervised practica, and discuss areas of personal interest with trusted and competent mentors. Second, no matter how accurate, extensive, and current this textbook may be, and no matter how thoroughly a student masters its content, he or she will not be fully qualified to function as a behavior analyst. Successful completion of the required coursework in behavior analysis is but one step in the preparation to become a BCBA or a BCaBA. For the most recent information on the BACB requirements, visit the Behavior Analyst Certification Board's website at www.BACB.com.

Acknowledgments

The third edition of *Applied Behavior Analysis* is the product of the collective and cumulative efforts of many people. Although space limitations prevent us from thanking everyone by name, we would like to acknowledge those who made substantial contributions to the book's content or production during the 3 years we spent revising the text. First and foremost, we are deeply grateful to the authors of the seven contributed chapters: Rick Smith and Brian Iwata (Negative Reinforcement); Jack Michael and Caio Miguel (Motivating Operations); Mark Sundberg (Verbal Behavior); Carol Pilgrim (Equivalence-based Instruction); Tom Critchfield and Ruth Anne Rehfeldt (Engineering Emergent Learning with Nonequivalence Relations); Stephanie Peterson and Nancy Neef (Functional Behavior Assessment); and Tom Freeman, Linda LeBlanc, and Jose Martinez-Diaz (Ethical and Professional Responsibilities of Applied Behavior Analysts). Because of their efforts, third edition readers will be introduced to important topics in applied behavior analysis by scholars whose research has helped to define and develop those areas.

We thank the Behavior Analyst Certification Board (BACB) for allowing us to integrate the Behavior Analyst Certification Board® BCBA/BCaBA Task List (5th ed.) throughout the revised edition of our text. We are especially grateful to Jim Carr, Chief Executive Officer of the Behavior Analyst Certification Board. Jim graciously continued the arrangement with the BACB we first developed with Jerry Shook for the second edition.

In-depth reviews of the second edition by Jan Montgomery (Florida Institute of Technology), Bethany Raiff (Rowan University), Corey Robertson (Florida Institute of Technology), Tina Sidener (Caldwell University), and Carlos A. Zuluaga (Florida Institute of Technology) offered helpful recommendations for improvement that we incorporated into this edition. The third edition is also enhanced by input and assistance from the following colleagues: Bill Ahearn (New England Center for Children), Sheila Alber-Morgan (The Ohio State University), Nikolay Alipov (Russian National Investigation Medical University), Fernando Armendariz (FABA, Inc.), Judah Axe (Simmons College), Vince Carbone (The Carbone Clinic), Sharon Chien (SEEK), Darlene Crone-Todd (Salem University), Alyce Dickinson (Western Michigan University), Anca Dumitrescu (ATCA, Romania), Ronnie Dietrich (Wing Institute), Tim Hackenberg (Reed College), Louis Hagopian (Kennedy Krieger Institute), Rob Holdsambeck (Cambridge Center for Behavioral Studies), Mickey Keenan (Ulster University, Northern Ireland), Tracy Kettering (Bancroft), Jonathan Kimball (private practice, Maine), Moira Konrad (The Ohio State University), Douglas Kostewicz (University of Pittsburgh), Rick Kubina (Penn State University), Ed Morris (University of Kansas), Dave Palmer (Smith College), Robert Ross (Beacon ABA Services), Hank Schlinger (California State University, Los Angeles), Majda Seuss (Association for Behavior Analysis International), and Janet Twyman (Center for Innovations in Learning).

Turning more than 2500 pages of manuscript into the book you are holding required the support and contributions of a talented team of publishing professionals at Pearson. Copy editor Joanne "Bonnie" Boehme's talent in turning rough prose into clear and understandable text is evident on every page. The bumpy spots that remain are our responsibility. Production Editor Clara Bartunek and Content Producer Janelle Rogers worked closely and patiently with us throughout. Ann Castel Davis, our former editor, was instrumental in convincing us to tackle this edition. We are grateful to Ann and to Director and Publisher Kevin Davis, for their long-standing commitment not only to this title but also to publishing books on behavior analysis and evidence-based practices in special education.

Last, but certainly not least, among those we wish to acknowledge for important and continuing contributions to the "White Book" is Keith "Dutch" Van Norman. Dutch designed the creative and captivating covers of the second and third editions. Thanks, Dutch!

Throughout our careers, each of us has benefited immensely from mentors, colleagues, and students who provided us with the instruction, models, and inspiration needed to attempt to write a book like *Applied Behavior Analysis*. To the extent that our goals in writing this book are achieved, each of them will have played an important role. To the professors who first taught us about applied behavior analysis—Saul Axelrod, Vance Cotter, Todd Eachus, Dick Malott, Jack Michael, Joe Spradlin, and Don Whaley—we will be indebted always. Many faculty colleagues at Ohio State helped us create and sustain an academic environment where work to advance, teach, and apply behavior analysis for the betterment of learners with disabilities is valued. Their individual and collective support is appreciated. We'd be remiss not to single out our longtime department chair, Thomas M. Stephens, for his sustained support and leadership. Although not formerly trained as a behavior analyst, Tom was deeply committed to evidence-based instruction and direct and frequent measurement of student performance. Tom provided much-needed administrative backing, sometimes in the form of covering fire that allowed us to build an applied behavior analysis program in a college dominated by nonbehavioral perspectives. We also wish to thank the many students whom we have been lucky enough to teach and learn with over the years. Your enthusiasm and dedication inspired, encouraged, and motivated us.

Finally, we want to acknowledge the support of our families, past and present: Bunny, Chris, Sharon, Greg, Brian, and Carroll and Vera Cooper; Marge Heron, Kathy, Patrick, and Leia Rogers, Christine, Matt, Audrey and Brady Harsh, and Ray and Bernice Heron; and Jill Dardig, Lee Heward, Lynn Heward and Marcus Bonde, and Joe and Helen Heward. Without their enduring love and support, we would never have attempted the first edition of this book, let alone a second and a third!

BRIEF CONTENTS

CONTENTS

GLOBAL EDITION ACKNOWLEDGMENTS

Pearson would like to thank Ruchika Kanwal for her work on this Global Edition.

PART 1

Introduction and Basic Concepts

We believe that prior to learning specific principles and procedures for analyzing and changing behavior, the student of applied behavior analysis should be introduced to the historical and conceptual foundations of the science. Basic knowledge and appreciation of the scientific and philosophical underpinnings of behavior analysis are requisites to a thorough understanding of the discipline's nature, scope, and potential. We also believe a preliminary overview of basic concepts, principles, and terminology makes the in-depth study of behavior analysis to follow more effective. The two chapters in Part 1 support these two beliefs. Chapter 1 describes the scientific, conceptual, and philosophical roots of applied behavior analysis and identifies the discipline's defining dimensions, characteristics, and overall goals. Chapter 2 defines the field's fundamental elements—behavior and the environmental antecedent and consequential events that influence it—and introduces key terms and principles that describe relationships among these elements.

CHAPTER 1

Definition and Characteristics of Applied Behavior Analysis

LEARNING OBJECTIVES

- Describe the basic characteristics and goals of science.
- Explain behavior in accordance with the philosophical assumptions of behavior analysis.
- Explain determinism as it relates to behavior analysis.
- State distinguishing features of mentalistic and environmental explanations of behavior.
- Describe and explain behavior in behavior analytic terms.
- State and describe each of the dimensions of applied behavior analysis.

[S]ince I was a child I always found my biggest reinforcer was something called understanding. I liked to know how things worked. And of all of the things in the world there are to understand, it became clear to me that the most fascinating was what people do. I started with the usual physical science stuff, and it was intriguing to me to understand how radios work, and how electricity works, and how clocks work, etcetera. But when it became clear to me that we could also learn how people work—not just biologically, but behaviorally—I thought that's the best of all. Surely, everyone must agree that that's the most fascinating subject matter. That there could be a science of behavior, of what we do, of who we are? How could you resist that?

—Donald M. Baer in Heward & Wood, (2003, p. 302)

Applied behavior analysis is a science devoted to understanding and improving human behavior. Other disciplines have similar intents. What sets applied behavior analysis apart? The answer lies in its focus, goals, and methods. Applied behavior analysts focus on behaviors of social importance, they intervene with research-based strategies and tactics to improve the targeted behaviors, and they use scientific methods—objective description, measurement, and experimentation—to demonstrate reliable relations between their interventions and the behavioral improvements. In short, applied behavior analysis, or ABA, is a scientific approach for discovering environmental variables that reliably influence socially significant behavior and for developing a technology of behavior change that takes practical advantage of those discoveries.

This chapter briefly outlines the history and development of behavior analysis, discusses the philosophy that underlies the science, and identifies defining dimensions and characteristics of applied behavior analysis. Because applied behavior analysis is first and foremost a science, we begin with an overview of precepts shared by scientists in all disciplines.

SCIENCE: BASIC CHARACTERISTICS AND A DEFINITION

Science is a systematic approach for seeking and organizing knowledge about the natural world. Before offering a definition of science, we discuss the purpose of science and the basic assumptions and attitudes that guide the work of all scientists, irrespective of their fields of study.

Purpose of Science

The overall goal of science is to achieve a thorough understanding of the phenomena under study—socially important behavior change, in the case of applied behavior analysis. Science differs from other sources of knowledge or ways we obtain knowledge about the world around us (e.g., contemplation, common sense, logic, authority figures, religious or spiritual beliefs, political campaigns, advertisements, testimonials). Science seeks to discover nature's truths: facts and universal laws that exist and operate independent of the opinions and beliefs of any person or group, including the scientist. Therefore, scientific knowledge must be separated from any personal, political, economic, or other reasons for which it was sought. Although it is frequently misused, science is not a tool for validating the cherished or preferred versions of "the truth" held by any group, corporation, government, or institution.

Different types of scientific investigations yield knowledge enabling one or more of three levels of understanding: description, prediction, and control. Each level of understanding contributes to the scientific knowledge base of a given field of inquiry.

Description

Systematic observation enhances the understanding of a given phenomenon by enabling scientists to describe it accurately. Descriptive knowledge consists of a collection of facts about the observed events that can be quantified, classified, and examined for possible relations with other known facts—a necessary and important activity for any scientific discipline. The knowledge obtained from descriptive studies often suggests possible hypotheses or questions for additional research.

The work of John James Audubon, a naturalist and painter in the early 19th century, provides a classic example of descriptive science. While observing birds in their natural habitat, Audubon documented their habits with extensive field notes and made detailed drawings. He identified 25 new species of birds. His major work, *The Birds of America* (Audubon, 1827–1838), contains 435 hand-colored life-sized prints of birds in their natural habitat and is considered one of the finest ornithological works ever completed.

White's (1975) study of classroom teachers' "natural rates" of approval (verbal praise or encouragement) and disapproval (criticisms, reproach) is an example of descriptive research in applied behavior analysis. Observations of 104 classroom teachers in grades 1 to 12 yielded two major findings: (a) Rates of teacher praise dropped with each grade level, and (b) in every grade after second, teachers delivered statements of disapproval to students at rates exceeding their rates of praise. The results of this descriptive study led to dozens of subsequent studies aimed at discovering factors responsible for the disappointing findings, analyzing the effects of disproportionate rates of disapproval and praise on student behavior, and increasing teachers' effective use of praise (e.g., Alber, Heward, & Hippler, 1999; Duchaine, Jolivette, & Fredrick, 2011; Fullerton, Conroy, & Correa, 2009; Mrachko, Kostewicz, & Martin, 2017; Niwayama & Tanaka-Matsumi, 2016; Sutherland, Wehby, & Yoder, 2002).

Prediction

A second level of scientific understanding occurs when repeated observations reveal that two events consistently covary with each other. That is, in the presence of one event (e.g., approaching winter) another event occurs (or fails to occur) with some specified probability (e.g., certain birds fly south). When systematic covariation between two events is found, this relationship—termed a *correlation*—can be used to predict the relative probability that one event will occur, based on the presence of the other event. "We obviously cannot intervene or manipulate the movement of the stars or planets, but by studying their movements we can gauge the seasons and when we can plant crops to produce a bountiful harvest" (Moore, 2010, p. 48).

Because no variables are manipulated or controlled by the researcher, a correlational study cannot demonstrate whether one of the observed variables is responsible for the changes in the other variable, and no such relations should be inferred. A strong correlation exists between hot weather and an increased incidence of drowning deaths, but we should not assume that a hot and humid day causes anyone to drown. Hot weather also correlates with other factors, such as an increased number of people (both swimmers and nonswimmers) seeking relief in the water, and many instances of drowning have been found to be a function of factors such as the use of alcohol or drugs, the relative swimming skills of the victims, strong riptides, and the absence of supervision by lifeguards.[1]

In addition to their usefulness in aiding prediction, the findings of correlational studies can suggest the possibility of causal relations, which can then be explored with experimental studies. The most common type of correlational study reported in the applied behavior analysis literature compares the relative rates or conditional probabilities of two or more observed (but not manipulated) variables (e.g., Atwater & Morris, 1988; Symons, Hoch, Dahl, & McComas, 2003; Thompson & Iwata, 2001). For example, McKerchar and Thompson (2004) found correlations between problem behavior exhibited by 14 preschool children and the following consequent events: teacher attention (100% of the children), presentation of some material or item to the child (79% of the children), and escape from instructional tasks (33% of the children). The results of this study not only provide empirical validation for the social consequences typically used in clinical settings to analyze the variables maintaining children's problem behavior, but also increase confidence in the prediction that interventions based on the findings from such assessments will be relevant to the conditions that occur naturally in preschool classrooms (see Chapter 27). In addition, by revealing the high probabilities with which teachers responded to problem behavior in ways that are likely to maintain and strengthen it, McKerchar and Thompson's findings also point to the need to train teachers in more effective ways to respond to problem behavior.

Control

The ability to predict with a certain degree of confidence is a valuable and useful result of science; prediction enables preparation. However, the greatest potential benefits from science are derived from the third, and highest, level of scientific understanding—control. Evidence of the kinds of control that can be derived from scientific findings in the physical and biological sciences surrounds us in the everyday technologies we take for granted: pasteurized milk and the refrigerators we store it in; flu shots and the automobiles we drive to go get them; pain relievers and the televisions that bombard us with advertisements and news stories about the drugs.

> The scientific "system," like the law, is designed to enable us to handle a subject matter more efficiently . . . When we have discovered the laws which govern a part of the world about us, we are then ready to deal effectively with that part of the world. By predicting the occurrence of an event we are able to prepare for it. By arranging conditions in ways specified by the laws of a system, we not only predict, we control: we "cause" an event to occur or to assume certain characteristics. (Skinner, 1953, pp. 13–14)

Functional relations, the primary products of basic and applied research in behavior analysis, provide the kind

of scientific understanding that is most valuable and useful to the development of a technology for changing behavior. A **functional relation** exists when a well-controlled experiment demonstrates that a specific change in one event (the *dependent variable*) is reliably produced by specific manipulations of another event (the *independent variable*), and that the change in the dependent variable was unlikely to be the result of other extraneous factors (*confounding variables*).

Johnston and Pennypacker (1980) described functional relations as "the ultimate product of a natural scientific investigation of the relation between behavior and its determining variables" (p. 16).

> Such a "co-relation" is expressed as $y = f(x)$, where x is the independent variable or argument of the function, and y is the dependent variable. In order to determine if an observed relation is truly functional, it is necessary to demonstrate the operation of the values of x in isolation and show that they are sufficient for the production of y. . . . [H]owever, a more powerful relation exists if necessity can be shown (that y occurs *only if* x occurs). The most complete and elegant form of empirical inquiry involves applying the experimental method to identifying functional relations. (Johnston & Pennypacker, 1993a, p. 239)

The understanding gained by the scientific discovery of functional relations is the basis of applied technologies in all fields.

Assumptions and Attitudes of Science

> *Science is first of all a set of attitudes.*
>
> —B. F. Skinner, (1953, p. 12)

The definition of science lies not in test tubes, spectrometers, or electron accelerators, but in the behavior of scientists. To begin to understand any science, we need to look past the apparatus and instrumentation that are most readily apparent and examine what scientists do.[2] The pursuit of knowledge is properly called *science* when it is carried out according to general methodological precepts and expectations that define science. All scientists share a fundamental assumption about the nature of events that are amenable to investigation by science, general notions about basic strategy, and perspectives on how to view their findings. These attitudes of science—determinism, empiricism, experimentation, replication, parsimony, and philosophic doubt—constitute a set of overriding assumptions and values that guide the work of all scientists (Whaley & Surratt, 1968).

Determinism

Science is predicated on the assumption of **determinism**. All scientists presume that the universe is a lawful and orderly place in which all phenomena occur as the result of other events. In other words, events do not just happen willy-nilly; they are related in systematic ways to other factors, which are themselves physical phenomena amenable to scientific investigation.

If the universe were governed by *accidentalism,* a philosophical position antithetical to determinism that holds that events occur by accident or without cause, or by *fatalism,* the belief that events are predetermined, the scientific discovery of functional relations and use of those discoveries to improve things would be impossible.

> If we are to use the methods of science in the field of human affairs, we must assume behavior is lawful and determined. We must expect to discover what a man does is the result of specifiable conditions and that once these conditions have been discovered, we can anticipate and to some extent determine his actions. (Skinner, 1953, p. 6)

Determinism plays a pivotal dual role in the conduct of scientific practice: It is at once a philosophical stance that does not lend itself to proof and the confirmation that is sought by each experiment. In other words, the scientist first assumes lawfulness and then proceeds to look for lawful relations (Delprato & Midgley, 1992).

Empiricism

> *When you can measure what you are speaking about, and express it in numbers, you know something about it; but when you cannot measure it, when you cannot express it in numbers, your knowledge is of a meagre and unsatisfactory kind*
>
> — Lord Kelvin, (1824–1907)

Scientific knowledge is built on, above all, **empiricism**—the practice of objective observation and measurement of the phenomena of interest. Objectivity in this sense means "independent of the individual prejudices, tastes, and private opinions of the scientist. Results of empirical methods are objective in that they are open to anyone's observation and do not depend on the subjective belief of the individual scientist" (Zuriff, 1985, p. 9).

In the prescientific era (and in nonscientific and pseudoscientific activities today) (Nichols, 2017), knowledge was (and is) the product of contemplation, speculation, personal opinion, authority, and the "obvious" logic of common sense. The scientist's empirical attitude, however, demands objective observation based on thorough description, systematic and repeated measurement, and precise quantification of the phenomena of interest.

As it is in every scientific field, empiricism is the foremost rule in behavior analysis. Every effort to understand, predict, and improve behavior hinges on the behavior analyst's ability to completely define, systematically observe, and accurately and reliably measure occurrences and nonoccurrences of the behavior of interest.

Experimentation

Experimentation is the basic strategy of most sciences. Whaley and Surratt (1968) used the following anecdote to introduce the need for experimentation.

> A man who lived in a suburban dwelling area was surprised one evening to see his neighbor bow to the four winds, chant a strange melody, and dance around his front lawn beating a small drum. After witnessing the same ritual for over a month, the man became overwhelmed with curiosity and decided to look into the matter.

> "Why do you go through this same ritual each evening?" the man asked his neighbor.
>
> "It keeps my house safe from tigers," the neighbor replied.
>
> "Good grief!" the man said. "Don't you know there isn't a tiger within a thousand miles of here?"
>
> "Yeah," the neighbor smiled. "Sure works, doesn't it!" (pp. 23–2 to 23–3)

When events are observed to covary or occur in close temporal sequence, a functional relation may exist, but other factors may be responsible for the observed values of the dependent variable. To investigate the possible existence of a functional relation, an experiment (or better, a series of experiments) must be performed in which the factor(s) suspected of having causal status are systematically controlled and manipulated while the effects on the event under study are carefully observed.

Reliably predicting and controlling any phenomena, including the presence of tigers in one's backyard, requires identifying and manipulating the factors that influence those phenomena. One way that the individual described previously could use the experimental method to evaluate the effectiveness of his ritual would be to first move to a neighborhood in which tigers are regularly observed and then systematically manipulate the use of his anti-tiger ritual (e.g., 1 week off, 1 week on, 1 week off, 1 week on) while observing and recording the presence of tigers under the no-ritual and ritual conditions.

> The experimental method is a method for isolating the relevant variables within a pattern of events. . . . [W]hen the experimental method is employed, it is possible to change one factor at a time (independent variable) while leaving all other aspects of the situation the same, and then to observe what effect this change has on the target behavior (dependent variable). Ideally, a functional relation may be obtained. Formal techniques of experimental control are designed to make sure that the conditions being compared are otherwise the same. Use of the experimental method serves as a necessary condition (sine qua non) to distinguish the experimental analysis of behavior from other methods of investigation. (Dinsmoor, 2003, p. 152)

Thus, an **experiment** is a controlled comparison of some measure of the phenomenon of interest (the dependent variable) under two or more different conditions in which only one factor at a time (the independent variable) differs from one condition to another. Strategies and tactics for conducting experiments in applied behavior analysis are described in Chapters 7 through 10.

Most of the studies cited in this text are experiments that have demonstrated or discovered a functional relation between a target behavior and one or more environmental variables. Such studies are said to have achieved a functional analysis. The term **functional analysis** has two meanings in contemporary behavior analysis literature. In its original and most fundamental usage, *functional analysis* denotes demonstrations of functional relations between environmental variables and behavior. Schlinger and Normand (2013) reported that Skinner used the term 36 times in *Science and Human Behavior* and cited this example:

> The external variables of which behavior is a function provide for what may be called a causal or *functional analysis*. We undertake to predict and control the behavior of the individual organism. This is our "dependent variable"—the effect for which we are to find the cause. Our "independent variables"—the causes of behavior—are the external conditions of which behavior is a function. Relations between the two—the "cause-and-effect relationships" in behavior—are the laws of a science. (Skinner, 1953, p. 35, italics added)

Iwata, Dorsey, Slifer, Bauman, and Richman (1982) introduced the second and today most widely recognized usage of *functional analysis* in their groundbreaking article describing an experimental methodology for determining environmental variables and contingencies maintaining problem behavior (see Chapter 27). In its original meaning, functional analysis provides the very foundation for an experimental science of behavior; as a method for assessing the controlling variables for problem behavior, functional analysis informs the design of effective treatments.

Replication

The results of a single experiment—no matter how well it was designed and conducted, no matter how clear and impressive the findings—are never sufficient to earn an accepted place among the scientific knowledge base of any field. Although the data from a single experiment have value in their own right and cannot be discounted, only after an experiment has been replicated a number of times with the same basic pattern of results are scientists convinced of the findings.

Replication—repeating of experiments (as well as repeating independent variable conditions within experiments)—"pervades every nook and cranny of the experimental method" (Johnston & Pennypacker, 1993a, p. 244). Replication is the primary method with which scientists determine the reliability and usefulness of their findings and discover their mistakes (Johnston & Pennypacker, 1980; 1993a; Sidman, 1960). Replication—not the infallibility or inherent honesty of scientists—is the primary reason science is a self-correcting enterprise that ultimately gets it right (Skinner, 1953).

How many times must an experiment be repeated with the same results before the scientific community accepts the findings? There is no required number of replications, but the greater the importance of the findings to theory or practice, the greater the number of replications to be conducted. Chapters 7 through 10 explain the role of replication in behavioral research and describe replication strategies used by applied behavior analysts.

Parsimony

One dictionary definition of *parsimony* is great frugality, and in a special way this connotation accurately describes the behavior of scientists. As an attitude of science, **parsimony** requires

that all simple, logical explanations for the phenomenon under investigation be ruled out, experimentally or conceptually, before more complex or abstract explanations are considered. Parsimonious interpretations help scientists assess and fit new findings within the field's existing knowledge base. A fully parsimonious interpretation consists only of those elements that are necessary and sufficient to explain the phenomenon at hand. The attitude of parsimony is so critical to scientific explanations that it is sometimes referred to as the Law of Parsimony (Whaley & Surratt, 1968), a "law" derived from *Occam's Razor,* credited to William of Occam (c. 1285–1349), who stated: "One should not increase, beyond what is necessary, the number of entities required to explain anything." In other words, given a choice between two competing and compelling explanations for the same phenomenon, one should shave off extraneous variables and choose the simplest explanation, the one that requires the fewest assumptions.

Philosophic Doubt

The attitude of **philosophic doubt** requires the scientist to continually question the truthfulness of what is regarded as fact. Scientific knowledge must always be viewed as tentative. Scientists must be willing to set aside their most cherished beliefs and findings and replace them with the knowledge derived from new discoveries.

Good scientists maintain a healthy level of skepticism. Although being skeptical of others' research may be easy, a more difficult but critical characteristic of scientists is that they remain open to the possibility—as well as look for evidence—that their own findings or interpretations are wrong. "Science is a willingness to accept facts even when they are opposed to wishes" (Skinner, 1953, p. 12). As Oliver Cromwell (1650) stated in another context: "I beseech you . . . think it possible you may be mistaken." For the true scientist, "new findings are not problems; they are opportunities for further investigation and expanded understanding" (Todd & Morris, 1993, p. 1159).

Practitioners should be as skeptical as researchers. The skeptical practitioner not only requires scientific evidence before implementing a new practice, but also evaluates continually its effectiveness once the practice has been implemented. Practitioners must be particularly skeptical of extraordinary claims made for the effectiveness of new theories, therapies, or treatments (Foxx & Mulick, 2016; Maurice, 2017).

> Claims that sound too good to be true usually are. Extraordinary claims require extraordinary evidence (Sagan, 1996; Shermer, 2002). What constitutes extraordinary evidence? In the strictest sense, and the sense that should be employed when evaluating claims of educational effectiveness, evidence is the outcome of the application of the scientific method to test the effectiveness of a claim, a theory, or a practice. The more rigorously the test is conducted, the more often the test is replicated, the more extensively the test is corroborated, the more extraordinary the evidence. Evidence becomes extraordinary when it is extraordinarily well tested. (Silvestri & Heward, 2016, p. 149)

We end our discussion of philosophic doubt with two pieces of advice, one from Carl Sagan and one from B. F. Skinner: "The question is not whether we *like* the conclusion that emerges out of a train of reasoning, but whether the conclusion *follows* from the premise or starting point and whether that premise is true" (Sagan, 1996, p. 210). "Regard no practice as immutable. Change and be ready to change again. Accept no eternal verity. Experiment" (Skinner, 1979, p. 346).

Other Important Attitudes and Values

The six attitudes of science that we have examined are necessary features of science and provide an important context for understanding applied behavior analysis.

However, the behavior of most productive and successful scientists is also characterized by qualities such as thoroughness, curiosity, perseverance, diligence, ethics, and honesty. Scientists acquire these traits because behaving in such ways has proven beneficial to the progress of science.

A Definition of Science

Science has no universally accepted, standard definition. We offer the following definition as one that encompasses the previously discussed purposes and attitudes of science, irrespective of the subject matter. **Science** is a systematic approach to understanding natural phenomena—as evidenced by description, prediction, and control—that relies on determinism as its fundamental assumption, empiricism as its prime directive, experimentation as its basic strategy, replication as its necessary requirement for believability, parsimony as its conservative value, and philosophic doubt as its guiding conscience.

A BRIEF HISTORY OF BEHAVIOR ANALYSIS

The science of behavior analysis entails three interrelated domains: philosophy, basic research, and applied research. **Behaviorism** is the philosophy of the science of behavior, basic research is the province of the experimental analysis of behavior (EAB), and developing a technology for improving behavior is the concern of applied behavior analysis (ABA). To be fully understood, applied behavior analysis must be considered in the context of the philosophy and basic research traditions and findings from which it evolved and remains connected today. This section provides an elementary description of the basic tenets of behaviorism and outlines some of the major events that have marked the development of behavior analysis.[3] Table 1.1 lists major books, journals, and professional organizations that have contributed to the advancement of behavior analysis since the 1930s.

Watson's Stimulus–Response Behaviorism

Psychology in the early 1900s was dominated by the study of states of consciousness, images, and other mental processes. Introspection, the act of carefully observing one's own conscious thoughts and feelings, was a primary method of investigation.

B. F. Skinner *(left)* in his Indiana University lab circa 1945 and *(right)* circa 1967.

Although the authors of several texts in the first decade of the 20th century defined psychology as the science of behavior (see Kazdin, 1978), John B. Watson is widely recognized as the spokesman for a new direction in the field of psychology. In his influential article "Psychology as the Behaviorist Views It," Watson (1913) wrote:

> Psychology as the behaviorist views it is a purely objective experimental branch of natural science. Its theoretical goal is the prediction and control of behavior. Introspection forms no essential part of its methods, nor is the scientific value of its data dependent upon the readiness with which they lend themselves to interpretation in terms of consciousness. (p. 158)

Watson argued that the proper subject matter for psychology was not states of mind or mental processes but observable behavior. Further, the objective study of behavior as a natural science should consist of direct observation of the relationships between environmental stimuli (S) and the responses (R) they evoke. Watsonian behaviorism became known as stimulus–response (S–R) psychology. Although scientific evidence was insufficient to support S–R psychology as a workable explanation for most behavior, Watson was confident that his new behaviorism would lead to the prediction and control of human behavior and that it would allow practitioners to improve performance in areas such as education, business, and law. Watson (1924) made bold claims concerning human behavior, as illustrated in this famous quotation:

> Give me a dozen healthy infants, well-formed, and my own specified world to bring them up in and I'll guarantee to take any one at random and train him to become any type of specialist I might select—doctor, lawyer, artist, merchant-chief and, yes, even beggar-man and thief, regardless of his talents, penchants, tendencies, abilities, vocations, and race of his ancestors. I am going beyond my facts and I admit it, but so have the advocates of the contrary and they have been doing it for many thousands of years. (p. 104)

It is unfortunate that such extraordinary claims were made, exaggerating the ability to predict and control human behavior beyond the scientific knowledge available. The quotation just cited has been used to discredit Watson and continues to be used to discredit behaviorism in general, even though the behaviorism that underlies contemporary behavior analysis is fundamentally different from the S–R paradigm. Nevertheless, Watson's contributions were of great significance: He made a strong case for the study of behavior as a natural science on a par with the physical and biological sciences.[4]

Experimental Analysis of Behavior

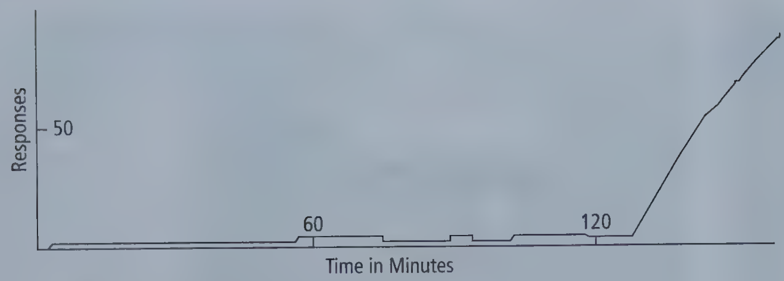
> *[Science] is a search for order. It begins, as we all begin, by observing single episodes, but it quickly passes on to the general rule, to scientific law.*
>
> —B. F. Skinner, (1953, pp. 13–14)

> *I had the clue from Pavlov: Control your conditions and you will see order.*
>
> —B. F. Skinner, (1956, p. 223)

The experimental branch of behavior analysis formally began with the publication of B. F. Skinner's *the Behavior of Organisms* (1938). The book summarized Skinner's laboratory research conducted from 1930 to 1937 and brought into perspective two kinds of behavior: respondent and operant.

Respondent behavior is reflexive behavior as in the tradition of Ivan Pavlov (1927). Respondents are elicited, or "brought out," by stimuli that immediately precede them. The antecedent stimulus (e.g., bright light) and the response it elicits (e.g., pupil constriction) form a functional unit called a *reflex.* Respondent behaviors are essentially involuntary and occur whenever the eliciting stimulus is presented.

Skinner was "interested in giving a scientific account of all behavior, including that which Descartes had set aside as 'willed' and outside the reach of science" (Glenn, Ellis, & Greenspoon, 1992, p. 1330). But, like other psychologists of the time, Skinner found that the S–R paradigm could not explain a great deal of behavior, particularly behaviors that had no



Original Conditioning
All responses to the lever were reinforced. The first three reinforcements were apparently ineffective. The fourth is followed by a rapid increase in rate.

Figure 1.1 The first data set in B. F. Skinner's *The Behavior of Organisms: An Experimental Analysis* (1938).

apparent antecedent causes in the environment. Compared to reflexive behavior with its clear eliciting events, much of the behavior of organisms appeared spontaneous or "voluntary." In an attempt to explain the mechanisms responsible for "voluntary" behavior, other psychologists postulated mediating variables inside the organism in the form of hypothetical constructs such as cognitive processes, drives, and free will. Skinner took a different tack. Instead of creating **hypothetical constructs**, presumed but unobserved entities that could not be manipulated in an experiment, Skinner continued to look in the environment for the determinants of behavior that did not have apparent antecedent causes.

> He did not deny that physiological variables played a role in determining behavior. He merely felt that this was the domain of other disciplines, and for his part, remained committed to assessing the causal role of the environment. This decision meant looking elsewhere in time. Through painstaking research, Skinner accumulated significant, if counterintuitive, evidence that behavior is changed less by the stimuli that precede it (though context is important) and more by the consequences that immediately follow it (i.e., consequences that are contingent upon it). The essential formulation for this notion is S–R–S, otherwise known as the three–term contingency. It did not replace the S–R model—we still salivate, for instance, if we smell food cooking when we are hungry. It did, however, account for how the environment "selects" the great part of learned behavior.
>
> With the three-term contingency Skinner gave us a new paradigm. He achieved something no less profound for the study of behavior and learning than Bohr's model of the atom or Mendel's model of the gene. (Kimball, 2002, p. 71)

Skinner called the second type of behavior *operant behavior.*[5] Operant behaviors are not elicited by preceding stimuli but instead are influenced by stimulus changes that have followed the behavior in the past. Skinner's most powerful and fundamental contribution to our understanding of behavior was his discovery and experimental analyses of the effects of consequences on behavior. The operant three-term contingency as the primary unit of analysis was a revolutionary conceptual breakthrough.

Skinner (1938) argued that the analysis of operant behavior "with its unique relation to the environment presents a separate important field of investigation" (p. 438). He named this new science the **experimental analysis of behavior** and outlined the methodology for its practice. Simply put, Skinner recorded the rate at which a single subject (he initially used rats and later, pigeons) emitted a given behavior in a controlled and standardized experimental chamber.

The first set of data Skinner presented in *The Behavior of Organisms* was a graph that "gives a record of the resulting change in behavior" (p. 67) when a food pellet was delivered immediately after a rat pressed a lever (see Figure 1.1). Skinner noted that the first three times that food followed a response "had no observable effect" but that "the fourth response was followed by an appreciable increase in rate showing a swift acceleration to a maximum" (pp. 67–68).

Skinner's investigative procedures evolved into an elegant experimental approach that enabled clear and powerful demonstrations of orderly and reliable functional relations between behavior and various types of environmental events.[6] By systematically manipulating the arrangement and scheduling of stimuli that preceded and followed behavior in literally thousands of laboratory experiments from the 1930s through the 1950s, Skinner and his colleagues and students discovered and verified the basic principles of operant behavior that continue to provide the empirical foundation for behavior analysis today. Description of these principles of behavior—general statements of functional relations between behavior and environmental events—and tactics for changing behavior derived from those principles constitute a major portion of this text.

Skinner's Radical Behaviorism

> *Behavior analysts dispense with the myth of the inner person as creator of behavior. Both philosophically and empirically to the behavior analyst, we are what we do, and when and where we do it.*
>
> —Murray Sidman, (2013, p. xvi)

In addition to being the founder of the experimental analysis of behavior, B. F. Skinner wrote extensively on the philosophy of that science. Without question, Skinner's writings have been the most influential both in guiding the practice of the science of behavior and in proposing the application of the principles of behavior to new areas.[7] In 1948 Skinner published *Walden Two,* a fictional account of how the philosophy and principles of behavior might be used in a utopian community (see Altus & Morris, 2009). This was

followed by his classic text, *Science and Human Behavior* (1953), in which he speculated on how the principles of behavior might be applied to complex human behavior in areas such as education, religion, government, law, and psychotherapy.

Much of Skinner's writing was devoted to the development and explanation of his philosophy of behaviorism. Skinner began his book *About Behaviorism* (1974) with these words:

> Behaviorism is not the science of human behavior; it is the philosophy of that science. Some of the questions it asks are these: Is such a science really possible? Can it account for every aspect of human behavior? What methods can it use? Are its laws as valid as those of physics and biology? Will it lead to a technology, and if so, what role will it play in human affairs? (p. 1)

The behaviorism Skinner pioneered differed significantly (indeed, radically) from other psychological theories, including other forms of behaviorism. Although there were, and remain today, many psychological models and approaches to the study of behavior, **mentalism** is the common denominator among most.

> In general terms, *mentalism* may be defined as an approach to the study of behavior which assumes that a mental or "inner" dimension exists that differs from a behavioral dimension. This dimension is ordinarily referred to in terms of its neural, psychic, spiritual, subjective, conceptual, or hypothetical properties. Mentalism further assumes that phenomena in this dimension either directly cause or at least mediate some forms of behavior, if not all. These phenomena are typically designated as some sort of act, state, mechanism, process, or entity that is causal in the sense of initiating or originating. Mentalism regards concerns about the origin of these phenomena as incidental at best. Finally, mentalism holds that an adequate causal explanation of behavior must appeal directly to the efficacy of these mental phenomena. (Moore, 2003, pp. 181–182)

Hypothetical constructs and explanatory fictions are the stock and trade of mentalism, which has dominated Western intellectual thought and most psychological theories (Descartes, Freud, Piaget), and it continues to do so into the 21st century. Freud, for example, created a complex mental world of hypothetical constructs—the id, ego, and superego—that he contended were key to understanding a person's actions.

Hypothetical constructs—"theoretical terms that refer to a possibly existing, but at the moment unobserved process or entity" (Moore, 1995, p. 36)—can be neither observed nor experimentally manipulated (MacCorquodale & Meehl, 1948; Zuriff, 1985). Free will, readiness, innate releasers, language acquisition devices, storage and retrieval mechanisms for memory, and information processing are all examples of hypothetical constructs that are inferred from behavior. Although Skinner (1953, 1974) clearly indicated that it is a mistake to rule out events that influence our behavior because they are not accessible to others, he believed that using presumed but unobserved mentalistic fictions (i.e., hypothetical constructs) to explain the causes of behavior contributed nothing to a functional account.

Consider a typical laboratory situation. A food-deprived rat pushes a lever each time a light comes on and receives food, but the rat seldom pushes the lever when the light is off (and if it does, no food is delivered). When asked to explain why the rat pushes the lever only when the light is on, most will say that the rat has "made the association" between the light being on and food being delivered when the lever is pressed. As a result of making that association, the animal now "knows" to press the lever only when the light is on. Attributing the rat's behavior to a hypothetical cognitive process such as associating or to something called "knowledge" adds nothing to a functional account of the situation. First, the environment (in this case, the experimenter) paired the light and food availability for lever presses, not the rat. Second, the knowledge or other cognitive process that is said to explain the observed behavior is itself unexplained, which begs for still more conjecture.

The "knowledge" that is said to account for the rat's performance is an example of an **explanatory fiction**, a fictitious variable that often is simply another name for the observed behavior that contributes nothing to an understanding of the variables responsible for developing or maintaining the behavior. Explanatory fictions are the key ingredient in "a circular way of viewing the cause and effect of a situation" (Heron, Tincani, Peterson, & Miller, 2005, p. 274) that lead to a false sense of understanding.

> Turning from observed behavior to a fanciful inner world continues unabated. Sometimes it is little more than a linguistic practice. We tend to make nouns of adjectives and verbs and must then find a place for the things the nouns are said to represent. We say that a rope is strong and before long we are speaking of its strength. We call a particular kind of strength tensile, and then explain that the rope is strong *because* it possesses tensile strength. The mistake is less obvious but more troublesome when matters are more complex.
>
> Consider now a behavioral parallel. When a person has been subject to mildly punishing consequences in walking on a slippery surface, he may walk in a manner we describe as cautious. It is then easy to say that he walks with caution or that he shows caution. There is no harm in this until we begin to say that he walks carefully *because* of his caution. (Skinner, 1974, pp. 165–166, emphasis added)

It is widely believed that Skinner rejected all events that could not be independently verified by agreement among observers. However, Skinner was explicit early on that he valued effective action over agreement among observers.

> The ultimate criterion for the goodness of a concept is not whether two people are brought into agreement but whether the scientist who uses the concept can operate successfully upon his material—all by himself if need be. What matters to Robinson Crusoe is not whether he is agreeing with himself but whether he is getting anywhere with his control over nature. (Skinner, 1945, p. 293).

Pragmatism, the philosophical position that "the truth value of a statement is a function of how well the statement promotes effective action" (Moore, 2008, p. 400), continues to be a primary criterion by which behavior analysts judge the value of their findings (Leigland, 2010; Moxley, 2004).[8]

In reality, there are many kinds of behaviorism—structuralism, methodological behaviorism, and forms of behaviorism that use cognitions as causal factors (e.g., cognitive behavior modification and social learning theory)—in addition to the radical behaviorism of Skinner. Structuralism and methodological behaviorism do reject all events that are not operationally defined by objective assessment. Structuralists avoid mentalism by restricting their activities to descriptions of behavior. They make no scientific manipulations; accordingly, they do not address questions of causal factors. Methodological behaviorists differ from the structuralists by using scientific manipulations to search for functional relations between events. Uncomfortable with basing their science on unobservable phenomena, some early behaviorists either denied the existence of "inner variables" or considered them outside the realm of a scientific account. Such an orientation is often referred to as **methodological behaviorism**.

Methodological behaviorists acknowledge the existence of mental events but do not consider them in the analysis of behavior (Skinner, 1974). Methodological behaviorists' reliance on public events, excluding private events, restricts the knowledge base of human behavior and discourages innovation in the science of behavior. Methodological behaviorism is restrictive because it ignores areas of major importance for an understanding of behavior.

Contrary to another common misconception, Skinner did not object to cognitive psychology's concern with private events (i.e., events taking place "inside the skin") (Moore, 2000). Skinner was the first behaviorist to view thoughts and feelings (he called them "private events") as behavior to be analyzed with the same conceptual and experimental tools used to analyze publicly observable behavior, not as phenomena or variables that exist within and operate according to principles of a separate mental world. "I contend that my toothache is just as physical as my typewriter" (Skinner, 1945, p. 294).

Essentially, Skinner's behaviorism makes three major assumptions regarding the nature of private events: (a) Private events such as thoughts and feelings are behavior; (b) behavior that takes place within the skin is distinguished from other ("public") behavior only by its inaccessibility; and (c) private behavior is influenced by (i.e., is a function of) the same kinds of variables as publicly accessible behavior.

> We need not suppose that events which take place within an organism's skin have special properties for that reason. A private event may be distinguished by its limited accessibility but not, so far as we know, by any special structure of nature. (Skinner, 1953, p. 257)

By incorporating private events into an overall conceptual system of behavior, Skinner created a **radical behaviorism** that includes and seeks to understand all human behavior. "What is inside the skin, and how do we know about it? The answer is, I believe, the heart of radical behaviorism" (Skinner, 1974, p. 218). The proper connotations of the word *radical* in radical behaviorism are *far-reaching* and *thoroughgoing,* connoting the philosophy's inclusion of all behavior, public and private. *Radical* is also an appropriate modifier for Skinner's form of behaviorism because it represents a dramatic departure from other conceptual systems in calling for

> probably the most drastic change ever proposed in our way of thinking about man. It is almost literally a matter of turning the explanation of behavior inside out. (Skinner, 1974, p. 256)

Skinner and the philosophy of radical behaviorism acknowledge the events on which fictions such as cognitive processes are based. Radical behaviorism does not restrict the science of behavior to phenomena that can be detected by more than one person. In the context of radical behaviorism, the term *observe* implies "coming into contact with" (Moore, 1984). Radical behaviorists consider private events such as thinking or sensing the stimuli produced by a damaged tooth to be no different from public events such as oral reading or sensing the sounds produced by a musical instrument. According to Skinner (1974), "What is felt or introspectively observed is not some nonphysical world of consciousness, mind, or mental life but the observer's own body" (pp. 18–19).

The analysis of private events is a major aspect of radical behaviorism and indispensable for a comprehensive science of behavior (Palmer, 2011). Moore (1980, 2015) stated it concisely:

> For radical behaviorism, private events are those events wherein individuals respond with respect to certain stimuli accessible to themselves alone. . . . The responses that are made to those stimuli may themselves be public, i.e., observable by others, or they may be private, i.e., accessible only to the individual involved. Nonetheless, to paraphrase Skinner (1953), it need not be supposed that events taking place within the skin have any special properties for that reason alone. . . . For radical behaviorism, then, one's responses with respect to private stimuli are equally lawful and alike in kind to one's responses with respect to public stimuli. (1980, p. 460)

> [T]hese events are critical to understanding behavior in all its complexity. Just as importantly, they need not be formulated in different terms and with different concepts that are publicly observable behavior events. (2015, p. 18)

Scientists and practitioners are affected by their own social context, and institutions and schools are dominated by mentalism (Heward & Cooper, 1992; Kimball, 2002). A firm grasp of the philosophy of radical behaviorism, in addition to knowledge of principles of behavior, can help the scientist and practitioner resist the mentalistic approach of dropping the search for controlling variables in the environment and drifting toward explanatory fictions in the effort to understand behavior. The principles of behavior and the procedures presented in this text apply equally to public and private events. Radical

behaviorism is the philosophical position underlying the content presented in this text.

As Friman (2017) noted, Skinner's behaviorism viewed behavior as a natural science.

> By taking this stand, he was promoting a larger idea, specifically that behavior was solely a physical phenomenon brought about, maintained, strengthened, or weakened solely by physical (environmental) events. In other words, he was promoting the idea that behavior is a function of environmental circumstances and their context. This is the most powerful idea ever invented by mankind for understanding, knowing, and approaching human behavior especially when it is a problem. (p. 176)

A thorough discussion of radical behaviorism is far beyond the scope of this text. The serious student of applied behavior analysis will devote considerable study to Skinner's original writings and to other authors who have critiqued, analyzed, and extended the philosophical foundations of the science of behavior.[9] (See Box 1.1 for Don Baer's perspectives on the meaning and importance of radical behaviorism.)

Applied Behavior Analysis

The first study to report the human application of principles of operant behavior was conducted by Fuller (1949). The subject was an 18-year-old boy with profound developmental disabilities who was described in the language of the time as a "vegetative idiot." He lay on his back, unable to roll over. Fuller filled a syringe with a warm sugar-milk solution and injected a small amount of the fluid into the young man's mouth every time he moved his right arm (that arm was chosen because he moved it infrequently). Within four sessions the boy was moving his arm to a vertical position at a rate of three times per minute.[10]

> The attending physicians . . . thought it was impossible for him to learn anything—according to them, he had not learned anything in the 18 years of his life—yet in four experimental sessions, by using the operant conditioning technique, an addition was made to his behavior which, at this level, could be termed appreciable. Those who participated in or observed the experiment are of the opinion that if time permitted, other responses could be conditioned and discriminations learned. (Fuller, 1949, p. 590)

During the 1950s and into the early 1960s researchers used the methods of the experimental analysis of behavior to determine whether the principles of behavior demonstrated in the laboratory with nonhuman subjects could be replicated with humans. According to Thompson and Hackenberg (2009), "the field of applied analysis emerged from the experimental analysis of behavior, like Adam's rib" (p. 271).

Much of the early research with human subjects was conducted in clinic or laboratory settings. Although the participants typically benefited from these studies by learning new behaviors, the researchers' major purpose was to determine whether the basic principles of behavior discovered in the laboratory operated with humans. For example, Sidney Bijou (1955, 1957, 1958)[11] researched several principles of behavior with typically developing subjects and people with intellectual disabilities; Don Baer (1960, 1961, 1962) examined the effects of punishment, escape, and avoidance contingencies on preschool children; and Ogden Lindsley (1956; Lindsley & Skinner, 1954) assessed the effects of operant conditioning on the behavior of adults with schizophrenia. These early researchers clearly established that the principles of behavior are applicable to human behavior, and they set the stage for the later development of applied behavior analysis.

The branch of behavior analysis that would later be called applied behavior analysis (ABA) can be traced to the 1959 publication of Ayllon and Michael's paper titled "The Psychiatric Nurse as a Behavioral Engineer." The authors described how direct care personnel in a state hospital used a variety of techniques based on the principles of behavior to improve the functioning of residents with psychotic disorders or intellectual disabilities. During the 1960s many researchers began to apply principles of behavior in an effort to improve socially important behavior, but these early pioneers faced many problems. Laboratory techniques for measuring behavior and for controlling and manipulating variables were sometimes unavailable, or their use was inappropriate in applied settings. As a result, the early practitioners of applied behavior analysis had to develop new experimental procedures as they went along. There was little funding for the new discipline, and researchers had no ready outlet for publishing their studies, making it difficult to communicate among themselves about their findings and solutions to methodological problems. Most journal editors were reluctant to publish studies using an experimental method unfamiliar to mainstream social science, which relied on large numbers of subjects and tests of statistical inference.

Despite these problems it was an exciting time, and major new discoveries were being made regularly. For example, many pioneering applications of behavior principles to education occurred during this period (see, e.g., O'Leary & O'Leary, 1972; Ulrich, Stachnik, & Mabry 1974), from which were derived teaching procedures such as contingent teacher praise and attention (Hall, Lund, & Jackson, 1968), token reinforcement systems (Birnbrauer, Wolf, Kidder, & Tague, 1965), curriculum design (Becker, Engelmann, & Thomas, 1975), and programmed instruction (Bijou, Birnbrauer, Kidder, & Tague, 1966; Markle, 1962). The basic methods for reliably improving student performance developed by those early applied behavior analysts provided the foundation for behavioral approaches to curriculum design, instructional methods, classroom management, and the generalization and maintenance of learning that continue to be used decades later (cf., Twyman, 2013).

University programs in behavior analysis were begun in the 1960s and 1970s at Arizona State University, Florida State University, the State University of New York at Stony Brook,

BOX 1.1

What Is Behaviorism?

Don Baer loved the science of behavior. He loved to write about it, and he loved to talk about it. Don was famous for his unparalleled ability to speak extemporaneously about complex philosophical, experimental, and professional issues in a way that always made thorough conceptual, practical, and human sense. He did so with the vocabulary and syntax of a great author and the accomplished delivery of a master storyteller. The only thing Don knew better than his audience was his science.

On three occasions, in three different decades, graduate students and faculty in the special education program at The Ohio State University were fortunate to have Professor Baer serve as Distinguished Guest Faculty for a doctoral seminar, Contemporary Issues in Special Education and Applied Behavior Analysis. The questions and responses that follow were selected from transcripts of two of Professor Baer's three OSU teleconference seminars.

If a person on the street approached you and asked, "What's behaviorism?" how would you reply?

The key point of behaviorism is that what people do can be understood. Traditionally, both the layperson and the psychologist have tried to understand behavior by seeing it as the outcome of what we think, what we feel, what we want, what we calculate, and etcetera. But we don't have to think about behavior that way. We could look upon it as a process that occurs in its own right and has its own causes. And those causes are, very often, found in the external environment.

Behavior analysis is a science of studying how we can arrange our environments so they make very likely the behaviors we want to be probable enough, and they make unlikely the behaviors we want to be improbable. Behaviorism is understanding how the environment works so that we can make ourselves smarter, more organized, more responsible; so we can encounter fewer punishments and fewer disappointments. A central point of behaviorism is this: We can remake our environment to accomplish some of that much more easily than we can remake our inner selves.

An interviewer once asked Edward Teller, the physicist who helped develop the first atomic bomb, "Can you explain to a nonscientist what you find so fascinating about science, particularly physics?" Teller replied, "No." I sense that Teller was suggesting that a nonscientist would not be able to comprehend, understand, or appreciate physics and his fascination with it. If a nonscientist asked you, "What do you find so fascinating about science, particularly the science of human behavior?" what would you say?

Ed Morris organized a symposium on just this topic a couple of years ago at the Association for Behavior Analysis annual convention, and in that symposium, Jack Michael commented on the fact that although one of our discipline's big problems and challenges is communicating with our society about who we are, what we do, and what we can do, he didn't find it reasonable to try to summarize what behavior analysis is to an ordinary person in just a few words. He gave us this example: Imagine a quantum physicist is approached at a cocktail party by someone who asks, "What is quantum physics?" Jack said that the physicist might very well answer, and probably should answer, "I can't tell you in a few words. You should register for my course."

I'm very sympathetic with Jack's argument. But I also know, as someone who's confronted with the politics of relating our discipline to society, that although it may be a true answer, it's not a good answer. It's not an answer that people will hear with any pleasure, or indeed, even accept. . . . Therefore, I think we have to engage in a bit of honest show business. So, if I had to somehow state some connotations of what holds me in the field, I guess I would say that since I was a child I always found my biggest reinforcer was something called understanding. I liked to know how things worked. And of all of the things in the world there are to understand, it became clear to me that the most fascinating was what people do. I started with the usual physical science stuff, and it was intriguing to me to understand how radios work, and how electricity works, and how clocks work, etcetera. But when it became clear to me that we could also learn how people work—not just biologically, but behaviorally—I thought that's the best of all. Surely, everyone must agree that that's the most fascinating subject matter. That there could be a science of behavior, of what we do, of who we are? How could you resist that?

Stokes (Eds.), *A Small Matter of Proof: The Legacy of Donald M. Baer* (pp. 293–310). Reno, NV: Context Press. Used by permission.

the University of Illinois, Indiana University, the University of Kansas, The Ohio State University, the University of Oregon, the University of Southern Illinois, the University of Washington, West Virginia University, and Western Michigan University, among others. Through their teaching and research, faculty at each of these programs made major contributions to the rapid growth of the field.[12]

Two significant events in 1968 mark that year as the formal beginning of contemporary applied behavior analysis. First, the *Journal of Applied Behavior Analysis (JABA)* began publication. *JABA* was the first journal in the United States to deal with applied problems that gave researchers using methodology from the experimental analysis of behavior an outlet for publishing their findings. *JABA* was and continues to be the flagship journal

of applied behavior analysis. Many of the early articles in *JABA* became model demonstrations of how to conduct and interpret applied behavior analysis, which in turn led to improved applications and experimental methodology.

The second major event of 1968 was the publication of the paper "Some Current Dimensions of Applied Behavior Analysis" by Donald M. Baer, Montrose M. Wolf, and Todd R. Risley. These authors, the founding fathers of the new discipline, recommended criteria for judging the adequacy of research and practice in applied behavior analysis and outlined the scope of work they envisioned for those engaged in the science. Their iconic paper is the most widely cited publication in applied behavior analysis and generally regarded as the standard description of the discipline.

CHARACTERISTICS OF APPLIED BEHAVIOR ANALYSIS

Baer, Wolf, and Risley (1968) recommended that applied behavior analysis be *applied, behavioral, analytic, technological, conceptually systematic, effective,* and capable of appropriately *generalized outcomes.* In 1987 Baer and colleagues reported that the "seven self-conscious guides to behavior analytic conduct" (p. 319) they had offered 20 years earlier "remain functional; they still connote the current dimensions of the work usually called applied behavior analysis" (p. 314). The seven dimensions they posed continue to serve as useful and relevant signposts for identifying research in applied behavior analysis.

Applied

The *applied* in applied behavior analysis signals ABA's commitment to effecting improvements in behaviors that enhance and improve people's lives. To meet this criterion, the researcher or practitioner must select behaviors to change that are socially significant for participants: social, language, academic, daily living, self-care, vocational, and/or recreation and leisure behaviors that improve the day-to-day life experience of the participants and/or affect their significant others (parents, teachers, peers, employers) in such a way that they behave more positively with and toward the participant.

Behavioral

At first it may seem superfluous to include such an obvious criterion—of course applied *behavior* analysis must be *behavioral.* However, Baer and colleagues (1968) made three important points relative to the behavioral criterion. First, not just any behavior will do; the behavior chosen for study must be *the* behavior in need of improvement, not a similar behavior that serves as a proxy for the behavior of interest or the subject's verbal description of the behavior. Behavior analysts conduct studies *of* behavior, not studies *about* behavior. For example, in a study evaluating the effects of a program to teach school children to get along with one another, an applied behavior analyst would directly observe and measure clearly defined classes of interactions between and among the children instead of using indirect measures such as the children's answers on a sociogram or responses to a questionnaire about how they believe they get along with one another.

Second, the behavior must be measurable; the precise and reliable measurement of behavior is just as critical in applied research as it is in basic research. Applied researchers must meet the challenge of measuring socially significant behaviors in their natural settings, and they must do so without resorting to the measurement of nonbehavioral substitutes.

Third, when changes in behavior are observed during an investigation, it is necessary to ask whose behavior has changed. Perhaps only the behavior of the observers has changed. "Explicit measurement of the reliability of human observers thus becomes not merely good technique, but a prime criterion of whether the study was appropriately behavioral" (Baer et al., 1968, p. 93). Or perhaps the experimenter's behavior has changed in an unplanned way, making it inappropriate to attribute any observed change in the subject's behavior to the independent variables that were manipulated. The applied behavior analyst should attempt to monitor the behavior of all persons involved in a study.

Analytic

A study in applied behavior analysis is *analytic* when the experimenter has demonstrated a functional relation between the manipulated events and a reliable change in some measurable dimension of the targeted behavior. In other words, the experimenter must be able to control the occurrence and nonoccurrence of the behavior. Sometimes, however, society does not allow the repeated manipulation of important behaviors to satisfy the requirements of experimental method. Therefore, applied behavior analysts must demonstrate control to the greatest extent possible, given the restraints of the setting and behavior; and then they must present the results for judgment by the consumers of the research. The ultimate issue is believability: Has the researcher achieved experimental control to demonstrate a reliable functional relation?

The analytic dimension enables ABA not only to demonstrate effectiveness but also to provide the "acid test proof" of functional and replicable relations between the interventions it recommends and socially significant outcomes.

> Because we are a data- and design-based discipline, we are in the remarkable position of being able to prove that behavior can work in the way that our technology prescribes. We are not theorizing about how behavior *can* work; we are describing systematically how it *has* worked many times in real-world applications, in designs too competent and with measurement systems too reliable and valid to doubt. Our ability to prove that behavior can work that way does not, of course, establish that behavior *cannot* work any other way: we are not in a discipline that can deny any other approaches, only in one that can affirm itself as knowing many of its *sufficient* conditions at the level of experimental proof . . . our subject matter is behavior change, and we can specify some *actionable* sufficient conditions for it. (D. M. Baer, personal communication, October 21, 1982, emphasis in original)

Technological

A study in applied behavior analysis is *technological* when all of its operative procedures are identified and described with sufficient detail and clarity "such that a reader has a fair chance of replicating the application with the same results" (Baer, Blount, Detrich, & Stokes, 1987, p. 320).

> It is not enough to say what is to be done when the subject makes response R_1; it is essential also whenever possible to say what is to be done if the subject makes the alternative responses, R_2, R_3, etc. For example, one may read that temper tantrums in children are often extinguished by closing the child in his room for the duration of the tantrums plus ten minutes. Unless that procedure description also states what should be done if the child tries to leave the room early, or kicks out the window, or smears feces on the walls, or begins to make strangling sounds, etc., it is not precise technological description. (Baer et al., 1968, pp. 95–96)

No matter how powerful its effects in any given study, a behavior change method will be of little value if practitioners are unable to replicate it. The development of a replicable technology of behavior change has been a defining characteristic and continuing goal of ABA from its inception. Behavioral tactics are replicable and teachable to others. Interventions that cannot be replicated with sufficient fidelity to achieve comparable outcomes are not considered part of the technology.

A good check of the technological adequacy of a procedural description is to have a person trained in applied behavior analysis carefully read the description and then act out the procedure in detail. If the person makes any mistakes, adds any operations, omits any steps, or has to ask any questions to clarify the written description, then the description is not sufficiently technological and requires improvement.

Conceptually Systematic

Although Baer and colleagues (1968) did not state so explicitly, a defining characteristic of applied behavior analysis concerns the types of interventions used to improve behavior. Although an infinite number of tactics and specific procedures can be used to alter behavior, almost all are derivatives and/or combinations of a relatively few basic principles of behavior. Thus, Baer and colleagues recommended that research reports of applied behavior analysis be *conceptually systematic,* meaning that the procedures for changing behavior and any interpretations of how or why those procedures were effective should be described in terms of the relevant principle(s) from which they were derived.

Baer and colleagues (1968) provided a strong rationale for the use of conceptual systems in applied behavior analysis. First, relating specific procedures to basic principles might enable the research consumer to derive other similar procedures from the same principle(s). Second, conceptual systems are needed if a technology is to become an integrated discipline instead of a "collection of tricks." Loosely related collections of tricks do not lend themselves to systematic expansion, and they are difficult to learn and to teach.

Effective

An effective application of behavioral techniques must improve the behavior under investigation to a practical degree. "In application, the theoretical importance of a variable is usually not at issue. Its practical importance, specifically its power in altering behavior enough to be socially important, is the essential criterion" (Baer et al., 1968, p. 96). Whereas some investigations produce results of theoretical importance or statistical significance, to be judged *effective* an applied behavior analysis study must produce behavior changes that reach clinical or social significance.

How much a given behavior of a given subject needs to change for the improvement to be considered socially important is a practical question. Baer and colleagues stated that the answer is most likely to come from the people who must deal with the behavior; they should be asked how much the behavior needs to change. The necessity of producing behavioral changes that are meaningful to the participant and/or those in the participant's environment has pushed behavior analysts to search for "robust" variables, interventions that produce large and consistent effects on behavior (Baer, 1977a).

When they revisited the dimension of effectiveness 20 years later, Baer and colleagues (1987) recommended that the effectiveness of ABA also be judged by a second kind of outcome: the extent to which changes in the target behaviors result in noticeable changes in the reasons those behaviors were selected for change originally. If such changes in the subjects' lives do not occur, ABA may achieve one level of effectiveness yet fail to achieve a critical form of social validity (Wolf, 1978).

> We may have taught many social skills without examining whether they actually furthered the subject's social life; many courtesy skills without examining whether anyone actually noticed or cared; many safety skills without examining whether the subject was actually safer thereafter; many language skills without measuring whether the subject actually used them to interact differently than before; many on-task skills without measuring the actual value of those tasks; and, in general, many survival skills without examining the subject's actual subsequent survival. (Baer et al., 1987, p. 322)

Generality

A behavior change has *generality* if it lasts over time, appears in environments other than the one in which the intervention that initially produced it was implemented, and/or spreads to other behaviors not directly treated by the intervention. A behavior change that continues after the original treatment procedures are withdrawn has generality. And generality is

evident when changes in targeted behavior occur in nontreatment settings or situations as a function of treatment procedures. Generality also exists when behaviors change that were not the focus of the intervention. Although not all instances of generality are adaptive (e.g., a beginning reader who has just learned to make the sound for the letter *p* in words such as *pet* and *ripe,* might make the same sound when seeing the letter *p* in the word *phone*), desirable generalized behavior changes are important outcomes of an applied behavior analysis program because they represent additional dividends in terms of behavioral improvement. Strategies and tactics for promoting desirable generalization of behavior changes are detailed in Chapter 30.

More than 50 years have passed since Baer, Wolf, and Risley (1968) proposed these seven dimensions as the defining features of applied behavior analysis. For insightful discussion of the usefulness of these dimensions for contemporary ABA research, see Axelrod (2017), Cataldo (2017), Critchfield and Reed (2017), and Friman (2017).

Other Characteristics of ABA

Applied behavior analysis offers society an approach toward solving problems that is accountable, public, doable, empowering, and optimistic (Heward, 2005). These characteristics should make behavior analysts "feel good" and increase the extent to which decision makers and consumers in many areas look to applied behavior analysis as a valuable and important source of knowledge for achieving improved outcomes.

Accountable

Applied behavior analysts' commitment to effectiveness, their focus on accessible environmental variables that reliably influence behavior, and their reliance on direct and frequent measurement to detect changes in behavior yield an inescapable and socially valuable form of accountability. Direct and frequent measurement—the foundation and most important component of ABA practices—enables behavior analysts to identify their successes and, equally important, their failures so they can make changes in an effort to change failure to success (Bushell & Baer, 1994; Greenwood & Maheady, 1997).

> Failure is always informative in the logic of behavior analysis, just as it is in engineering. The constant reaction to lack of progress [is] a definitive hallmark of ABA. (Baer, 2005, p. 8)

Gambrill (2003) described the sense of accountability and self-correcting nature of applied behavior analysis very well.

> Applied behavior analysis is a scientific approach to understanding behavior in which we guess and critically test ideas, rather than guess and guess again. It is a process for solving problems in which we learn from our mistakes. Here, false knowledge and inert knowledge are not valued. (p. 67)

Public

"Everything about ABA is visible and public, explicit and straightforward. . . . ABA entails no ephemeral, mystical, or metaphysical explanations; there are no hidden treatments; there is no magic" (Heward, 2005, p. 322). The transparent, public nature of ABA should raise its value in fields such as education, parenting and child care, employee productivity, geriatrics, health and safety, and social work—to name only a few—whose goals, methods, and outcomes are of vital interest to many constituencies.

Doable

Classroom teachers, parents, coaches, workplace supervisors, and sometimes the participants themselves implemented the interventions found effective in many ABA studies. This demonstrates the pragmatic element of ABA. "Although 'doing ABA' requires far more than learning to administer a few simple procedures, it is not prohibitively complicated or arduous. As many teachers have noted, implementing behavioral strategies in the classroom . . . might best be described as good old-fashioned hard work" (Heward, 2005, p. 322).

Empowering

ABA gives practitioners real tools that work. Knowing how to do something and having the tools to accomplish it instills confidence in practitioners. Seeing the data showing behavioral improvements in one's clients, students, or teammates, or in oneself, not only feels good but also raises one's self-assurance in assuming even more difficult challenges in the future.

Optimistic

Practitioners knowledgeable and skilled in behavior analysis have genuine cause to be optimistic for four reasons. First, as Strain and Joseph (2004) noted:

> The environmental view promoted by behaviorism is essentially optimistic; it suggests that (except for gross genetic factors) all individuals possess roughly equal potential. Rather than assuming that individuals have some essential internal characteristic, behaviorists assume that poor outcomes originate in the way the environment and experience shaped the individual's current behavior. Once these environmental and experiential factors are identified, we can design prevention and intervention programs to improve the outcomes. . . . Thus, the emphasis on external control in the behavioral approach . . . offers a conceptual model that celebrates the possibilities for each individual. (Strain et al., 1992, p. 58)

Second, direct and continuous measurement enables practitioners to detect small improvements in performance that might otherwise be overlooked. Third, the more often a practitioner uses behavioral tactics with positive outcomes (the most common result of behaviorally based interventions), the more optimistic she becomes about the prospects for future success.

> A sense of optimism, expressed by the question "Why not?" has been a central part of ABA and has had an enormous impact on its development from its earliest days. Why can't we teach a person who does not yet talk to talk? Why shouldn't we go ahead and try to change the environments of young children so that they will display more creativity? Why would we assume that this person with a developmental disability could not learn to do the same things that many of us do? Why not try to do it? (Heward, 2005, p. 323)

Fourth, ABA's peer-reviewed literature provides many examples of success in teaching students who had been considered unteachable. ABA's continuous record of achievements evokes a legitimate feeling of optimism that future developments will yield solutions to behavioral challenges that are currently beyond the existing technology. For example, in response to the perspective that some people have disabilities so severe and profound that they should be viewed as ineducable, Don Baer offered this perspective:

> Some of us have ignored both the thesis that all persons are educable and the thesis that some persons are ineducable, and instead have experimented with ways to teach some previously unteachable people. Those experiments have steadily reduced the size of the apparently ineducable group relative to the obviously educable group. Clearly, we have not finished that adventure. Why predict its outcome, when we could simply pursue it, and just as well without a prediction? Why not pursue it to see if there comes a day when there is such a small class of apparently ineducable persons left that it consists of one elderly person who is put forward as ineducable. If that day comes, it will be a very nice day. And the next day will be even better. (D. M. Baer, February 15, 2002, personal communication, as cited in Heward, Alber-Morgan, & Konrad, 2017, p. 404)

A DEFINITION OF APPLIED BEHAVIOR ANALYSIS

We began this chapter by stating that applied behavior analysis is a science with a dual purpose of understanding and improving socially important behavior. We then described attitudes, assumptions, and methods that are fundamental to scientific inquiry, briefly reviewed the development of the science and philosophy of behavior analysis, and examined the characteristics of ABA. All of that provided necessary context for offering the following definition of applied behavior analysis:

> **Applied behavior analysis** is the science in which tactics derived from the principles of behavior are applied systematically to improve socially significant behavior and experimentation is used to identify the variables responsible for behavior change.

This definition includes six key components. First, applied behavior analysis is a science, which means ABA researchers and practitioners are guided by the attitudes and methods of scientific inquiry. Second, all behavior change procedures are described and implemented in a systematic, technological manner. Third, not any means of changing behavior qualifies as applied behavior analysis: The field circumscribes only those tactics conceptually derived from the basic principles of behavior. Fourth, the focus of applied behavior analysis is socially significant behavior. The fifth and sixth parts of the definition specify the twin goals of applied behavior analysis: improvement and understanding. Applied behavior analysis seeks to make meaningful improvement in important behavior and to achieve an analysis of the factors responsible for that improvement.[13]

Four Interrelated Domains of Behavior Analytic Science and Professional Practice Guided by That Science

The science of behavior analysis and its application to human problems consists of four domains: the three branches of behavior analysis—radical behaviorism, EAB, and ABA—and professional practice in various fields that is informed and guided by that science. Figure 1.2 identifies defining features and characteristics of each domain. Although most behavior analysts work primarily in one or two of the domains shown in Figure 1.2, it is common for a behavior analyst to function in multiple domains at one time or another (Hawkins & Anderson, 2002; Moore & Cooper, 2003).

Radical behaviorism, the philosophical domain of behavior analysis, entails pursuing theoretical and conceptual issues. Examples of theoretical and conceptual behavior analysis are Glenn's (2004) exploration on the interplay of behavioral and cultural practices; Schlinger's (2008b) analysis of listening as behaving verbally; Dillenburger and Keenan's (2005) discussion of bereavement; Layng's (2017) theoretical account of emotions and emotional behavior; and M. Malott's (2016) examination of leadership.

The experimental analysis of behavior is the basic research branch of the science. Basic research consists of experiments in (mostly) laboratory settings with both human and nonhuman subjects with a goal of discovering, extending, and clarifying fundamental principles of behavior. Examples of the wide range of topics investigated by EAB researchers include how organisms direct their attention in complex environments (Shahan, 2013); choice making (Mazur & Fantino, 2014); remembering and forgetting (White, 2013); delay discounting (Odum, 2011); and variability of operant behavior (Neuringer & Jensen, 2013).[14, 15]

Applied behavior analysts conduct experiments aimed at discovering and clarifying functional relations between socially significant behavior and its controlling variables, with which they can contribute to the further development of humane and effective technologies of behavior change. Examples of ABA research include Tarbox, Wallace, and Williams's (2003)

Figure 1.2 Comparisons and relationships among the four domains of behavior analysis science and practice.

	Radical Behaviorism	**Experimental Analysis of Behavior (EAB)**	*Translational Behavior Analysis**	**Applied Behavior Analysis (ABA)**	**Practice Guided by Behavior Analysis**
Province	Theory and philosophy	Basic research		Applied research	Helping people behave more successfully
Primary activity	Conceptual and philosophical analysis	Design, conduct, interpret, and report basic experiments		Design, conduct, interpret, and report applied experiments	Design, implement, and evaluate behavior change programs
Primary goal and product	Theoretical account of all behavior consistent with existing data	Discover and clarify basic principles of behavior; functional relations between behavior and controlling variables		A technology for improving socially significant behavior; functional relations between socially significant behavior and controlling variables	Improvements in the lives of participants/clients as a result of changes in their behavior
Secondary goals	Identify areas in which empirical data are absent and/or conflict and suggest resolutions	Identify questions for EAB and/or ABA to investigate further; raise theoretical issues		Identify questions for EAB and/or ABA to investigate further; raise theoretical issues	Increased efficiency in achieving primary goal; may identify questions for ABA and EAB
Agreement with existing database	As much as possible, but theory must go beyond database by design	Complete—Although differences among data sets exist, EAB provides the basic research database		Complete—Although differences among data sets exist, ABA provides the applied research database	As much as possible, but practitioners must often deal with situations not covered by existing data
Testability	Partially—All behavior and variables of interest are not accessible (e.g., phylogenic contingencies)	Mostly—Technical limitations preclude measurement and experimental manipulation of some variables		Mostly—Same limitations as EAB plus those posed by applied settings (e.g., ethical concerns, uncontrolled events)	Partially—All behavior and variables of interest are not accessible (e.g., a student's home life)
Scope	**Most** ←	←		→	→ **Least**
	Wide scope because theory attempts to account for all behavior	As much scope as the EAB database enables		As much scope as the ABA database enables	Narrow scope because practitioner's primary focus is helping the specific situation
Precision	**Least** ←	←		→	→ **Most**
	Minimal precision is possible because experimental data do not exist for all behavior encompassed by theory	As much precision as EAB's current technology for experimental control and the researcher's skills enable		As much precision as ABA's current technology for experimental control and the researcher's skills enable	Maximum precision is needed to change behavior most effectively in specific instance

*Translational behavior analysis bridges between EAB and ABA (see McIlvane, 2009).

assessment and treatment of elopement (running or walking away from a caregiver without permission) by individuals with disabilities; Romanowich and Lamb's (2015) research on the effects of various schedules of reinforcement on smokers' abstinence; Crabtree, Alber-Morgan, and Konrad's (2010) experiment on the effects of self-monitoring of story elements on the reading comprehension of high school students with learning disabilities; and Poling and colleagues' teaching giant African pouched rats to find unexploded landmines (Poling et al., 2010), detect patients infected with tuberculosis (Poling et al., 2017), and find people trapped under debris from collapsed structures resulting from natural disasters, acts of war or terrorism, or engineering mistakes (La Londe et al., 2015).

"Behavior analysis is not merely the sum of its basic and applied research and conceptual programs. It is their interrelationship, wherein each branch draws strength and integrity from the others. With the unity of behavior analysis clarified, the whole of behavior analysis emerges as greater than the sum of its parts" (Morris, Todd, Midgley, Schneider, & Johnson, 1990, p. 136).

Translational research is evidence of the symbiotic relation between the basic and applied domains. Translational research includes basic research that "bridges" basic and applied areas and applied research that translates the knowledge derived from basic research "into state-of-the-art clinical practices for use in the community" (Lerman, 2003, p. 415). In a review of translational research on token reinforcement, Hackenberg (2018) suggested that all three domains of behavior analysis science benefit when basic and applied research inform each other.

> Unlike standard translational research, based on a unidirectional model in which the analysis moves from laboratory to the applied realm, work in the area of token systems is best served by a bidirectional interplay between laboratory and applied research, where applied questions inspire research on basic mechanisms. When based on and contributing to an analysis, applied research on token economies can be on the leading edge of theoretical advances, helping set the scientific research agenda. (p. 393)[16]

The delivery of professional services informed by behavior analysis occurs in the fourth domain. Behavior analytic practitioners design, implement, and evaluate behavior change programs that consist of behavior change tactics derived from fundamental principles of behavior discovered by basic researchers and experimentally validated for their effects on socially significant behavior by applied researchers. An example is when a therapist providing home-based treatment for a child with autism embeds frequent opportunities for the child to use emerging social and language skills in the context of naturalistic, daily routines and ensures that the child's responses are followed with reinforcing events. Another example is a classroom teacher trained in behavior analysis who uses positive reinforcement and stimulus fading to teach students to identify and classify fish into their respective species by the shape, size, and location of their fins.

Although each of the four domains can be defined and practiced in its own right, none of the domains are, or should be, completely independent of and uninformed by developments in the others. Both the science and the effective application of its findings benefit when the four domains are interrelated and influence one another.

The Promise and Potential of ABA

In a paper titled "A Futurist Perspective for Applied Behavior Analysis," Jon Bailey (2000) stated that

> It seems to me that applied behavior analysis is more relevant than ever before and that it offers our citizens, parents, teachers, and corporate and government leaders advantages that cannot be matched by any other psychological approach. . . . I know of no other approach in psychology that can boast state-of-the-art solutions to the most troubling social ills of the day. (p. 477)

We, too, believe that ABA's pragmatic, natural science approach to discovering environmental variables that reliably influence socially significant behavior and to developing a technology to take practical advantage of those discoveries offers humankind its best hope for solving many of its problems. It is important to recognize that the knowledge afforded by ABA of "how behavior works" is incomplete, even at the level of fundamental principles, as is the technology for changing behavior derived from that knowledge. There are aspects of behavior about which relatively little is known, and additional research, both basic and applied, is needed to clarify, extend, and fine-tune all existing knowledge.

Nevertheless, applied behavior analysis research and practice have improved human performance and the quality of participants' lives across a wide range of areas. Figure 1.3 lists some of the more than 230 applied behavior analysis research topics identified by an informal literature search and survey (Heward & Critchfield, 2019). As diverse and impressive as this A-to-Z list of topics may seem, no behavioral problem or learning goal has been solved completely, and many important problems and challenges await analysis. The remainder of this text presents a foundation of knowledge that can lead to a fuller and more complete understanding of the still young and promising science of applied behavior analysis.

Figure 1.3 ABA: Improving people's quality of life from A to Z.

A
ADHD (Bicard & Neef, 2002), aging (Baker & LeBlanc, 2014), aggression (Brosnan & Healy, 2011), AIDS (DeVries et al., 1991), alcohol abuse (Fournier et al., 2004), Alzheimer's (LeBlanc et al., 2006), anorexia nervosa (Solanto et al., 1994), animal training (Protopopova et al., 2016), autism (Ahearn & Tiger, 2013), aviation safety (Rantz & Van Houten, 2013)

B
baseball (Heward, 1978), basketball (Kladopoulos & McComas, 2001), bedtime refusal (Friman et al., 1999), behavioral pharmacology (Roll, 2014), bicycle safety (Okinaka & Shimazaki, 2011), blackjack skills (Speelman et al., 2015), braille (Scheithauer & Tiger, 2014), breast cancer detection (Bones et al., 2016), bruxism (Barnoy et al., 2009), bullying (Ross et al., 2009)

C
caffeinism (Foxx & Rubinoff, 1979), cancer prevention (Lombard et al., 1991), child abuse (Van Camp et al., 2003), climate change (Heward & Chance, 2010), coaching athletes (Stokes et al., 2010), college teaching (Kellum et al., 2001), compassion (Geller, 2012), cooperative learning (Maheady et al., 2006), creativity (Winston & Baker, 1985), crying (Bowman, 2013), culturally responsive social skills instruction (Lo et al., 2015)

D
dance (Quinn et al., 2015), delusional speech (Travis & Sturmey, 2010), dementia (Engelman et al., 1999), depression (Follette & Darrow, 2014), developmental disabilities (Kurtz & Lind, 2013), diabetes (Raiff et al., 2016), drug addiction (Silverman et al., 2011), dyslexia (Denton & Meindl, 2016)

E
education (Heward et al., 2005), elopement (Kodak et al., 2004), energy conservation (Staats et al., 2000), enuresis (Friman & Jones, 2005)

F
fear of dental procedures (Conyers et al., 2004), feeding disorders (Volkert & Piazza, 2012), figure skating (Hume et al., 1985), fire safety (Garcia et al., 2016), food bank donations (Farrimond & Leland, 2006), football (Ward & Carnes, 2002), foster-family care (Hawkins et al., 1985)

G
gambling (Dixon et al., 2015), gamification (Morford et al., 2014) gender-based violence (Szabo et al., 2019), gerontology (Gallagher & Keenan, 2000), golf (Simek et al., 1994), gun safety (Miltenberger et al., 2005)

H
hairpulling (Rapp et al., 1999), handwriting (Trap et al., 1978), happiness (Parsons et al., 2012), headaches (Fitterling et al., 1988), highway safety (Van Houten et al., 1985), homework (Alber et al., 2002), horseback riding (Kelley & Miltenberger, 2016), horse training (Fox & Belding, 2015), hostage negotiation (Hughes, 2006), hygiene (Fournier & Berry, 2013)

I
impulsivity (Barry & Messer, 2003), incontinence (Adkins & Mathews, 1997), industrial safety (Fox et al., 1987), infant care (Dachman, et al., 1986), infection control (Babcock et al., 1992), intellectual disabilities (Frederick et al., 2013)

J
job finding (Azrin et al., 1975), joint attention (Taylor & Hoch, 2008), juvenile justice (Kirigin et al., 1982)

K
keyboard training (DeFulio, 2011), kidnapping prevention (Gunby et al., 2010), kitchen skills (Trask-Tyler et al., 1994), kleptomania (Kohn, 2006)

L
landmine detection (Edwards et al., 2015), language acquisition (Drasgow, et al., 1998), learning disabilities (Wolfe et al., 2000), leisure skills Schleien et al., 1981), littering (Powers et al., 1973), lockdown drill procedures (Dickson & Vargo, 2017)

M
martial arts (BenitezSantiago & Miltenberger, 2016), math (Hunter et al., 2016), medical procedures (Hagopian & Thompson, 1999), medical training (Levy et al., 2016), mental health (A-tjak et al., 2015), music skills (Griffith et al., 2018), myopia (Collins et al., 1981)

N
nail biting (Heffernan & Lyons, 2016), nervous habits (see nail biting, hair pulling), noise (Ring et al., 2014), noncompliance (Mace et al., 1988), nutrition (Horne et al., 2009)

O
obesity (De Luca & Holborn, 1992), observational learning (DeQuinzio & Taylor, 2015), obsessive-compulsive disorder (Penney et al., 2016), organizational behavior management (Rodriguez, 2011), otitis media (O'Reilly, 1997)

P
panic disorders, parenting (Miltenberger & Crosland, 2014), pediatrics (Friman & Piazza, 2011), phobias (Tyner et al., 2016), physical activity (Kuhl et al., 2015), physical education (McKenzie et al., 2009), pica (Hagopian et al., 2011), play skills (Davis-Temple et al., 2014), Prader-Willi syndrome (Page et al., 1983), problem solving (Axe et al., in press), procrastination (Johnson et al., 2016), public health (Biglan & Glenn, 2013), public speaking (Mancuso & Miltenberger, 2016)

Q
quality control (Kortick & O'Brien, 1996) quantitative analysis skills (Fienup & Critchfield, 2010), question asking/answering (Ingvarsson et al., 2007)

R
x-ray sheilding, reading (Twyman et al., 2005), recycling (O'Conner et al., 2010), robbery (Schnelle et al., 1979), rugby (Mellalieu et al., 2006), rumination (Woods et al., 2013)

S
safe sex (Honnen & Kleinke, 1990), school-wide behavior support (Freeman et al., 2016), seat-belt use (Van Houten et al., 2010), second language acquisition (May et al., 2016), self-injury (Lerman & Iwata, 1993), self-management (Reynolds et al., 2014), sexual abuse (Lumley et al., 1998), sharing (Marzullo-Kerth et al., 2011), sleep disorders (Piazza et al., 1997), soccer (Brobst & Ward, 2002), spelling (McNeish et al., 1992), stereotypy (Ahearn et al., 2003), stuttering (Wagaman et al., 1995), substance abuse (Roll et al., 2009), sustainability (Leeming et al., 2013), swimming (Hume & Crossman, 1992)

T
tantrums (Williams, 1959), TB detection (Poling et al., 2017), teacher training (Kretlow et al., 2012), thumb sucking (Friman, 2000), tobacco use (Romanowich & Lamb, 2015), toileting (Greer et al., 2016), toothbrushing (Poche et al., 1982), Tourette syndrome (Azrin & Peterson, 1988), track and field (Scott et al., 1997), traumatic brain injury (Heinicke et al., 2009)

U

SUMMARY

Science: Basic Characteristics and a Definition

1. Different types of scientific investigations yield knowledge that enables the description, prediction, and/or control of the phenomena studied.
2. Descriptive studies yield a collection of facts about the observed events that can be quantified, classified, and examined for possible relations with other known facts.
3. Knowledge gained from a study that finds the systematic covariation between two events—termed a correlation—can be used to predict the probability that one event will occur based on the occurrence of the other event.
4. Results of experiments that show that specific manipulations of one event (the independent variable) produce a reliable change in another event (the dependent variable), and that the change in the dependent variable was unlikely the result of extraneous factors (confounding variables)—a finding known as a functional relation—can be used to control the phenomena under investigation.
5. The behavior of scientists in all fields is characterized by a common set of assumptions and attitudes:
   - Determinism—the assumption that the universe is a lawful and orderly place in which phenomena occur as a result of other events.
   - Empiricism—the objective observation of the phenomena of interest.
   - Experimentation—the controlled comparison of some measure of the phenomenon of interest (the dependent variable) under two or more different conditions in which only one factor at a time (the independent variable) differs from one condition to another.
   - Replication—repeating experiments (and independent variable conditions within experiments) to determine the reliability and usefulness of findings.
   - Parsimony—simple, logical explanations must be ruled out, experimentally or conceptually, before more complex or abstract explanations are considered.
   - Philosophic doubt—continually questioning the truthfulness and validity of all scientific theory and knowledge.

A Brief History of Behavior Analysis

6. Behavior analysis consists of three major branches: behaviorism, the experimental analysis of behavior (EAB), and applied behavior analysis (ABA).
7. Watson espoused an early form of behaviorism known as stimulus–response (S–R) psychology, which did not account for behavior without obvious antecedent causes.
8. Skinner founded the experimental analysis of behavior (EAB), a natural science approach for discovering orderly and reliable relations between behavior and the environmental variables of which it is a function.
9. EAB is characterized by these methodological features:
   - Rate of response is the most common dependent variable.
   - Repeated or continuous measurement is made of carefully defined response classes.
   - Within-subject experimental comparisons are used instead of designs comparing the behavior of experimental and control groups.
   - The visual analysis of graphed data is preferred over statistical inference.
   - A description of functional relations is valued over formal theory testing.
10. Through thousands of laboratory experiments, Skinner and his colleagues and students discovered and verified the basic principles of operant behavior that provide the empirical foundation for behavior analysis today.
11. Skinner wrote extensively about a philosophy for a science of behavior he called radical behaviorism. Radical behaviorism attempts to explain all behavior, including private events such as thinking and feeling.
12. Methodological behaviorism is a philosophical position that considers behavioral events that cannot be publicly observed to be outside the realm of the science.
13. Mentalism is an approach to understanding behavior that assumes that a mental, or "inner," dimension exists that differs from a behavioral dimension and that phenomena in this dimension either directly cause or at least mediate some forms of behavior; it relies on hypothetical constructs and explanatory fictions.
14. Pragmatism is the philosophical position that the truth or value of a scientific statement is determined by the extent to which it promotes effective action.
15. The first published report of the application of operant conditioning with a human subject was a study by Fuller (1949), in which an arm-raising response was conditioned in an adolescent with profound disabilities.
16. The formal beginnings of applied behavior analysis can be traced to 1959 and the publication of Ayllon and Michael's article "The Psychiatric Nurse as a Behavioral Engineer."
17. Contemporary applied behavior analysis (ABA) began in 1968 with the publication of the first issue of the *Journal of Applied Behavior Analysis (JABA).*

Characteristics of Applied Behavior Analysis

18. Baer, Wolf, and Risley (1968) stated that a research study or behavior change program should meet seven defining dimensions to be considered applied behavior analysis:

- Applied—investigates socially significant behaviors with immediate importance to the subject(s).
- Behavioral—entails precise measurement of the actual behavior in need of improvement and documents that it was the subject's behavior that changed.
- Analytic—demonstrates experimental control over the occurrence and nonoccurrence of the behavior—that is, if a functional relation is demonstrated.
- Technological—the written description of all procedures used in the study is sufficiently complete and detailed to enable others to replicate it.
- Conceptually systematic—behavior change interventions are derived from basic principles of behavior.
- Effective—improves behavior sufficiently to produce practical results for the participant/client.
- Generality—produces behavior changes that last over time, appear in other environments, and/or spread to other behaviors.

19. ABA offers society an approach toward solving many of its problems that is accountable, public, doable, empowering, and optimistic.

A Definition of Applied Behavior Analysis

20. Applied behavior analysis is the science in which tactics derived from the principles of behavior are applied systematically to improve socially significant behavior and experimentation is used to identify the variables responsible for behavior change.

21. Behavior analysts work in one or more of four interrelated domains: behaviorism (theoretical and philosophical issues), the experimental analysis of behavior (basic research), applied behavior analysis (applied research), and professional practice (providing behavior analytic services to consumers).

22. Translational research bridges basic and applied research and informs both domains.

23. ABA's natural science approach to discovering environmental variables that reliably influence socially significant behavior and developing a technology to take practical advantage of those discoveries offers humankind its best hope for solving many of its problems.

24. Applied behavior analysis research and practice have improved human performance and the quality of participants' lives across a wide range of areas, but no problem has been solved completely, and many important problems, challenges, and opportunities remain.

KEY TERMS

applied behavior analysis (ABA)
behaviorism
determinism
empiricism
experiment
experimental analysis of behavior (EAB)
explanatory fiction
functional analysis
functional relation
hypothetical construct
mentalism
methodological behaviorism
parsimony
philosophic doubt
pragmatism
radical behaviorism
replication
science

MULTIPLE-CHOICE QUESTIONS

1. The level of investigation that involves the collection of facts about observed events that can be quantified, classified, and examined for possible relations with other known facts, and often suggests hypotheses or questions for additional research is:

   a. Prediction
   b. Experimentation
   c. Description
   d. Control

   Hint: (See "Science: Basic Characteristics and a Definition")

2. The level of investigation that demonstrates correlation between events and is based on repeated observations is:

   a. Prediction
   b. Experimentation
   c. Description
   d. Control

   Hint: (See "Science: Basic Characteristics and a Definition")

3. The level of investigation in which functional relations can be derived is:
   a. Prediction
   b. Experimentation
   c. Description
   d. Control
   Hint: (See "Science: Basic Characteristics and a Definition")

4. The overall goal of ________ is to achieve a thorough understanding of the phenomenon under study.
   a. Behavior Analysis
   b. Science
   c. Experimentation
   d. Functional relationships
   Hint: (See "Science: Basic Characteristics and a Definition")

5. A functional relation means that:
   a. Specific change in the independent variable can reliably be produced by specific manipulations in the dependent variable, and the change in the independent variable was unlikely to be the result of confounding variables.
   b. Specific change in the dependent variable can reliably be produced by specific manipulations in the independent variable, and the change in the independent variable was unlikely to be the result of confounding variables.
   c. Specific change in the dependent variable can reliably be produced by specific manipulations in the independent variable, and the change in the dependent variable was unlikely to be the result of confounding variables.
   d. Specific change in the dependent variable can reliably be produced by specific manipulations in the confounding variable, and the change in the dependent variable was unlikely to be the result of the independent variable.
   Hint: (See "Science: Basic Characteristics and a Definition")

6. This is the assumption upon which science is predicated, the idea that the universe is a lawful and orderly place in which all phenomena occur as a result of other events.
   a. Mentalism
   b. Determinism
   c. Empiricism
   d. Philosophic Doubt
   Hint: ("Science: Basic Characteristics and a Definition")

7. This is the idea that simple, logical explanations must be ruled out, experimentally or conceptually, before more complex or abstract explanations are considered.
   a. Philosophic Doubt
   b. Experimentation
   c. Replication
   d. Parsimony
   Hint: ("Science: Basic Characteristics and a Definition")

8. This is the branch of behavior analysis that focuses on basic research:
   a. Applied behavior analysis
   b. Behaviorism
   c. Experimental analysis of behavior
   d. Radical behaviorism
   Hint: (See "A Brief History of Behavior Analysis")

9. The S-R-S model of psychology is also known as:
   a. Three-term contingency
   b. Watsonian psychology
   c. Respondent behavior model
   d. Reflexive behavior model
   Hint: (See "A Brief History of Behavior Analysis")

10. This person is considered to be the founder of experimental analysis of behavior.
    a. John B. Watson
    b. B.F. Skinner
    c. Ivan Pavlov
    d. Don Baer
    Hint: (See "A Brief History of Behavior Analysis")

11. This is the approach to understanding behavior that assumes that a mental or "inner" dimension exists that differs from a behavioral dimension and that phenomena in this dimension either directly cause or at least mediate some forms of behavior.
    a. Radical behaviorism
    b. Methodological behaviorism
    c. Structuralism
    d. Mentalism
    Hint: (See "A Brief History of Behavior Analysis")

12. These events marked the formal beginning of contemporary applied behavior analysis.
    a. "Some Current Dimensions of Applied Behavior Analysis," by Baer, Wolf, and Risley, was published and "The Psychiatric Nurse as a Behavioral Engineer," by Ayllon and Michael, was published.
    b. "The Psychiatric Nurse as a Behavioral Engineer," by Ayllon and Michael, was published and Fuller conducted a study in which human application of operant behavior occurred.
    c. The Journal of Applied Behavior Analysis began publication and "Some Current Dimensions of Applied Behavior Analysis," by Baer, Wolf, and Risley, was published.
    d. The Journal of Applied Behavior Analysis began publication and "The Psychiatric Nurse as a Behavioral Engineer," by Ayllon and Michael, was published.
    Hint: (See "A Brief History of Behavior Analysis")

13. This is the defining characteristic of behavior analysis that focuses on investigating socially significant behaviors with immediate importance to the participant(s).
    a. Effective
    b. Applied
    c. Behavioral
    d. Analytical
    Hint: (See "Characteristics of Applied Behavior Analysis")

14. This is the defining characteristic of applied behavior analysis that demonstrates experimental control over the occurrence and non-occurrence of the behavior.
    a. Effective
    b. Analytic
    c. Applied
    d. Experimentation
    Hint: (See "Characteristics of Applied Behavior Analysis")

ESSAY-TYPE QUESTIONS

1. Describe the goal of science and the three different levels of investigation.
   Hint: ("Science: Basic Characteristics and a Definition")
2. State and describe the different scientific attitudes.
   Hint: ("Science: Basic Characteristics and a Definition")
3. Discuss similarities and differences between different perspectives on behavior (i.e., mentalism, radical behaviorism, methodological behaviorism, and structuralism).
   Hint: (See "A Brief History of Behavior Analysis")
4. Discuss the origin of applied behavior analysis, including early history of the field and defining events of contemporary applied behavior analysis.
   Hint: (See "A Brief History of Behavior Analysis")
5. Compare and contrast the different branches of behavior analysis.
   Hint: (See "A Brief History of Behavior Analysis")
6. State and describe each of the defining dimensions of applied behavior analysis.
   Hint: (See "Characteristics of Applied Behavior Analysis")

NOTES

1. Spurious correlations result from measures of two randomly chosen variables closely tracking each other (e.g., rise in annual organic food sales and increased incidence of autism [Redditor Jasonp55, 2018], per capita margarine consumption and the divorce rate in Maine [Vigen, 2015]). For more silly examples, see Vigen (2015); for detailed explanation of the fallacy, see West, Bergstrom, and Bergstrom (2010).
2. Skinner (1953) noted that although telescopes and cyclotrons give us a "dramatic picture of science in action" (p. 12), and science could not have advanced very far without them, such devices and apparatus are not science themselves. "Nor is science to be identified with precise measurement. We can measure and be mathematical without being scientific at all, just as we may be scientific without these aids" (p. 12). Scientific instruments bring scientists into greater contact with their subject matter and, with measurement and mathematics, enable a more precise description and control of key variables.
3. Informative and interesting descriptions of the history of behavior analysis can be found in Goodall (1972); Guericio (2018); Hackenberg (1995); Michael (2004); Morris, Todd, Midgley, Schneider, and Johnson (1990); Mountjoy and Cone (1997); Risley (2005); Sidman (2002); Skinner (1956, 1979); Stokes (2003); Vargas, Vargas, and Knapp (2017); and in a special section of articles in the Fall 2003 issue of *The Behavior Analyst*.
4. For interesting biographies and scholarly examinations of J. B. Watson's life and contributions to behavior analysis, see Catania (1993); Morris (2013); and Morrow (2017).
5. In *The Behavior of Organisms,* Skinner called the conditioning of respondent behavior Type S conditioning and the conditioning of operant behavior Type R conditioning, but these terms were soon dropped. Respondent and operant conditioning and the three-term contingency are further defined and discussed in Chapter 2.
6. Most of the methodological features of the experimental approach pioneered by Skinner (e.g., rate of response as the primary dependent variable, within-subject experimental comparisons, visual analysis of graphic data displays) continue to characterize both basic and applied research in behavior analysis (e.g., Fisher, Piazza, & Roane, 2011; Lattal, 2013; Perone & Hursh, 2013). The five chapters in Part III describe how applied behavior analysts use this experimental approach.
7. Skinner, considered by many the most eminent psychologist of the 20th century (Haagbloom et al., 2002), authored or coauthored 291 primary-source works and a three-volume autobiography (*Particulars of My Life,* 1976; *The Shaping of a Behaviorist,* 1979; *A Matter of Consequences,* 1983). Many of Skinner's books are available as name-your-price products at the B. F. Skinner Foundation (bfskinner.org). Numerous biographical books and articles have been written about Skinner, both before and after his death. *Burrhus Frederic Skinner (1904–1990): A Thank You* by Fred Keller (1976), *B. F. Skinner—The Last Few Days* by his daughter Julie Vargas (1990), *B. F. Skinner, Organism* by Charles Catania (1992), *B. F. Skinner: A Life* by Daniel Bjork (1997), *Skinner as Self-Manager* by Robert Epstein (1997), *Burrhus F. Skinner: Shaper of Behaviour* by Frederik Toates (2009), and a series of articles in the 2017, Quarter 1 issue of *Operants* provide interesting and informative insights about Skinner and his work. Morris, Altus, and Smith (2005) detail Skinner's contributions to ABA. Smith and Morris (2018) maintain a continually updated bibliography of citations, references, and other materials related to Skinner's writings.
8. The nature and role of pragmatism in radical behaviorism are long-running topics of discussion and debate (e.g., Barnes-Holmes, 2000; Baum, 2017; Moore, 2008; Schoneberger, 2016; Tourinho & Neno, 2003; Zuriff, 1980).
9. Excellent discussions and spirited debates about the meaning and usefulness of radical behaviorism as the philosophy for a science of behavior can be found in Baum (2011, 2017); Catania and Harnad (1988); Chiesa (1994); Diller and Lattal (2008); Johnston (2013); Moore (2008, 2011); Palmer (2011); and Rachlin (2018).
10. Boyle and Greer (1983) published an extension of Fuller's classic study with comatose patients.
11. Sidney Bijou's remarkable career and the numerous ways he contributed to the founding and advancement of behavior analysis are detailed with a personal touch by Morris (2008, 2009).

12. Articles describing the histories of the applied behavior analysis programs at five of these universities can be found in the winter 1993 issue of *JABA*. Kenneth Goodall's article, *The Behavior Shapers* (1972), provides a fascinating look at the work of some of the field's pioneers.
13. Furman and Lepper (2018) take issue with this definition of applied behavior analysis because it "employs a subjective criterion (i.e., social relevance and/or importance to man and society), taking it out of the realm of an objective science" (p. 103) and suggest that ABA be defined as "the scientific study of behavior change, using the principles of behavior, to evoke or elicit a targeted behavioral change" (p. 104). We believe *socially significant behavior* is an essential element of the definition of ABA. The science and the philosophy of behaviorism it embodies purposely seek behavior changes that improve people's quality of life (Kimball & Heward, 1993; Skinner, 1971; 1974). Objective (i.e., scientific) methods for assessing and validating the social importance of behaviors targeted for change and the extent to which behavior change improves participants' quality of life are described in Chapters 3 and 10.
14. Choice making in concurrent schedules, delay discounting, and operant variability are discussed in Chapters 13, 27, and 29, respectively.
15. For perspectives on the status, role, and future of basic research in behavior analysis, see Killeen (2018), Marr (2017), and a special series of articles invited by Li, Mahoney, and Poling (2018).
16. To learn more about translational research, see Critchfield (2011a, b) and articles in the Fall 2009 and Spring 2011 issues of *The Behavior Analyst*.

CHAPTER 2

Basic Concepts and Principles

LEARNING OBJECTIVES

- Define behavior, response, and response class.
- State examples of behavior, response, and response class.
- Define stimulus and stimulus class.
- Define and state examples of positive reinforcement.
- Define and state examples of negative reinforcement.
- Define and provide examples of conditioned and unconditioned reinforcement.
- Define and state examples of positive punishment.
- Define and state examples of negative punishment.
- Define and provide examples of stimulus control.
- Define and provide examples of establishing operations.
- Describe a behavioral contingency.
- Describe the respondent conditioning paradigm.
- Provide an example of the respondent conditioning paradigm.
- Describe the operant conditioning paradigm.
- Provide an example of the operant conditioning paradigm.

> One must understand how the organism is modified by its interactions with the environment, how new environment–behavior relations are learned and unlearned.
>
> —Jack L. Michael (2004, p. 1)

This chapter defines the basic concepts required for a scientific analysis of behavior and introduces fundamental principles discovered by such analyses. Behavior, the first concept we examine, is the most fundamental of all. Because the controlling variables of primary importance to applied behavior analysts are located in the environment, the concepts of environment and stimulus are defined next. We then introduce several essential findings that the scientific study of behavior–environment relations has discovered. Two types of behavior—respondent and operant—are described, and the basic ways the environment influences each type—respondent conditioning and operant conditioning—are introduced. The three-term contingency—a concept for expressing temporal and functional relations between operant behavior and environment—and its importance as a focal point in applied behavior analysis are then explained.[1] The chapter's final section recognizes the enormous complexity of human behavior, reminds us that behavior analysts possess an incomplete, though ever-expanding and progressively sophisticated, knowledge of their subject matter, and identifies some of the obstacles and challenges faced by those who strive to change behavior in applied settings.

BEHAVIOR

What, exactly, is behavior? In a nutshell, behavior is the activity of living organisms. Human behavior is everything people do, including how they move and what they say, think, and feel. Tearing open a bag of peanuts is behavior, and so is thinking how good the peanuts will taste once the bag is open. Reading this sentence is behavior, and if you're holding the book, so is feeling its weight and shape in your hands.

Although words such as *activity* and *movement* communicate the general notion of behavior, a more precise definition is needed for scientific purposes. How a scientific discipline defines its subject matter exerts profound influence on the methods of measurement, experimentation, and theoretical analyses that are appropriate and possible.

Building on Skinner's (1938) definition of behavior as "the movement of an organism or of its parts in a frame of reference provided by the organism or by various external objects or fields" (p. 6), Johnston and Pennypacker (1980, 1993, 2009) articulated the most conceptually sound and empirically complete definition of behavior to date. In *Strategies and Tactics of Behavioral Research*, third edition, these authors define **behavior** as follows:

> Behavior is that portion of an organism's interaction with its environment that involves movement of some part of the organism (2009, p. 31).

Johnston and Pennypacker discuss each part of this definition as it relates to researchers and practitioners. The phrase *of an organism* restricts the subject matter to the activity of living organisms, leaving notions such as the "behavior" of the stock market outside the realm of the scientific use of the term. The phrase *an organism's interaction with its environment* "avoids implying that behavior is a possession of the organism and highlights the requirement for an interactive condition" (2009, p. 31). The authors elaborated on this critical part of the definition in the second edition of their text:

> Behavior is not a property or attribute of the organism. It happens only when there is an interactive condition between an organism and its surroundings, which include its own body. This means that independent states of the organism, whether real or hypothetical, are not behavioral events, because there is no interactive process. *Being hungry* or *being anxious* are examples of states that are sometimes confused with the behavior that they are supposed to explain. Neither phrase specifies an environmental agent with which the hungry or anxious organism interacts, so no behavior is implied.
>
> Similarly, independent conditions or changes in the environment do not define behavioral occurrences because no interaction is specified. Someone walking in the rain gets wet, but "getting wet" is not an instance of behavior. A child may receive tokens for correctly working math problems, but "receiving a token" is not behavior. Receiving a token implies changes in the environment but does not suggest or require change in the child's movement. In contrast, both doing math problems and putting the token in a pocket are behavioral events because the environment both prompts the child's actions and is then changed by them. (Johnston & Pennypacker, 1993, p. 24, emphasis added)

In addition to excluding static states of the organism, the definition does not include bodily movements produced by independent physical forces as behavioral events. For example, being blown over by a strong gust of wind is not behavior; given sufficient wind, nonliving objects and organisms move similarly.[2]

The phrase *movement of some part of the organism* identified behavior as movement, regardless of scale. "To be observed, a response must affect the environment—it must have an effect upon an observer or upon an instrument, which in turn can affect an observer. This is as true of the contraction of a small group of muscle fibers as of pressing a lever or pacing a figure 8" (Skinner, 1969, p. 130). Behavior includes movement of body parts within the skin not accessible for observation by others. As Catania (2013) noted, shifting one's attention to different instruments while listening to recorded music need not involve the movement of the head or eyes or any other obvious body part.

The word *behavior* is usually used in reference to a class of responses sharing certain functions (e.g., eating behavior, greeting behavior, writing behavior).[3] The term *response* refers to a specific instance of behavior. A technical definition of **response** is an "*action of an organism's effector.* An effector is an organ at the end of an efferent nerve fiber that is specialized for altering its environment mechanically, chemically, or in terms of other energy changes" (Michael, 2004, p. 8, italics in original). Human effectors include the striated muscles (i.e., skeletal muscles such as biceps and quadriceps), smooth muscles (e.g., stomach and bladder muscles), and glands (e.g., adrenal and pituitary glands).

Behavior can also be described by its form, or physical characteristics. *Response topography* refers to the physical shape or form of behavior. For example, the hand and finger movements used to open a bag of peanuts can be described by their topographical elements. However, careful observation will reveal that the topography differs somewhat each time a person opens a bag of snacks. The difference may be slight, but each "bag opening response" will vary somewhat from all others.

Although describing behavior by its topography is sometimes useful, behavior analysis is characterized by a *functional analysis* of the effects of behavior on the environment. A **response class** is a group of responses with the same function (that is, each response in the group produces the same effect on the environment). Some response classes comprise responses of widely varying form—imagine the tremendous variability in responses to the request to "do something unpredictable" (Neuringer, 2009)—whereas the topographical variation among members of other response classes is limited (e.g., a person's signature, proper grip for a four-seam fastball).

Another reason underscoring the importance of a functional analysis of behavior over a structural or topographical description is that two responses of the same topography can be completely different behaviors depending on the controlling variables. For example, saying "fire" while looking at the letters, *f-i-r-e,* is a vastly different behavior from yelling "Fire!" when smelling smoke or seeing flames in a crowded theater.

Behavior analysts use the term **repertoire** in at least two ways. *Repertoire* is sometimes used to refer to all of the behaviors a person can do. More often the term denotes a person's collection of knowledge and skills relevant to particular settings or tasks. In the latter sense, each of us has learned multiple repertoires. For example, each of us has a repertoire of behaviors appropriate for informal social situations that differs somewhat (or a lot) from the behaviors we use to navigate formal situations. And each person has repertoires with respect to language skills, academic tasks, everyday routines, recreation, and so on. After studying this text, your repertoire of knowledge and skills in applied behavior analysis will be advanced.

ENVIRONMENT

All behavior occurs within an environmental context; behavior cannot be emitted in an environmental void or vacuum. Johnston and Pennypacker (2009) defined environment and noted the implications of that definition for a science of behavior as follows:

> **Environment** refers to the full set of physical circumstances in which the organism exists. The term is comprehensive in that any facets of the physical world may be considered for their contribution to behavior. The term is specific in that for any particular behavior, the focus is usually on only those environmental events that are functionally related to individual responses. . . .

> The relevant environment can even include the organism doing the behaving. . . . [W]hen you scratch an itch, the stimulation from your skin probably increases the effectiveness of relief from the itching as a negative reinforcer and makes the behavior of scratching more likely. Our bodies are an ongoing source of antecedent and consequent environmental events related to responding. This fact reminds us that the skin is not an especially important boundary in understanding of behavior. (p. 29)

The environment is a complex, dynamic universe of events that differs from moment to moment. When behavior analysts describe particular aspects of the environment, they talk in terms of stimulus conditions or events. A **stimulus** is "an energy change that affects an organism through its receptor cells" (Michael, 2004, p. 7). Humans have receptor systems that detect stimulus changes occurring outside and inside the body. *Exteroceptors* are sense organs that detect external stimuli and enable vision, hearing, olfaction, taste, and cutaneous touch. Two types of sense organs sensitive to stimulus changes within the body are *interoceptors,* which are sensitive to stimuli originating in the viscera (e.g., feeling a stomach ache), and *proprioceptors,* which enable the kinesthetic and vestibular senses of movement and balance. Applied behavior analysts most often study the effects of stimulus changes that occur outside the body. External stimulus conditions and events are not only more accessible to observation and manipulation than are internal conditions, but also are key features of the physical and social world in which people live.

The environment influences behavior primarily by stimulus change and not static stimulus conditions. As Michael (2004) noted, when behavior analysts speak of the presentation or occurrence of a stimulus, they usually mean stimulus change.

> For example, in respondent conditioning the conditioned stimulus may be referred to as a tone. However, the relevant event is actually a change from the absence of tone to the tone sounding . . . , and although this is usually understood without having to be mentioned, it can be overlooked in the analysis of more complex phenomena. Operant discriminative stimuli, conditioned reinforcers, conditioned punishers, and conditioned motivative variables are also usually important as stimulus changes, not static conditions (Michael, 2004, pp. 7–8).[4]

Box 2.1, "The Behavioral Stream," illustrates the continuous, ever-changing nature of behavior and the environment.

Classifying and Describing Stimuli

Stimulus events can be described formally (by their physical features), temporally (by when they occur with respect to a behavior of interest), and functionally (by their effects on behavior). Behavior analysts used the term **stimulus class** to refer to any group of stimuli sharing a predetermined set of common elements in one or more of these dimensions.

Formal Dimensions of Stimuli

Behavior analysts often describe, measure, and manipulate stimuli according to their formal dimensions, such as size, color, intensity, weight, and spatial position relative to other objects. Stimuli can be nonsocial (e.g., a red light, a high-pitched sound) or socially mediated (e.g., a friend asking, "Want some more peanuts?").

Temporal Loci of Stimuli

Because behavior and the environmental conditions that influence it occur within and across time, the temporal location of stimulus changes is important. In particular, behavior is affected most by stimulus changes that occur prior to and soon after the behavior. The term **antecedent** refers to environmental conditions or stimulus changes that exist or occur prior to the behavior of interest.

Because behavior cannot occur in an environmental void or vacuum, every response takes place in the context of a particular situation or set of antecedent conditions. These antecedent events play a critical part in learning and motivation, and they do so irrespective of whether the learner or someone in the role of behavior analyst or teacher has planned or is even aware of them.

> For example, just some of the functionally relevant antecedents for a student's performance on a timed math test might include the following: the amount of sleep the student had the night before; the temperature, lighting, and seating arrangements in the classroom; the teacher reminding the class that students who beat their personal best scores on the test will get a free homework pass; and the specific type, format, and sequence of math problems on the test. Each of those antecedent variables (and others) has the potential to exert a great deal, a little, or no noticeable effect on performance as a function of the student's experiences with respect to a particular antecedent. (Heward & Silvestri, 2005, p. 1135)

A **consequence** is a stimulus change that follows a behavior of interest. Some consequences, especially those that are relevant to current motivational states and follow the behavior closely in time, have significant influence on future behavior; other consequences have little effect.

Like antecedent stimulus events, consequences may also be nonsocial events or socially mediated. In a **socially mediated contingency**, another person presents an antecedent stimulus and/or the consequence for the behavior. Table 2.1 on page 47 shows examples of various combinations of nonsocial and socially mediated antecedent and consequent events for four behaviors.

Multiple Functions of Single Stimulus Changes

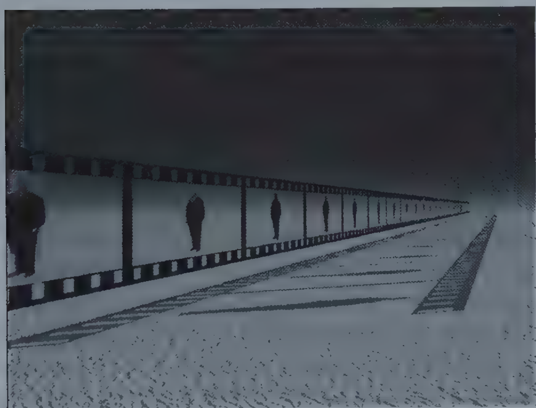
Some stimulus changes exert immediate and powerful control over behavior, whereas others have delayed effects, or no apparent effect. Even though we can and often do describe stimuli by their physical characteristics (e.g., the pitch and decibel level of a tone, the topography of a person's hand and arm movements), stimulus changes are understood best through a functional analysis of their effects on behavior. For example, the same decibel tone that functions in one environment and set of conditions as a prompt for checking the clothes in the dryer may function as a warning signal to fasten a seat belt in another setting or situation; the same hand and arm motion that produces a smile and a "Hi" from another person in one set of conditions occasions a scowl and obscene gesture in another.

Stimulus changes can have one or both of two kinds of basic functions or effects on behavior: (a) an immediate but

BOX 2.1

The Behavioral Stream

Although the concepts of stimulus and response have proven useful for conceptual, experimental, and applied analyses of behavior, it is important to recognize that stimuli and responses do not exist as discrete events in nature. The stimuli and responses identified by scientists and practitioners are detectable "slices" of the continuous, ever-dynamic interaction between an organism and its environment. Mickey Keenan and Karola Dillenburger (2013) call this process the "behavioral stream." They illustrate and describe it as follows:

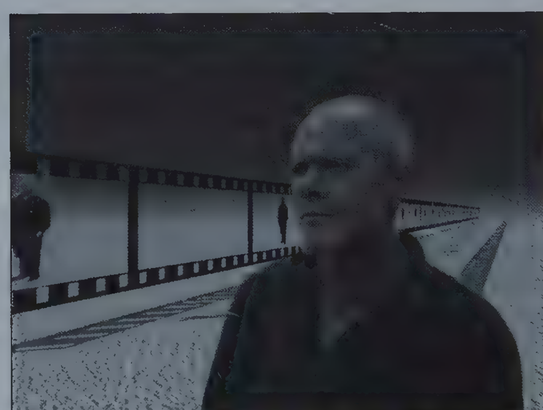


This figure shows the life of an individual to be a continuous process.

Upon first meeting a person, we observe only a snapshot in his life.

The image of a person as a continuous process is difficult to retain.

A consequence of this is that we usually engage in a mentalistic analysis. That is, we attempt to explain a person's behavior by referring to something taking place inside him, in his brain or in his mind.



A natural science perspective, however, enables us to retain the image of a person as a continuous process. From this perspective, the purpose of scientific enquiry is to relate segments of this continuous process to the independent variables that produce them. So-called mental events are part of the continuous process, not the explanation for what is observed.

TABLE 2.1 Antecedent (Situation) and Consequent Events Can Be Nonsocial (Italicized), Socially Mediated (Boldface), or a Combination of Social and Nonsocial

Environmental situation	Response	Consequence
Drink machine	Deposit coins	*Cold drink*
Five cups on table	"One-two-three-four-five cups"	***Teacher nods and smiles***
Friend says "Turn left"	Turn left	*Arrive at destination*
Friend asks "What time is it?"	"Six-fifteen"	***Friend says "Thanks"***

From "Individual Behavior, Culture, and Social Change" by S. S. Glenn, 2004, *The Behavior Analyst, 27*, p. 136. Copyright 2004 by the Association for Behavior Analysis. Used by permission.

temporary effect of increasing or decreasing the frequency of the behavior and/or (b) a delayed but relatively permanent effect in terms of the frequency of that type of behavior in the future (Michael, 1995). For example, a sudden downpour on a cloudy day is likely to increase immediately the occurrence of all behavior that has resulted in escape from rain in the past, such as deploying an umbrella or running for cover under an awning. A person caught in the rain without an umbrella may be more likely to bring one on cloudy days in the future.

RESPONDENT BEHAVIOR

All biologically intact organisms enter the world able to respond in predictable ways to certain stimuli; no learning is required. These ready-made behaviors protect against harmful stimuli (e.g., eyes watering and blinking to remove particles on the cornea), help regulate the internal balance and economy of the organism (e.g., changes in heart rate and respiration in response to changes in temperature and activity levels), and promote reproduction (e.g., sexual arousal). Each of these stimulus–response relations, called a **reflex**, is part of the organism's genetic endowment, a product of natural evolution because of its survival value to the species. At birth, each intact member of a given species comes equipped with the same repertoire of unconditioned (or unlearned) reflexes. Reflexes provide the organism with a set of built-in responses to specific stimuli; these are behaviors the individual organism would not have time to learn. Table 2.2 shows examples of unconditioned reflexes common to humans.

The response component of the stimulus–response reflex is called respondent behavior. **Respondent behavior** is behavior that is elicited by antecedent stimuli. Respondent behavior is induced, or brought out, by a stimulus that precedes the

TABLE 2.2 Examples of Unconditioned Reflexes in Humans

Unconditioned Stimulus	Unconditioned Response	Type of Effector
Loud sound or touch to cornea	Eye blink (lid closes)	Striped muscle
Tactile stimulus under lid or chemical irritant (smoke)	Lacrimal gland secretion (eyes watering)	Gland
Irritation to nasal mucosa	Sneezing	Striped and smooth muscle
Irritation to throat	Coughing	Striped and smooth muscle
Low temperature	Shivering, surface vasoconstriction	Striped and smooth muscle
High temperature	Sweating, surface vasodilation	Gland, smooth muscle
Loud sound	Contraction of tensor tympani and stapedius muscles (reduces amplitude of eardrum vibrations)	Striped muscles
Food in mouth	Salivation	Gland
Indigestible food in stomach	Vomiting	Striped and smooth muscle
Pain stimulus to hand or foot	Hand or foot withdrawal	Striped muscle
A single stimulus that is painful or very intense or very unusual	Activation syndrome—all of the following:	
	Heart rate increase	Cardiac muscle
	Adrenaline secretion	Gland
	Liver release of sugar into bloodstream	Gland
	Constriction of visceral blood vessels	Smooth muscle
	Dilation of blood vessels in skeletal muscles	Smooth muscle
	Galvanic skin response (GSR)	Gland
	Pupillary dilation (and many more)	Smooth muscle

From *Concepts and Principles of Behavior Analysis* (rev. ed.) by J. L. Michael, 2004, pp. 10–11. Copyright 2004 by Society for the Advancement of Behavior Analysis, Kalamazoo, MI.

behavior; nothing else is required for the response to occur. For example, bright light in the eyes (antecedent stimulus) will elicit pupil contraction (respondent). If the relevant body parts (i.e., receptors and effectors) are intact, pupil contraction will occur every time. However, if the eliciting stimulus is presented repeatedly over a short span of time, the strength or magnitude of the response will diminish, and in some cases the response may not occur at all. This process of gradually diminishing response strength is known as **habituation**.

Respondent Conditioning

Formerly neutral stimuli can acquire the ability to elicit respondents through a learning process called **respondent conditioning** (also called *Pavlovian conditioning* and *classical conditioning*). While studying the digestive system of dogs, the Russian physiologist Ivan Petrovich Pavlov (1849–1936) noticed that the animals salivated every time his laboratory assistant opened the cage door to feed them. Dogs do not naturally salivate at the sight of someone in a lab coat, but in Pavlov's laboratory they consistently salivated when the door was opened. His curiosity aroused, Pavlov (1927) designed and conducted an historic series of experiments.[5]

Pavlov started a metronome just an instant before feeding the dogs. Prior to being exposed to this **stimulus–stimulus pairing** procedure, food in the mouth, an **unconditioned stimulus (US)**, elicited salivation, but the sound of the metronome, a **neutral stimulus (NS)**, did not. After several trials consisting of the sound of the metronome followed by the presentation of food, the dogs began salivating in response to the sound of the metronome. The metronome had thus become a **conditioned stimulus (CS)**, and a **conditioned reflex** was established.[6] Respondent conditioning is most effective when the NS is presented just before or simultaneous with the US. However, some conditioning effects can sometimes be achieved with considerable delay between the onset of the NS and the onset of the US, and even with backward conditioning in which the US precedes the NS.

Respondent Extinction

Pavlov also discovered that once a conditioned reflex was established, it would weaken and eventually cease altogether if the conditioned stimulus was presented repeatedly in the absence of the unconditioned stimulus. For example, if the sound of the metronome was presented repeatedly without being accompanied or followed by food, it would gradually lose its ability to elicit salivation. The procedure of repeatedly presenting a conditioned stimulus without the unconditioned stimulus until the conditioned stimulus no longer elicits the conditioned response is called **respondent extinction**.

Figure 2.1 shows schematic representations of respondent conditioning and respondent extinction. In this example, a puff

Before Conditioning	US (air puff)	→	UR (eye blink)
	NS (clicking sound)	----------	no eye blink
Respondent Conditioning	NS + US (click & air puff)	→	UR (eye blink)
	⇓		
	NS + US (click & air puff)	→	UR (eye blink)
	⇓ (more trials)		
Product of Respondent Conditioning	US (air puff)	→	UR (eye blink)
	CS (clicking sound)	→	CR (eye blink)
Respondent Extinction	CS (clicking sound)	→	CR (eye blink)

	CS (clicking sound)	→	CR (eye blink)
	⇓		
	CS (clicking sound)	→	CR (eye blink)
	⇓ (more trials)		
Results of Respondent Extinction	US (air puff)	→	UR (eye blink)
	NS (clicking sound)	----------	no eye blink

Figure 2.1 Schematic representation of respondent conditioning and respondent extinction. The top panel shows an unconditioned reflex: A puff of air (unconditioned stimulus, or US) elicits an eye blink (an unconditioned response, or UR). Before conditioning, a clicking sound (a neutral stimulus, or NS) has no effect on eye blinking. Respondent conditioning consists of a stimulus–stimulus pairing procedure in which the clicking sound is presented repeatedly just prior to, or simultaneously with, the air puff. The product of respondent conditioning is a conditioned reflex (CR): In this case the clicking sound has become a conditioned stimulus (CS) that elicits an eye blink when presented alone. The bottom two panels illustrate the procedure and outcome of respondent extinction: Repeated presentations of the CS alone gradually weaken its ability to elicit eye blinking to the point where the CS eventually becomes an NS again. The unconditioned reflex remains unchanged before, during, and after respondent conditioning.

of air produced by a glaucoma-testing machine is the US for the eye blink reflex. The ophthalmologist's finger pressing the button of the machine makes a faint clicking sound. But prior to conditioning, the clicking sound is an NS: It has no effect on eye blinking. After being paired with the air puff just a few times, the finger-on-the-button sound becomes a CS: It elicits eye blinking as a conditioned reflex.

Conditioned reflexes can also be established by stimulus–stimulus pairing of an NS with a CS. This form of respondent conditioning is called **higher-order** (or *secondary*) **conditioning**. For example, secondary respondent conditioning could occur in a patient who has learned to blink at the clicking sound of the button during the glaucoma-testing situation as follows. The patient detects a slight movement of the ophthalmologist's finger (NS) just before it contacts the button that makes the clicking sound (CS). After several NS–CS pairings, movement of the ophthalmologist's finger may become a CS capable of eliciting blinking.[7]

The form, or topography, of respondent behaviors changes little, if at all, during a person's lifetime. There are two exceptions: (1) Certain reflexes disappear with maturity, such as that of grasping an object placed in the palm of the hand, a reflex usually not seen after the age of 3 months (Bijou & Baer, 1965); and (2) several unconditioned reflexes first appear later in life, such as those related to sexual arousal and reproduction. However, during a person's lifetime an infinite range of stimuli that were previously neutral (e.g., the high-pitched whine of the dentist's drill) can come to elicit respondents (e.g., increased heartbeat and perspiration).

Respondents make up a small percentage of the behaviors typically of interest to applied behavior analysts. As Skinner (1953) pointed out, "Reflexes, conditioned or otherwise, are mainly concerned with the internal physiology of the organism. We are most often interested, however, in behavior which has some effect upon the surrounding world" (p. 59). It is this latter type of behavior, and the process by which it is learned, that we will now examine.

OPERANT BEHAVIOR

A baby in a crib moves her hands and arms, setting in motion a mobile dangling above. The baby is literally operating on her environment, and the mobile's movement and musical sounds—stimulus changes produced by the baby's batting at the toy with her hands—are consequences of her behavior. Her movements are continuously changing as a result of those consequences.

Members of a species whose only way of interacting with the world is a genetically determined fixed set of responses would find it difficult to survive, let alone thrive, in a complex environment that differed from the environment in which their distant ancestors evolved. Although respondent behavior comprises a critically important set of "hard-wired" responses, respondent behavior does not provide an organism with the ability to learn from the consequences of its actions. An organism whose behavior is unchanged by its effects on the environment will be unable to adapt to a changing environment.

Fortunately, in addition to her repertoire of genetically inherited respondent behaviors, our baby entered the world with some *uncommitted behavior* that is highly malleable and susceptible to change through its consequences. This type of behavior, called operant behavior, enables the baby over the course of her life to learn novel, increasingly complex responses to an ever-changing world.[8]

Operant behavior is any behavior determined primarily by its history of consequences. Unlike respondent behavior, which is elicited by antecedent events, operant behavior is selected, shaped, and maintained by the consequences that have followed it in the past.

Unlike respondent behaviors, whose topography and basic functions are predetermined, operant behaviors can take a virtually unlimited range of forms. The form and function of respondent behaviors are constant. By comparison, however, the "meaning" of operant behavior cannot be determined by its topography. Operants are defined functionally, by their effects. Not only does the same operant often include responses of widely different topographies (e.g., a diner may obtain a glass of water by nodding his head, pointing to a glass of water, or saying yes to a waiter), but also, as Skinner (1969) explained, the same movements comprise different operants under different conditions.

> Allowing water to pass over one's hands can perhaps be adequately described as topography, but "washing one's hands" is an "operant" defined by the fact that, when one has behaved this way in the past, one's hands have become clean—a condition which has become reinforcing because, say, it has minimized a threat of criticism or contagion. Behavior of precisely the same topography would be part of another operant if the reinforcement had consisted of simple stimulation (e.g., "tickling") of the hands or the evocation of imitative behavior in a child whom one is teaching to wash his hands. (p. 127)

Topography is of little or no use in identifying behavior as respondent or operant. For example, crying elicited by painful stimuli is respondent behavior, but the same tear production is operant when a function of parental attention (cf., Bowman, Hardesty, & Mendres-Smith, 2013; Epstein, 2012).

Table 2.3 compares and contrasts defining features and key characteristics of respondent behavior and operant behavior.

Selection by Consequences

> *Human behavior is the joint product of (i) the contingencies of survival responsible for the natural selection of the species and (ii) the contingencies of reinforcement responsible for the repertoires acquired by its members, including (iii) the special contingencies maintained by the social environment. [Ultimately, of course, it is all a matter of natural selection, since operant conditioning is an evolved process, of which cultural practices are special applications.]*
>
> —B. F. Skinner (1981 p. 502)

Skinner's discovery and subsequent elucidation of operant selection by consequences have rightly been called "revolutionary" and

TABLE 2.3 Comparing and Contrasting Defining Features and Key Characteristics of Respondent and Operant Behavior

Characteristics or features	Respondent behavior	Operant behavior
Definition	Behavior elicited by antecedent stimuli.	Behavior selected by its consequences.
Basic unit	Reflex: an antecedent stimulus elicits a particular response (S–R).	Operant response class: A group of responses each of which produces the same effect on the environment; described by three-term contingency relation of antecedent stimulus conditions, behavior, and consequence (A–B–C).
Examples	Newborn's grasping and suckling to touch; pupil constriction to bright light; cough/gag to irritation in throat; salivation at smell of food; withdrawing hand from painful stimulus; sexual arousal to stimulation.	Talking, walking, playing the piano, riding a bike, counting change, baking a pie, hitting a curveball, laughing at a joke, thinking about a grandparent, reading this book.
Body parts (effectors) that most often produce the response (not a defining feature)	Primarily smooth muscles and glands (adrenaline squirt); sometimes striated (skeletal) muscles (e.g., knee-jerk to tap just below patella).	Primarily striated (skeletal) muscles; sometimes smooth muscles and glands.
Function or usefulness for individual organism	Maintains internal economy of the organism; provides a set of "ready-made" survival responses the organism would not have time to learn.	Enables effective interaction and adaptation in an ever-changing environment that could not be anticipated by evolution.
Function or usefulness for species	Promotes continuation of species indirectly (protective reflexes help individuals survive to reproductive age) and directly (reflexes related to reproduction).	Individuals whose behavior is most sensitive to consequences are more likely to survive and reproduce.
Conditioning process	Respondent (also called classical or Pavlovian) conditioning: Through a stimulus–stimulus pairing procedure in which a neutral stimulus (NS) presented just prior to or simultaneous with an unconditioned (US) or conditioned (CS) eliciting stimulus, the NS becomes a CS that elicits the response and a conditioned reflex is created. (See Figure 2.1)	Operant conditioning: Some stimulus changes following a response closely in time increase (reinforcement) or decrease (punishment) future occurrences of similar responses under similar conditions. Previously neutral stimulus changes become conditioned reinforcers or punishers as result of stimulus–stimulus pairing with other reinforcers or punishers.
Repertoire limits	Topography and function of respondents determined by natural evolution of species (phylogeny). All biologically intact members of a species possess the same set of unconditioned reflexes. Although new forms of respondent behavior are not learned, an infinite number of conditioned reflexes may emerge in an individual's repertoire, depending on the stimulus–stimulus pairing the individual has experienced (ontogeny).	Topography and function of each person's repertoire of operant behaviors are selected by consequences during the individual's lifetime (ontogeny). New and more complex operant response classes can emerge. Response products of some human operants (e.g., airplanes) enable some behaviors not possible by anatomical structure alone (e.g., flying).

"the bedrock on which other behavioral principles rest" (Glenn, 2004, p. 134). **Selectionism** "anchors a new paradigm in the life sciences. . . . A basic tenet of this position is that all forms of life, from single cells to complex cultures, evolve as a result of selection with respect to function" (Pennypacker, 1994, pp. 12–13).

Selection by consequences operates during the lifetime of the individual organism (**ontogeny**) and is a conceptual parallel to Darwin's (1872/1958) natural selection in the evolutionary history of a species (**phylogeny**).[9] In response to the question "Why do giraffes have long necks?" Baum (2017) provides this excellent description of natural selection:

> Darwin's great contribution was to see that a relatively simple mechanism could help explain why phylogeny followed the particular course it did. The history of giraffes' necks, Darwin saw, is more than a sequence of changes; it is a history of selection. What does the selecting? Not an omnipotent Creator, not Mother Nature, not the giraffes, but a natural, mechanical process: natural selection.
>
> Within any population of organisms, individuals vary. They vary partly because of environmental factors (e.g., nutrition), and also because of genetic inheritance. Among the giraffe ancestors that lived in what is now the Serengeti Plain, for instance, variation in genes meant that some had shorter necks and some had longer necks.
>
> As the climate gradually changed, however, new, taller types of vegetation became more frequent. The giraffe ancestors that had longer necks, being able to reach higher,

got a little more to eat, on the average. As a result, they were a little healthier, resisted disease a little better, evaded predators a little better—on the average. Any one individual with a longer neck may have died without offspring, but on the average longer-necked individuals had more offspring, which tended on the average to survive a little better and produce more offspring. As longer necks became frequent, new genetic combinations occurred, with the result that some offspring had still longer necks than those before, and they did still better. As the longer-necked giraffes continued to out-reproduce the shorter-necked ones, the population consisted more and more of longer-necked individuals, and the average neck length of the whole population grew. (pp. 59–60)

Just as natural selection requires a population of individual organisms with varied physical features (e.g., giraffes with necks of different lengths), operant selection by consequences requires variation in behavior. Those behaviors that produce the most favorable outcomes are selected and "survive," which leads to a more adaptive repertoire. Natural selection has endowed humans with an initial population of uncommitted behavior (e.g., babies babbling and moving their limbs about) that is highly malleable and susceptible to the influence of the consequences that follow it. As Glenn (2004) noted,

> By outfitting humans with a largely uncommitted behavioral repertoire, natural selection gave our species a long leash for local behavioral adaptations. But the uncommitted repertoire of humans would be lethal without the . . . susceptibility of human behavior to operant selection. Although this behavioral characteristic is shared by many species, humans appear to be most exquisitely sensitive to behavioral contingencies of selection (Schwartz, 1974). (p. 139)

Operant Conditioning

> *Operant conditioning may be seen everywhere in the multifarious activities of human beings from birth until death. . . . It is present in our most delicate discriminations and our subtlest skills; in our earliest crude habits and the highest refinements of creative thought.*
>
> —Keller and Schoenfeld (1950, p. 64)

Operant conditioning refers to the process and selective effects of consequences on behavior.[10] From an operant conditioning perspective, a functional consequence is a stimulus change that follows a given response closely in time and alters the occurrence of similar responses in the future. "In operant conditioning we 'strengthen' an operant in the sense of making a response more probable or, in actual fact, more frequent" (Skinner, 1953, p. 65). If the movement and sounds produced by the baby's batting at the mobile with her hands increase the occurrence of hand movements in the direction of the toy, operant conditioning has taken place.

When operant conditioning consists of an increase in response rate, *reinforcement* has taken place, and the consequence responsible, in this case the movement and sound of the mobile, would be called a **reinforcer**.[11] Although operant conditioning is used most often to refer to the "strengthening" effects of reinforcement, as Skinner described earlier, it also encompasses the principle of punishment. If the mobile's movement and musical sounds resulted in a decrease in the rate at which the baby bats it with her hands, *punishment* has occurred, and the mobile's movement and sound would be called **punishers**. Before we examine the principles of reinforcement and punishment further, it is important to identify several important qualifications concerning how consequences affect behavior.

Consequences Affect Only Future Behavior

Consequences affect only future behavior. Specifically, a behavioral consequence affects the relative rate at which similar responses will be emitted in the future under similar stimulus conditions. This point may seem too obvious to merit mention because it is both logically and physically impossible for a consequent event to affect a behavior that preceded it, when that behavior is over before the consequent event occurs. Nevertheless, the statement "behavior is controlled by its consequences" raises the question. (See Box 2.2, "When the Phone Rings," for further discussion of this apparent logical fallacy.)

Consequences Select Response Classes, Not Individual Responses

Responses emitted because of the effects of reinforcement will differ slightly from previously reinforced responses, but will share at least one functional element with the former responses to produce the same consequence.

> Reinforcement strengthens responses which differ in topography from the response reinforced. When we reinforce pressing a lever, for example, or saying Hello, responses differing quite widely in topography grow more probable. This is a characteristic of behavior which has strong survival value . . . , since it would be very hard for an organism to acquire an effective repertoire if reinforcement strengthened only identical responses. (Skinner, 1969, p. 131)

It is the response class—topographically different, but functionally similar responses—that is strengthened or weakened by operant conditioning. "An operant activity is a population of actions all of which have the same environmental effect" (Baum, 2017, p. 84). The concept of response class is "implied when it is said that reinforcement increases the future frequency of the *type* of behavior that immediately preceded the reinforcement" (Michael, 2004, p. 9). As will be shown in later chapters, the concept of response class is a key to the development and elaboration of new behavior.

If consequences (or natural evolution) selected only a very narrow range of responses (or genotypes), the effect would "tend toward uniformity and a perfection of sorts" (Moxley, 2004, p. 110) that would place the behavior (or species) at risk of extinction should the environment change. For example, if the mobile's movement and sound reinforced only arm and hand movements that fell within an exact and narrow range of motion and no similar movements survived, the baby would be unable to contact that reinforcement if one day her mother mounted the mobile in a different location above the crib.

BOX 2.2

When the Phone Rings

The professor was ready to move on to his next point, but a raised hand in the front row caught his attention.

Professor: Yes?

Student: You said that operant behavior, like talking, writing, running, reading, driving a car, most everything we do—you said all of those behaviors are controlled by their consequences, by things that happen *after* the response was emitted?

Professor: I said that. Yes.

Student: Well, I have a hard time with that. When my telephone rings and I pick up the receiver, that's an operant response, right? I mean, answering the phone when it rings certainly didn't evolve genetically as a reflex to help our species survive. So, we're talking about operant behavior, correct?

Professor: Correct.

Student: All right then. How can we say my picking up my telephone is controlled by its consequence? I answer the phone *because* it is ringing. So does everyone. Ringing controls the response. And ringing can't be a consequence because it comes before the response.

The professor hesitated replying just long enough for the student to believe himself the hero, nailing a professor for pontificating about some theoretical concept that has little or no relevance to the everyday real world. Simultaneously sensing victory, other students began to pile on.

Another Student: How about stepping on the brake when you see a stop sign? The sign controls the braking response, and that's not a consequence either.

A Student from the Back of the Room: And take a common classroom example. When a kid sees the problem 2 + 2 on his worksheet and writes 4, writing the numeral 4 has to be controlled by the written problem itself. Otherwise, how could anyone learn the correct answers to any question or problem?

Most of the Class: Yah, that's right!

Professor: (with a wry smile) All of you are correct. . . . So, too. am I.

Someone Else in the Class: What do you mean?

Professor: That was exactly my next point, and I was hoping you would pick up on it. (The professor smiled a thank you at the student who had started the discussion and went on.) All around us, every day, we are exposed to countless changing stimulus conditions. The situations you've described are excellent examples of what behavior analysts call *stimulus control*. When the rate of a given behavior is higher in the presence of a given stimulus than when that stimulus is absent, we say that stimulus control is at work. Stimulus control is a fundamentally important principle in behavior analysis, and it will be the subject of much discussion this semester.

But, and here's the important point: A discriminative stimulus, the antecedent event that comes before the response of interest, acquires its ability to evoke a particular response class because of its pairing with certain consequences in the past. It's not just the phone's ring that causes you to pick up the receiver. It is the fact that in the past, answering the phone when it was ringing was followed by the sound of a person's voice. It's that person talking to you, the consequence of picking up the receiver, that selected phone-answering behavior in the first place, but you only answer ringing phones. Why? Because you have learned that there's someone on the other end only when the phone's ringing. So we can still speak of consequences as having the ultimate control in terms of selecting operant behavior, but antecedent stimuli, by virtue of being paired with differential consequences, can indicate what kind of consequence is likely. This concept is called the three-term contingency, and its understanding, analysis, and manipulation are central to applied behavior analysis.

Immediate Consequences Have the Greatest Effect

Behavior is most sensitive to stimulus changes that occur immediately after, or within a few seconds of, a response.

> It is essential to emphasize the importance of the immediacy of reinforcement. Events that are delayed more than a few seconds after the response do not *directly* increase its future frequency. When human behavior is apparently affected by long-delayed consequences, the change is accomplished by virtue of the human's complex social and verbal history, and should not be thought of as an instance of the simple strengthening of behavior by reinforcement. (p. 110) . . . [As with reinforcement,] the longer the time delay between the occurrence of the response and the occurrence of the stimulus change (between R and S^P), the less effective the punishment will be in changing the relevant response frequency, but not much is known about upper limits. (Michael, 2004, p. 36, emphasis in original, words in brackets added)

Consequences Select Any Behavior

Reinforcement and punishment are "equal opportunity" selectors. No logical or healthy or (in the long run) adaptive connection between a behavior and the consequence that functions to strengthen or weaken it is necessary. Any behavior that

immediately precedes reinforcement (or punishment) will be increased (or decreased).

It is the *temporal relation* between behavior and consequence that is functional, not the topographical or logical ones. "So far as the organism is concerned, the only important property of the contingency is temporal. The reinforcer simply *follows* the response. How this is brought about does not matter" (Skinner, 1953, p. 85, emphasis in original). The arbitrary nature of which behaviors are reinforced (or punished) in operant conditioning is exemplified by the appearance of idiosyncratic behaviors that have no apparent purpose or function. An example is the superstitious routine of a poker player who taps and arranges his cards in a peculiar fashion because similar movements in the past were followed by winning hands.

Operant Conditioning Occurs Automatically

Operant conditioning does not require a person's awareness. "A reinforcing connection need not be obvious to the individual [whose behavior is] reinforced" (Skinner, 1953, p. 75, words in brackets added). This statement refers to the **automaticity of reinforcement**; that is, behavior is modified by its consequences regardless of whether the individual is aware that her behavior is, or has been, reinforced.[12] A person does not have to understand or verbalize the relation between her behavior and a consequence, or even know that a consequence has occurred, for reinforcement to "work."

Reinforcement

Reinforcement is the most important principle of behavior and a key element of most behavior change programs designed by behavior analysts (Flora, 2004; Northup, Vollmer, & Serrett, 1993). When a response is followed by a stimulus change that results in similar responses occurring more often, **reinforcement** has taken place.[13] Sometimes the delivery of just one reinforcer results in significant behavior change, although most often several responses must be followed by reinforcement before significant conditioning will occur.

Most stimulus changes that function as reinforcers can be described operationally as either (a) a new stimulus added to the environment (or increased in intensity), or (b) an already present stimulus removed from the environment (or reduced in intensity).[14] These two operations provide for two forms of reinforcement, called positive and negative (see Figure 2.2).

In **positive reinforcement**, a response is followed immediately by the presentation of a stimulus that results in similar responses occurring more often. Our baby's increased batting of the mobile with her hands, when doing so produces movement and music, is an example of positive reinforcement. Likewise, a child's independent play is reinforced when it increases as a result of his parent's giving praise and attention when he plays. Positive reinforcement and procedures for using it to promote desired behaviors are described in detail in Chapter 11.

When a behavior occurs more often because past responses have resulted in the withdrawal or termination of a stimulus, the operation is called **negative reinforcement**. Skinner (1953) used the term **aversive stimulus** to refer to, among other things, stimulus conditions whose termination functioned as reinforcement. Let us assume now that a parent programs the mobile to automatically play music for a period of time. Let us also assume that if the baby bats the mobile with hands or feet, the music immediately stops for a few seconds. If the baby bats the mobile more often when doing so terminates the music, negative reinforcement is at work, and the music can be called *aversive*.

Negative reinforcement is characterized by escape or avoidance contingencies. Jumping out of the shower when the water suddenly becomes too hot is negatively reinforced by *escape* from the burning water. Being sent to the principal's office for acting out may function as negative reinforcement if it enables the misbehaving student to *avoid* an aversive (to him) classroom activity.

The concept of negative reinforcement has confused many students of behavior analysis. Much of the confusion can be traced to the inconsistent early history and development of the term and to psychology and education textbooks and professors who have used the term inaccurately.[15] The most common mistake is equating negative reinforcement with punishment. To help avoid the error, Michael (2004) suggested the following:

> Think about how you would respond if someone asked you (1) whether or not you like negative reinforcement; also if you were asked (2) which you prefer, positive or negative

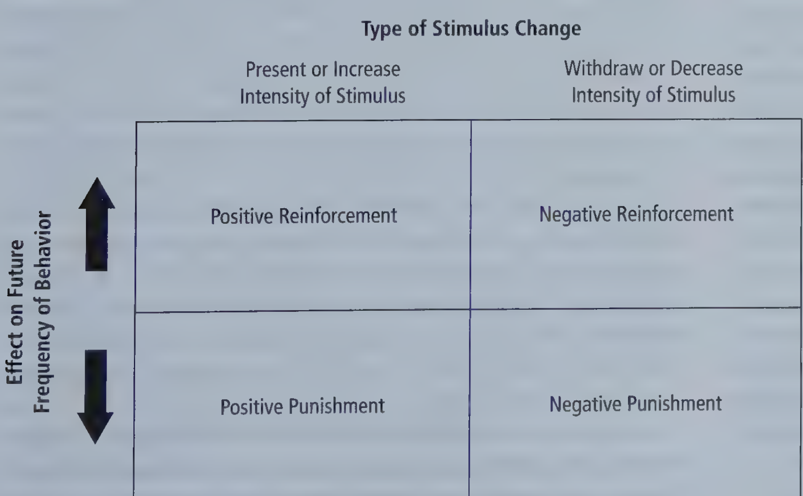

Figure 2.2 Positive and negative reinforcement and positive and negative punishment are defined by the type of stimulus change operation that follows a behavior and the effect that operation has on future occurrences of that type of behavior.

> reinforcement. Your answer to the first question should be that you do indeed like negative reinforcement, which consists of the removal or termination of an aversive condition that is already present. The term *negative reinforcement* refers **only** to the termination of the stimulus. In a laboratory procedure the stimulus must, of course, be turned on and then its termination can be made contingent upon the critical response. No one wants an aversive stimulus turned on, but once it is on, its termination is usually desirable. Your answer to the second question should be that you cannot choose without knowing the specifics of the positive and negative reinforcement involved. The common error is to choose positive reinforcement, but removal of a very severe pain would certainly be preferred over the presentation of a small monetary reward or an edible, unless the food deprivation was very severe. (p. 32, italics and bold type in original)

Negative reinforcement is examined in detail in Chapter 12. Remembering that the term *reinforcement* always means an increase in the occurrence of the behavior and that the modifiers *positive* and *negative* describe the type of stimulus change operation that best characterizes the consequence (i.e., adding or withdrawing a stimulus) should facilitate the discrimination of the principles and application of positive and negative reinforcement.

After a behavior has been established with reinforcement, it need not be reinforced each time it occurs. Many behaviors are maintained at high levels by schedules of *intermittent reinforcement*. Chapter 13 describes various *schedules of reinforcement* and their effects on behavior. However, if reinforcement is withheld for all members of a previously reinforced response class, a procedure based on the principle of **extinction**, the behavior will gradually decrease in rate to its pre-reinforcement level or cease to occur altogether. Chapter 24 describes the principle of extinction and the use of behavior change tactics based on extinction to decrease undesired behavior.

Punishment

Punishment, like reinforcement, is defined functionally. When a response is followed immediately by a stimulus change that results in similar responses occurring less often, **punishment** has taken place. Punishment can be accomplished by either of two types of stimulus change operations (see the bottom two boxes of Figure 2.2). As with reinforcement, the modifiers in the terms *positive punishment* and *negative punishment* connote neither the intention nor the desirability of the behavior change produced; they indicate only that the stimulus change that served as the punishing consequence was presented (**positive punishment**) or withdrawn (**negative punishment**).[16]

As with positive and negative reinforcement, numerous behavior change procedures incorporate the two basic punishment operations. Although some textbooks reserve the term *punishment* for procedures involving positive punishment and describe *time-out from positive reinforcement* and *response cost* as separate "principles" or types of punishment, both methods for reducing behavior are based on negative punishment (see Chapter 15).

Reinforcement and punishment can each be accomplished by either of two different operations, depending on whether the consequence consists of presenting a new stimulus (or increasing the intensity of a current stimulus) or withdrawing (or decreasing the intensity of) a currently present stimulus in the environment (Morse & Kelleher, 1977; Skinner, 1953). Some behavior analysts argue that from a functional and theoretical standpoint only two principles are required to describe the basic effects of behavioral consequences—reinforcement and punishment.[17] However, from a procedural perspective (a critical factor for the applied behavior analyst), a number of behavior change tactics are derived from each of the four operations represented in Figure 2.2.

Most behavior change procedures involve several principles of behavior (see Box 2.3). It is critical for the behavior analyst to have a solid conceptual understanding of the basic principles of behavior. Such knowledge permits better analysis of current controlling variables as well as more effective design and assessment of behavioral interventions that recognize the role various principles may be playing in a given situation.

Stimulus Changes That Function as Reinforcers and Punishers

Because operant conditioning involves the consequences of behavior, it follows that anyone interested in using operant conditioning to change behavior must identify and control the occurrence of relevant consequences. For the applied behavior analyst, therefore, an important question becomes: What kinds of stimulus changes function as reinforcers and punishers?

Unconditioned Reinforcement and Punishment

Some stimulus changes function as reinforcement even though the organism has had no particular learning history with those stimuli. A stimulus change that can increase future occurrences of behavior without prior pairing with any other form of reinforcement is called an **unconditioned reinforcer**.[18] For example, stimuli such as food, water, and sexual stimulation that support the biological maintenance of the organism and survival of the species often function as unconditioned reinforcers. The words *can* and *often* in the two previous sentences recognize the important qualification that the momentary effectiveness of an unconditioned reinforcer is a function of current **motivating operations**. For example, a certain level of food **deprivation** is necessary for the presentation of food to function as a reinforcer. However, food is unlikely to function as reinforcement for a person who has recently eaten a heavy meal. The nature and functions of motivating operations are described in detail in Chapter 16.

Similarly, an **unconditioned punisher** is a stimulus change that can decrease the future occurrence of any behavior that precedes it without prior pairing with any other form of punishment. Unconditioned punishers include painful stimulation that can cause tissue damage (i.e., harm body cells). However, virtually any stimulus to which an organism's receptors are sensitive—light, sound, and temperature, to name a few—can be intensified to the point that its delivery will suppress behavior even though the stimulus is below levels that actually cause tissue damage (Bijou & Baer, 1965).

BOX 2.3

Distinguishing Between Principles of Behavior and Behavior Change Tactics

A principle of behavior describes a basic behavior–environment relation that has been demonstrated repeatedly in hundreds, even thousands, of experiments. A **principle of behavior** describes a functional relation between behavior and one or more of its controlling variables (in the form of $y = fx$) that has thorough generality across individual organisms, species, settings, and behaviors. A principle of behavior is an empirical generalization inferred from many experiments. Principles describe how behavior works. Some examples of principles are reinforcement, punishment, and extinction.

In general, a behavior change tactic is a method for operationalizing, or putting into practice, one or more principles of behavior. A **behavior change tactic** is a research-based, technologically consistent method for changing behavior that has been derived from one or more basic principles of behavior and that possesses sufficient generality across subjects, settings, and/or behaviors to warrant its codification and dissemination. Behavior change tactics constitute the technological aspect of applied behavior analysis. Examples of behavior change tactics include backward chaining, differential reinforcement of other behavior, shaping, response cost, and time-out from positive reinforcement.

So, principles describe basic scientific laws that delineate how behavior–environment relations work, and behavior change tactics are how applied behavior analysts put the principles to work to help people learn and use socially significant behaviors. There are relatively few behavior principles, but many derivative behavior change tactics. To illustrate further, reinforcement is a behavioral principle because it describes a lawful relation between behavior, an immediate consequence, and an increased occurrence of the behavior in the future under similar conditions. However, issuing of checkmarks in a token economy and providing contingent praise are behavior change tactics derived from the principle of reinforcement. To cite another example, punishment is a principle of behavior because it describes the established functional relation between the presentation of a consequence and the decreased occurrence of similar behavior in the future. Response cost and time-out, in contrast, are tactics for changing behavior based on the principle of punishment.

Events that function as unconditioned reinforcers and punishers are the product of the natural evolution of the species (phylogeny). Malott, Tillema, and Glenn (1978) described the natural selection of "rewards" and "aversives" as follows:[19]

> Some rewards and aversives control our actions because of the way our species evolved; we call these unlearned rewards or aversives. We inherit a biological structure that causes some stimuli to be rewarding or aversive. This structure evolved because rewards helped our ancestors survive, while aversives hurt their survival. Some of these unlearned rewards, such as food and fluid, help us survive by strengthening our body cells. Others help our species survive by causing us to produce and care for our offspring—these stimuli include the rewarding stimulation resulting from copulation and nursing. And many unlearned aversives harm our survival by damaging our body cells; such aversives include burns, cuts and bruises. (p. 9)

While unconditioned reinforcers and punishers are critically important and necessary for survival, relatively few behaviors that constitute the everyday routines of people as they go about working, playing, and socializing are directly controlled by such events. For example, although going to work each day earns the money that buys food, eating that food is far too delayed for it to exert any direct operant control over the behavior that earned it. Remember: Behavior is most affected by its immediate consequences.

Conditioned Reinforcers and Punishers

Stimulus events or conditions that are present or that occur just before, or simultaneous with, the occurrence of other reinforcers (or punishers) may acquire the ability to reinforce (or punish) behavior when they later occur on their own as consequences. Called **conditioned reinforcers** and **conditioned punishers**, these stimulus changes function as reinforcers and punishers because of their prior pairing with other reinforcers or punishers.[20] The stimulus–stimulus pairing procedure responsible for the creation of conditioned reinforcers or punishers is the same as that used for respondent conditioning except that the "outcome is a stimulus that functions as a reinforcer [or punisher] rather than a stimulus that will elicit a response" (Michael, 2004, p. 66, words in brackets added).

Conditioned reinforcers and punishers are not related to any biological need or anatomical structure; their ability to modify behavior is a result of each person's unique history of interactions with his or her environment (ontogeny). On the one hand, because no two people experience the world in exactly the same way, the roster of events that can serve as conditioned reinforcers and punishers at any particular time (given a relevant motivating operation) is idiosyncratic to each individual and always changing. On the other hand, to the extent that two people have had similar experiences (e.g., schooling, profession, the culture in general), they are likely to be affected in similar ways by similar events. Social praise and attention are examples of widely effective conditioned reinforcers in many cultures. Because social attention and approval (as well as disapproval) are often paired with many other reinforcers (and punishers), they exert powerful control over human behavior and will be featured in later chapters when specific behavior change tactics are presented.

Because people who live in a common culture share similar histories, it is not unreasonable for a practitioner to search

for potential reinforcers and punishers for a given client among classes of stimuli that have proven effective with other similar clients. However, in an effort to help the reader establish a fundamental understanding of the nature of operant conditioning, we have purposely avoided presenting a list of stimuli that may function as reinforcers and punishers. Morse and Kelleher (1977) made this important point very well.

> Reinforcers and punishers, as environmental "things," appear to have a greater reality than orderly temporal changes in ongoing behavior. Such a view is deceptive. There is no concept that predicts reliably when events will be reinforcers or punishers; *the defining characteristics of reinforcers and punishers are how they change behavior* [italics added]. Events that increase or decrease the subsequent occurrence of one response may not modify other responses in the same way.
>
> In characterizing reinforcement as the presentation of a reinforcer contingent upon a response, the tendency is to emphasize the event and to ignore the importance of both the contingent relations and the antecedent and subsequent behavior. It is *how* [italics added] they change behavior that defines the terms *reinforcer* and *punisher;* thus it is the orderly change in behavior that is the key to these definitions. It is *not* [italics added] appropriate to presume that particular environmental events such as the presentation of food or electric shock are reinforcers or punishers until a change in the rate of responding has occurred when the event is scheduled in relation to specified responses.
>
> A stimulus paired with a reinforcer is said to have become a conditioned reinforcer, but actually it is the behaving subject that has changed, not the stimulus. . . . It is, of course, useful shorthand to speak of conditioned reinforcers . . . just as it is convenient to speak about a reinforcer rather than speaking about an event that has followed an instance of a specific response and resulted in a subsequent increase in the occurrence of similar responses. The latter may be cumbersome, but it has the advantage of empirical referents. Because many different responses can be shaped by consequent events, and because a given consequent event is often effective in modifying the behavior of different individuals, it becomes common practice to refer to reinforcers without specifying the behavior that is being modified. These common practices have unfortunate consequences. They lead to erroneous views that responses are arbitrary and that the reinforcing or punishing effect of an event is a specific property of the event itself. (pp. 176–177, 180)

The point made by Morse and Kelleher (1977) is of paramount importance to understanding functional behavior–environment relations. Reinforcement and punishment are not simply the products of certain stimulus events, which are then called reinforcers and punishers without reference to a given behavior and environmental conditions. There are no inherent or standard physical properties of stimuli that determine their permanent status as reinforcers and punishers. In fact, a stimulus can function as a positive reinforcer under one set of conditions and a negative reinforcer under different conditions. Just as positive reinforcers are not defined with terms such as *pleasant* or *satisfying,* aversive stimuli are not defined with terms such as *annoying* or *unpleasant.* The terms *reinforcer* and *punisher* should not to be used on the basis of a stimulus event's assumed effect on behavior or on the basis of any inherent property of the stimulus event itself. Morse and Kelleher (1977) continued:

> When the borders of the table are designated in terms of stimulus classes (positive–negative; pleasant–noxious) and experimental operations (stimulus presentation–stimulus withdrawal), the cells of the table are, by definition, varieties of reinforcement and punishment. One problem is that the processes indicated in the cells have already been assumed in categorizing stimuli as positive or negative; a second is that there is a tacit assumption that the presentation or withdrawal of a particular stimulus will have an invariant effect. These relations are clearer if empirical operations are used to designate the border conditions. . . . The characterization of behavioral processes depends upon empirical observations. The same stimulus event, under different conditions, may increase behavior or decrease behavior. In the former case the process is called *reinforcement* and in the latter the process is called *punishment.* (p. 180)

At the risk of redundancy, we restate this important concept. Reinforcers and punishers denote functional classes of stimulus events, membership to which is not based on the physical nature of the stimulus changes or events themselves. Indeed, given a person's individual history and current motivational state, and the current environmental conditions, "any stimulus change can be a 'reinforcer' if the characteristics of the change, and the temporal relation of the change to the response under observation, are properly selected" (Schoenfeld, 1995, p. 184). Thus, the phrase "everything is relative" is thoroughly relevant to understanding functional behavior–environment relations.

The Discriminated Operant and Three-Term Contingency

We have discussed the role of consequences in influencing the future occurrence of behavior. But operant conditioning does much more than establish a functional relation between behavior and its consequences. Operant conditioning also establishes functional relations between behavior and certain antecedent conditions.

> In contrast to *if-A-then-B* formulations (such as S-R formulations), the *AB-because-of-C* formulation is a general statement that the relation between an event (B) and its context (A) is because of consequences (C). . . . Applied to Skinner's three-term contingency, the relation between (A) the setting and (B) behavior exists because of (C) consequences that occurred for previous AB (setting-behavior) relations. The idea [is] that reinforcement strengthens the setting-behavior relation rather than simply strengthening behavior. (Moxley, 2004, p. 111)

Reinforcement selects not just certain forms of behavior; it also selects the environmental conditions that in the future will evoke (make more likely) instances of the

response class. A behavior that occurs more often under some antecedent conditions than it does in others is called a **discriminated operant**. Because a discriminated operant occurs more often in the presence of a given stimulus than it does in the absence of that stimulus, it is said to be under **stimulus control**. Answering the phone, one of the everyday behaviors discussed by the professor and his students in Box 2.2, is a discriminated operant. The phone's ring functions as a **discriminative stimulus** ($\mathbf{S^D}$) for answering the phone. We answer the phone when it is ringing, and we do not answer the phone when it is silent.

Just as reinforcers or punishers cannot be identified by their physical characteristics, stimuli possess no inherent dimensions or properties that enable them to function as discriminative stimuli. Operant conditioning brings behavior under the control of various properties or values of antecedent stimuli (e.g., size, shape, color, spatial relation to another stimulus), and what those features are cannot be determined a priori. (Stimulus control is described in detail in Chapter 17.)

> Any stimulus present when an operant is reinforced acquires control in the sense that the rate will be higher when it is present. Such a stimulus does not act as a goad; it does not elicit the response in the sense of forcing it to occur. It is simply an essential aspect of the occasion upon which a response is made and reinforced. The difference is made clear by calling it a discriminative stimulus (or S^D). An adequate formulation of the interaction between an organism and its environment must always specify three things: (1) the occasion upon which a response occurs; (2) the response itself; and (3) the reinforcing consequences. The interrelationships among them are the "contingencies of reinforcement." (Skinner, 1969, p. 7)

The discriminated operant has its origin in the three-term contingency. The **three-term contingency**—*a*ntecedent, *b*ehavior, and *c*onsequence—is sometimes called the ABCs of behavior analysis. Figure 2.3 shows examples of three-term contingencies for positive reinforcement, negative reinforcement, positive punishment, and negative punishment.[21] Most of what the science of behavior analysis has discovered about the prediction and control of human behavior involves the three-term contingency, which is "considered the basic unit of analysis in the analysis of operant behavior" (Glenn, Ellis, & Greenspoon, 1992, p. 1332).

A four-term contingency analysis takes into account motivating events that make certain stimulus changes momentarily more or less reinforcing. The four-term contingency is introduced in Chapter 11 and described in detail in Chapter 16.

The term **contingency** appears in behavior analysis literature with several meanings signifying various types of temporal and functional relations between behavior and antecedent and consequent variables (Catania, 2013; Lattal, 1995; Lattal & Shahan, 1997; Vollmer & Hackenberg, 2001). Perhaps the most common connotation of contingency refers to the *dependency* of a particular consequence on the occurrence of the behavior. When a reinforcer (or punisher) is said to be **contingent** on a particular behavior, the behavior must be emitted for the consequence to occur. For example, after saying, "Name a carnivorous dinosaur," a teacher's "Well done!" depends on the student's response, "Tyrannosaurus Rex" (or another dinosaur of the same class).[22]

The term *contingency* is also used in reference to the *temporal contiguity* of behavior and its consequences. As stated

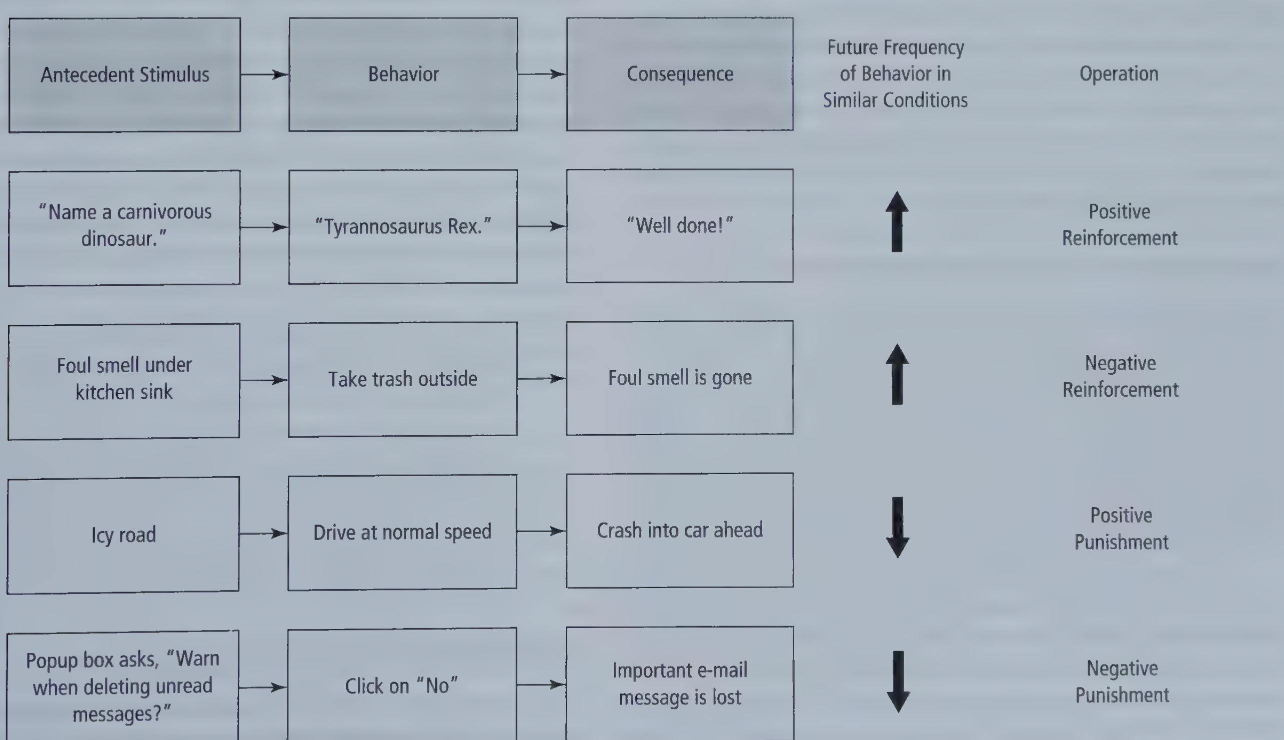

Figure 2.3 Three-term contingencies illustrating reinforcement and punishment operations.

previously, behavior is selected by the consequences that immediately follow it, irrespective of whether those consequences were produced by or depended on the behavior. This is the meaning of contingency in Skinner's (1953) statement, "So far as the organism is concerned, the only important property of the contingency is temporal" (1953, p. 85).

RECOGNIZING THE COMPLEXITY OF HUMAN BEHAVIOR

> *Behavior—human or otherwise—remains an extremely difficult subject matter.*
>
> —B. F. Skinner (1969, p. 114)

The experimental analysis of behavior has discovered a number of basic principles—statements about how behavior works as a function of environmental variables. These principles, several of which have been introduced in this chapter, have been demonstrated, verified, and replicated in thousands of experiments; they are scientific facts.[23] Tactics for changing behavior derived from these principles have been applied to a wide range of human behaviors in natural settings and analyzed in increasingly sophisticated and effective ways. An introduction to what has been learned from those applied behavior analyses makes up the majority of this book.

The systematic application of behavior analysis techniques sometimes produces behavior changes of great magnitude and speed, even for clients whose behavior had been unaffected by other forms of treatment and appeared intractable. When such a happy (but not rare) outcome occurs, the neophyte behavior analyst must resist the tendency to believe that we know more than we do about the prediction and control of human behavior. As acknowledged in Chapter 1, applied behavior analysis is a young science that has yet to achieve anything near a complete understanding and technological control of human behavior.

A major challenge facing applied behavior analysts is dealing with human behavior in applied settings where laboratory controls are impossible, impractical, or unethical. Numerous factors contributing to this difficulty coalesce around the complexity of the human repertoire, the myriad controlling variables, and individual differences.

Complexity of the Human Repertoire

Humans are capable of learning an incredible range of behaviors. Response sequences, sometimes of no apparent logical organization, contribute to the complexity of behavior (Skinner, 1953). In a response chain, effects produced by one response influence the emission of other responses. Returning a winter coat to the attic leads to rediscovering a scrapbook of old family photographs, which evokes a phone call to Aunt Helen, which sets the occasion for finding her recipe for apple pie, and so on.

Verbal behavior may be the most significant contributor to the complexity of human behavior (Donahoe & Palmer, 1994; Palmer, 1991; Skinner, 1957; see Chapter 18). Not only is a problem generated when the difference between saying and doing is not recognized, but verbal behavior itself is often a controlling variable for many other verbal and nonverbal behaviors. By following the contingency described in a verbal rule (e.g., "Pull the lever while simultaneously pushing the selection button.") we behave effectively (e.g., operate a complex vending machine in a foreign country) without direct experience with contingencies. "Rules can be learned more quickly than the behavior shaped by the contingencies they describe. . . . Rules are particularly valuable when contingencies are complex or unclear or for any other reason not very effective" (Skinner, 1974, p. 129). Skinner referred to behavior controlled by verbal statements as **rule-governed behavior**, distinguishing it from **contingency-shaped behavior** acquired by direct experience with contingencies.[24]

Operant learning does not always occur as a slow, gradual process. Sometimes new, complex repertoires appear quickly with little apparent direct conditioning (Epstein, 1991; Sidman, 1994). Murray Sidman's groundbreaking research on stimulus equivalence showed that under certain conditions learners acquire new skills and verbal relations without direct instruction on those skills and relations (cf., Critchfield, Barnes-Holmes, & Dougher, 2018). The new behaviors emerge as a product of instruction on related skills and relations. This research, which is found under various names in addition to stimulus equivalence, including generative instruction, equivalence-based instruction, and derived relational responding, is described in Chapters 19 and 20.

One type of rapid learning has been called *contingency adduction,* a process whereby a behavior that was initially selected and shaped under one set of conditions is recruited by a different set of contingencies and takes on a new function in the person's repertoire (Andronis, 1983; Layng & Andronis, 1984). Johnson and Layng (1992, 1994) described several examples of contingency adduction in which simple (component) skills (e.g., addition, subtraction, and multiplication facts, isolating and solving for *X* in a simple linear equation), when taught to fluency, combined without apparent instruction to form new complex (composite) patterns of behavior (e.g., factoring complex equations). Lessons can be designed in such a way that teaching select concepts and relations results in students acquiring concepts and relations that were not taught directly.

Intertwined lineages of different operants combine to form new complex operants (Glenn, 2004), which produce response products that in turn make possible the acquisition of behaviors beyond the spatial and mechanical restraints of anatomical structure.

> In the human case, the range of possibilities may be infinite, especially because the products of operant behavior have become increasingly complex in the context of evolving cultural practices. For example, anatomical constraints prevented operant flying from emerging in a human repertoire only until airplanes were constructed as behavioral products. Natural selection's leash has been greatly relaxed in the ontogeny of operant units. (Glenn et al., 1992, p. 1332)

Complexity of Controlling Variables

Behavior is selected by its consequences. This mega principle of operant behavior sounds deceptively (and naively) simple. However, "Like other scientific principles, its simple form masks the

complexity of the universe it describes" (Glenn, 2004, p. 134). The environment and its effects on behavior are complex.

Skinner (1957) noted that, "(1) the strength of a single response may be, and usually is, a function of more than one variable and (2) a single variable usually affects more than one response" (p. 227). Although Skinner was writing in reference to verbal behavior, multiple causes and multiple effects are characteristics of many behavior–environment relations.

Many behaviors result from multiple causes. In a phenomenon called **joint control** (Lowenkron, 1998, 2006; Palmer, 2006), two separate but interrelated forms of a person's own verbal behavior combine to acquire stimulus control of a response that would not have occurred in the absence of either. For example, a person writing on her laptop computer, while sitting in the kitchen, needs a particular book for a reference. She might say to herself, "I need *About Behaviorism*" and repeat the book's title (an echoic) several times while walking to the room containing her books. She reads the titles (another form of verbal behavior) of the books on the bookcase until she emits the response, "About Behaviorism," whose topography matches the self-echoic. The occurrence of these two sources of control mediates the selection of the desired book.[25]

Concurrent contingencies can also combine to make a behavior more or less likely to occur in a given situation. Perhaps we finally return our neighbor's weed trimmer not just because he usually invites us in for a cup of coffee, but also because returning the tool reduces the "guilt" we feel for keeping it for 2 weeks.

Concurrent contingencies often vie for control of incompatible behaviors. We cannot watch "Baseball Tonight" and study (properly) for an upcoming exam. Although not a technical term in behavior analysis, *algebraic summation* is sometimes used to describe the effect of multiple, concurrent contingencies on behavior. The behavior that is emitted is thought to be the product of the competing contingencies "canceling portions of each other out," as in an algebraic equation.

Behavioral covariation illustrates one type of multiple effect. For example, Lerman, Kelley, Vorndran, and Van Camp (2003) found that blocking the emission of one problem behavior decreased occurrences of that behavior but produced a collateral increase in other topographies of problem behaviors in the same response class. As another example of multiple effects, the presentation of an aversive stimulus may, in addition to suppressing future occurrences of the behavior it follows, elicit respondent behaviors and evoke escape and avoidance behaviors—three different effects from one event.

Emotions are often a commingling of respondent and operant behaviors. Interactions between respondent and operant conditioning further the difficulty of determining causal variables. For example Pavlovian (stimulus-reinforcer) contingencies embedded in stimulus control arrangements may limit the effectiveness of operant (response-reinforcer) contingencies (see Nevin, 2009). A study by Gorn (1982) suggests the possibility that pairing music a person likes (unconditioned stimulus for positive emotional responses) with an advertisement for a product (neutral stimulus) might condition emotional responses to the product functioning as a conditioned stimulus that elicits positive emotional responses that influence the operant behavior of purchasing the product.

All of these complex, concurrent, interrelated contingencies make it difficult for behavior analysts to identify and control relevant variables. It should not be surprising that the settings in which applied behavior analysts ply their trade are sometimes described as places where "reinforcement occurs in a noisy background" (Vollmer & Hackenberg, 2001, p. 251).

Consequently, as behavior analysts, we should recognize that meaningful behavior change might take time and many trials and errors as we work to understand the interrelationships and complexities of the controlling variables. Don Baer (1987) recognized that some of the larger problems that beset society (e.g., poverty, substance addiction, illiteracy), given our present level of technology, might be too difficult to solve at the moment. He identified three barriers to solving such complex problems:

> (a) We are not empowered to solve these bigger remaining problems, (b) we have not yet made the analysis of how to empower ourselves to try them, and (c) we have not yet made the system-analytic task analyses that will prove crucial to solving those problems when we do empower ourselves sufficiently to try them. . . . In my experience, those projects that seem arduously long are arduous because (a) I do not have a strong interim reinforcer compared to those in the existing system for status quo and must wait for opportunities when weak control may operate, even so, or (b) I do not yet have a correct task analysis of the problem and must struggle through trials and errors. By contrast (c) when I have an effective interim reinforcer and I know the correct task analysis of this problem, long problems are simply those in which the task analysis requires a series of many behavior changes, perhaps in many people, and although each of them is relatively easy and quick, the series of them requires not so much effort as time, and so it is not arduous but merely tedious. (pp. 335, 336–337)

Individual Differences

People often respond differently, sometimes drastically so, to the same set of environmental conditions. This fact is sometimes cited as evidence that principles of behavior based on environmental selection do not exist, at least not in a form that could provide the basis for a robust and reliable technology of behavior change. It is then argued that because people often respond differently to the same set of contingencies, control of behavior must come from within each person. In refuting that argument, Sidman (2013) recognizes the complex learning histories that account for much of our individual differences and points to the excitement of discovering the scientific principles that link us with one another and with the universe at large.

> Among the most powerful sources of behavioral control are our individual behavioral histories, in each of us a web of such complexity that it tempts us to give up and claim independence. . . . to claim control by an inner self. . . . Rather than needing to claim myself as prepotent, I have always found it exciting to recognize that I am at one with the rest

of the universe and to help discover the laws that relate me to everything else. (p. xvi)

As each of us experiences varying contingencies of reinforcement (and punishment), some behaviors are strengthened (selected by the contingencies) and others are weakened. This is the nature of operant conditioning, which is to say, human nature. Because no two people ever experience the world in exactly the same way, each of us arrives at a given situation with a different **history of reinforcement**. The repertoire of behaviors each person brings to any situation has been selected, shaped, and maintained by his or her unique history of reinforcement. Each human's unique repertoire defines him or her as a person. We are what we do, and we do what we have learned to do. "He begins as an organism and becomes a person or self as he acquires a repertoire of behavior" (Skinner, 1974, p. 231).

Individual differences in responding to current stimulus conditions, then, do not need to be attributed to differences in internal traits or tendencies, but to the orderly result of different histories of reinforcement. The behavior analyst must also consider people's varying sensitivities to stimuli (e.g., hearing loss, visual impairment) and differences in response mechanisms (e.g., cerebral palsy) and design program components to ensure that all participants have maximum contact with relevant contingencies (Heward, Alber-Morgan, & Konrad, 2017).

Obstacles to Changing Behavior in Applied Settings

Compounding the difficulty of tackling the complexity of human behavior in the "noisy" applied settings where people live, work, and play, applied behavior analysts are sometimes prevented from implementing an effective behavior change program due to logistical, financial, sociopolitical, legal, and/or ethical factors. Most applied behavior analysts work for agencies with limited resources, which may make the data collection required for a more complete analysis impossible. In addition, participants, parents, administrators, and even the general public may at times limit the behavior analyst's options for effective intervention (e.g., "We don't want students working for tokens"). Legal or ethical considerations may also preclude determining experimentally the controlling variables for an important behavior. Ethical considerations for behavior analysts are discussed in Chapter 31.

Each of these practical complexities combines with the behavioral and environmental complexities previously mentioned to make the applied behavior analysis of socially important behavior a challenging task. However, the task need not be overwhelming, and few tasks are as rewarding or as important for the betterment of humankind.

It is sometimes argued that the scientific study of behavior cannot account for such human creations as beauty and humor or the behavior of judging something to be beautiful. Hineline (2005), Palmer (2018), Mechner (2017), and Neuringer and Jensen (2013) discuss aesthetics and creativity from a behavior analytic point of view on topics ranging from literature aesthetics to the craftsmanship of woodworking tools.

Will knowing how such amazing behavior is learned somehow diminish the quality or enjoyment of the human experience? For example, will our increasing knowledge of the variables responsible for creative behavior lessen the feelings evoked by a powerful painting or a beautiful symphony, or reduce our appreciation of the artists who produced them? We think not, and we encourage you, as you read and study about the basic concepts introduced in this chapter and examined in more detail throughout the book, to consider Nevin's (2005) response to how a scientific account of behavior adds immeasurably to the human experience:

> At the end of *Origin of Species* (1859), Darwin invites us to contemplate a tangled bank, with its plants and its birds, its insects and its worms; to marvel at the complexity, diversity, and interdependence of its inhabitants; and to feel awe at the fact that all of it follows from the laws of reproduction, competition, and natural selection. Our delight in the tangled bank and our love for its inhabitants are not diminished by our knowledge of the laws of evolution; neither should our delight in the complex world of human activity and our love for its actors be diminished by our tentative but growing knowledge of the laws of behavior. Tony Nevin, personal communication (December 19, 2005.)

SUMMARY

Behavior

1. Behavior is the activity of living organisms.
2. Technically, behavior is "that portion of an organism's interaction with its environment that involves movement of some part of the organism" (Johnston & Pennypacker, 2009, p. 31).
3. The term *behavior* is usually used in reference to a larger set or class of responses that share certain topographical dimensions or functions.
4. *Response* refers to a specific instance of behavior.
5. *Response topography* refers to the physical shape or form of behavior.
6. A response class is a group of responses of varying topography, all of which produce the same effect on the environment.
7. *Repertoire* can refer to all of the behaviors a person can do or to a set of behaviors relevant to a particular setting or task.

Environment

8. Environment is the physical setting and circumstances in which the organism or referenced part of the organism exists.

9. Stimulus is "an energy change that affects an organism through its receptor cells" (Michael, 2004, p. 7).

10. The environment influences behavior primarily by stimulus change, not static stimulus conditions.

11. Stimulus events can be described formally (by their physical features), temporally (by when they occur), and functionally (by their effects on behavior).

12. A stimulus class is a group of stimuli that share specified common elements along formal, temporal, and/or functional dimensions.

13. Antecedent conditions or stimulus changes exist or occur prior to the behavior of interest.

14. Consequences are stimulus changes that follow a behavior of interest.

15. Stimulus changes can have one or both of two basic effects on behavior: (a) an immediate but temporary effect of increasing or decreasing the current occurrences of the behavior and/or (b) a delayed but relatively permanent effect in terms of the future occurrences of that type of behavior in the future.

Respondent Behavior

16. Respondent behavior is elicited by antecedent stimuli.

17. A reflex is a stimulus–response relation consisting of an antecedent stimulus and the respondent behavior it elicits (e.g., bright light–pupil contraction).

18. All healthy members of a given species are born with the same repertoire of unconditioned reflexes.

19. An unconditioned stimulus (e.g., food) and the respondent behavior it elicits (e.g., salivation) are called unconditioned reflexes.

20. Conditioned reflexes are the product of respondent conditioning: a stimulus–stimulus pairing procedure in which a neutral stimulus is presented with an unconditioned stimulus until the neutral stimulus becomes a conditioned stimulus that elicits the conditioned response.

21. Pairing a neutral stimulus with a conditioned stimulus can also produce a conditioned reflex—a process called higher-order (or secondary) respondent conditioning.

22. Respondent extinction occurs when a conditioned stimulus is presented repeatedly without the unconditioned stimulus until the conditioned stimulus no longer elicits the conditioned response.

Operant Behavior

23. Operant behavior is selected by its consequences.

24. Unlike respondent behavior, whose topography and basic functions are predetermined, operant behavior can take a virtually unlimited range of forms.

25. Selection of behavior by consequences operates during the lifetime of the individual organism (ontogeny) and is a conceptual parallel to Darwin's natural selection in the evolutionary history of a species (phylogeny).

26. Operant conditioning, which encompasses reinforcement and punishment, refers to the process and selective effects of consequences on behavior:
    - Consequences can affect only future behavior.
    - Consequences select response classes, not individual responses.
    - Immediate consequences have the greatest effect.
    - Consequences select any behavior that precedes them.
    - Operant conditioning occurs automatically.

27. Most stimulus changes that function as reinforcers or punishers can be described as either (a) a new stimulus added to the environment or (b) an already present stimulus removed from the environment.

28. Positive reinforcement: A response is followed by the presentation of a stimulus that results in similar responses occurring more often.

29. Negative reinforcement: A response is followed by the withdrawal of a stimulus that results in similar responses occurring more often.

30. The term *aversive stimulus* is often used to refer to stimulus conditions whose termination functions as reinforcement.

31. Extinction (withholding all reinforcement for a previously reinforced behavior) produces a decrease in response rate to the behavior's pre-reinforcement level.

32. Positive punishment: A response is followed by the presentation of a stimulus that results in similar responses occurring less often.

33. Negative punishment: A response is followed by the withdrawal of a stimulus that results in similar responses occurring less often.

34. A principle of behavior describes a functional relation between behavior and one or more of its controlling variables that has thorough generality across organisms, species, settings, and behaviors.

35. A behavior change tactic is a technologically consistent method for changing behavior that has been derived from one or more basic principles of behavior.

36. Unconditioned reinforcers and punishers function irrespective of any prior learning history.

37. Stimulus changes that function as conditioned reinforcers and punishers do so because of previous pairing with other reinforcers or punishers.

38. One important function of motivating operations is altering the current value of stimulus changes as reinforcement or punishment. For example, deprivation and satiation are

motivating operations that make food more or less effective as reinforcement.

39. A discriminated operant occurs more often under some antecedent conditions than it does under others, an outcome called stimulus control.

40. Stimulus control refers to differential rates of operant responding observed in the presence or absence of antecedent stimuli. Antecedent stimuli acquire the ability to control operant behavior by having been paired with certain consequences in the past.

41. The three-term contingency—*a*ntecedent, *b*ehavior, and *c*onsequence—is the basic unit of analysis in the analysis of operant behavior.

42. If a reinforcer (or punisher) is contingent on a particular behavior, the behavior must be emitted for the consequence to occur.

43. All applied behavior analysis procedures involve manipulation of one or more components of the three-term contingency.

Recognizing the Complexity of Human Behavior

44. Humans are capable of acquiring a huge repertoire of behaviors. Response chains and verbal behavior also make human behavior extremely complex.

45. The variables that govern human behavior are often highly complex. Many behaviors have multiple causes.

46. Individual differences in histories of reinforcement and organic impairments also make the analysis and control of human behavior difficult.

47. Applied behavior analysts are sometimes prevented from conducting an effective analysis of behavior because of practical, logistical, financial, sociopolitical, legal, and/or ethical reasons.

KEY TERMS

automatic reinforcement
automaticity of reinforcement
aversive stimulus
behavior
behavior change tactic
conditioned punisher
conditioned reflex
conditioned reinforcer
conditioned stimulus
consequence
contingency
contingency-shaped behavior
contingent
deprivation
discriminated operant
discriminative stimulus (S^D)
environment
extinction
habituation
higher-order conditioning
history of reinforcement
joint control
motivating operation
negative punishment
negative reinforcement
neutral stimulus
ontogeny
operant behavior
operant conditioning
phylogeny
positive punishment
positive reinforcement
principle of behavior
punisher
punishment
reflex
reinforcement
reinforcer
repertoire
respondent behavior
respondent conditioning
respondent extinction
response
response class
rule-governed behavior
selectionism
socially mediated contingency
stimulus
stimulus class
stimulus control
stimulus–stimulus pairing
three-term contingency
unconditioned punisher
unconditioned reinforcer
unconditioned stimulus

MULTIPLE-CHOICE QUESTIONS

1. The controlling variables of primary importance in applied behavior analysis are located in:
   a. The environment
   b. Consequences
   c. The mental states
   d. Reinforcement
   Hint: (See "Behavior")

2. Two functionally distinct types of behavior important to behavior analysis include:
   a. Learned and operant behavior
   b. Reflexive and respondent behavior
   c. Respondent and operant behavior
   d. Operant and conditioned behavior
   Hint: (See "Behavior")

3. Which of the following is considered a property of behavior amenable to measurement?
   a. Temporal Weight
   b. Temporal Locus
   c. Temporal Displacement
   d. Temporal Size
   Hint: (See "Behavior")
4. A _____ denotes a set or collection of knowledge and skills a person has learned that are relevant to particular settings or tasks.
   a. Repertoire
   b. Behavior
   c. Skill
   d. Response
   Hint: (See "Behavior")
5. Behavior is affected by stimulus changes that occur prior to and immediately after the behavior. The term _____ refers to environmental conditions or stimulus changes that exist or occur prior to the behavior of interest.
   a. Consequence
   b. Stimulus
   c. Event
   d. Antecedent
   Hint: (See "Environment")
6. A behavior that is elicited by antecedent stimuli and is "brought about" by a stimulus that precedes it is:
   a. Operant
   b. Learned
   c. Respondent
   d. New
   Hint: (See "Respondent Behavior")
7. A response is followed by a stimulus change, the effect of which is an increase in the future frequency of behavior. Which type of stimulus-change operation most likely occurred?
   a. Reinforcement
   b. Punishment
   c. Extinction
   d. Positive Punishment
   Hint: (See "Operant Behavior")
8. Water is an example of a ______ reinforcer, while money is an example of a _______ reinforcer.
   a. Conditioned, unconditioned
   b. Secondary, primary
   c. Unconditioned, conditioned
   d. Powerful, ineffective
   Hint: (See "Reinforcement")
9. Answering the door when you hear the door bell and not when it is silent is an example of behavior being under:
   a. Simultaneous prompting
   b. Equivalence
   c. Stimulus control
   d. Premack principle
   Hint: (See "Stimulus Changes That Function as Reinforcers and Punishers")
10. A behavior that occurs more frequently under some antecedent conditions than it does in others is called a(n):
    a. Stimulus control
    b. Operant behavior
    c. Discriminative stimulus
    d. Discriminated operant
    Hint: (See "Stimulus Changes That Function as Reinforcers and Punishers")
11. Food deprivation may alter the momentary effectiveness of food as a reinforcer. Food deprivation is an example of a(n):
    a. Satiation trial
    b. Motivating operation
    c. Operant behavior
    d. Experimental control
    Hint: (See "Unconditioned Reinforcement and Punishment")
12. The three-term contingency is made of these three terms:
    a. Attitude, behavior, reinforcement
    b. Antecedent, reinforcement, punishment
    c. Antecedent, behavior, consequence
    d. Antecedent, stimulus, control
    Hint: (See "The Discriminated Operant and Three-Term Contingency")
13. The term "contingent" as used in behavior analysis refers to the dependent relationship of a particular consequence on the occurrence of behavior and is also used in reference to the _________ contiguity of behavior and its consequences.
    a. Temporal
    b. Independent
    c. Dependent
    d. False
    Hint: (See "The Discriminated Operant and Three-Term Contingency")
14. _______ behavior is elicited by antecedent stimuli.
    a. Operant
    b. Temporal
    c. Respondent
    d. All
    Hint: (See "Behavior")

15. Conditioned _______ are the product of respondent conditioning.
    a. Antecedents
    b. Stimuli
    c. Punishers
    d. Reflexes
    Hint: (See "Behavior")
16. Operant behavior is selected by its:
    a. Consequences
    b. Antecedents
    c. Conditioners
    d. Respondent
    Hint: (See "Behavior")
17. Operant conditioning encompasses:
    a. Time and stimuli
    b. Antecedents and phylogeny
    c. Conditioned and unconditioned
    d. Reinforcement and punishment
    Hint: (See "Behavior")

ESSAY-TYPE QUESTIONS

1. Discuss the difference between a response and a behavior.
   Hint: (See "Behavior")
2. Discuss the importance of a functional analysis of behavior over a structural analysis of behavior.
   Hint: (See "Behavior")
3. Describe the effect of positive and negative reinforcement on subsequent behavior.
   Hint: (See "Operant Conditioning")
4. Give an example of negative reinforcement.
   Hint: (See "Operant Conditioning")
5. Discuss the difference between a principle of behavior and a behavior-change tactic.
   Hint: (See "Reinforcement")
6. Discuss the difference between conditioned and unconditioned reinforcers.
   Hint: (See "Reinforcement")
7. Describe the effect punishment contingencies have on subsequent behavior.
   Hint: (See "Selection by Consequences")
8. State an example of stimulus control.
   Hint: (See "The Discriminated Operant and Three-Term Contingency")
9. What effects do motivating operations have on reinforcers?
   Hint: (See "Unconditioned Reinforcement and Punishment")
10. Using an example from applied settings, construct a three-term contingency.
    Hint: (See "The Discriminated Operant and Three-Term Contingency")
11. Diagram an example of respondent conditioning. Identify and label the following: unconditioned stimulus, unconditioned response, neutral response, conditioned stimulus, and conditioned response.
    Hint: (See "Respondent Conditioning")
12. Classify the following behaviors as respondent or operant:
    - Talking
    - Walking
    - Baby's grasp
    - Salivation at smell of food
    - Baking a cake
    - Pupil constriction
    - Thinking about music
    - Playing the piano
    - Withdrawing hand from a fire

    Hint: (See "Respondent Conditioning")

NOTES

1. The reader should not be overwhelmed by the many technical terms and concepts in this chapter. With the exception of respondent behavior, each concept introduced in this chapter is explained in detail in subsequent chapters. This initial overview of basic concepts and principles provides background information that will facilitate understanding portions of the text that precede the more detailed explanations.
2. In the mid-1960s, Ogden Lindsley proposed what he called the *dead man test* as a way to help teachers determine whether they were targeting real behaviors for measurement and change as opposed to inanimate states such as "being quiet" (see Chapter 3). According to this test, if a dead man can do it, it isn't behavior. Getting blown over by strong wind is not behavior (a dead man would also be blown over), but moving arms and hands in front of one's face, tucking and rolling, and yelling "Whoa!" as one is being blown over are behaviors. Critchfield (2016) provides some historical background on the dead man test and a thoughtful critique of its usefulness as a guide for measurement.
3. Most behavior analysts use the word *behavior* both as a mass noun to refer to the subject matter of the field in general or a certain type or class of behavior (e.g., operant behavior, study behavior) and as a count noun to refer to specific instances (e.g., two aggressive behaviors). The word *behavior* is often implied and unnecessary to state. We agree with Friman's (2004) recommendation that in most cases, "If the object of our interest is hitting and spitting,

let's just say 'hitting' and 'spitting.' Subsequently, when we are gathering our thoughts with a collective term, we can call them behaviors" (p. 105).

4. Respondent conditioning and the operant principles mentioned here are introduced later in this chapter.
5. Gray (1979) provides an excellent and interesting description of Pavlov's research. "Although the experimental preparations for studying Pavlovian conditioning have expanded over the years, Pavlov's work with dogs describes many of the key empirical phenomena and theoretical processes that modern researchers continue to pursue. . . . The study of basic associative learning processes underlying Pavlovian conditioning has led to numerous insights into experimental design, how learning occurs, and how basic processes may lay the foundation for many putative higher forms of learning" (K. M. Lattal, 2013, p. 283).
6. *Unconditioned stimulus* and *conditioned stimulus* are the most commonly used terms to denote the stimulus component of respondent relations. However, because the terms ambiguously refer to both the immediate evocative (eliciting) effect of the stimulus change and its somewhat permanent and delayed function-altering effect (the conditioning effect on other stimuli), Michael (1995) recommended that the terms *unconditioned elicitor* (UE) and *conditioned elicitor* (CE) be used when referring to the evocative function of these variables.
7. To learn more about Pavlovian conditioning, see the detailed descriptions and numerous examples in Gottlieb and Begej (2014), K. M. Lattal (2013), and Williams (2014).
8. The verb *emit* is used in conjunction with operant behavior. Its use fits well with the definition of operant behavior, allowing reference to the consequences of behavior as the major controlling variables. The verb *elicit* is inappropriate to use with operant behavior because it implies that an antecedent stimulus has primary control of the behavior. Domjan (2016) argues that the terms *elicited* and *emitted* are no longer useful or accurate for distinguishing classically conditioned (respondent) behavior from operant behavior.
9. To learn more about the role of selectionism in Darwinian evolutionary biology and Skinnerian behaviorism, see Leão, Laurenti, and Haydu (2016); Moxley (2004); and Reese (1994).
10. Unless noted otherwise, the term *behavior* will refer to operant behavior throughout the remainder of the text.
11. Skinner (1966) used rate of responding as the fundamental datum for his research. To strengthen an operant is to make it more frequent. However, rate is not the only measurable and malleable dimension of behavior. As we will see in Chapters 3 and 4, sometimes the duration, latency, magnitude, and/or topography of behavior changes are of practical importance.
12. *Automaticity of reinforcement* and *automatic reinforcement* are different concepts. **Automatic reinforcement** refers to the hypothesis that a behavior produces its own reinforcement, as in the sensory stimulation from scratching an itch (Vaughn & Michael, 1982). In practice, when an experimental analysis fails to identify the reinforcers maintaining a problem behavior, some form of *automatic reinforcement* is assumed. Automatic reinforcement is described in Chapters 11 and 27.
13. Prominent behavior analysts disagree on whether delayed consequences can function as reinforcement (Bradley & Poling, 2010). Chapters 11, 29, and 30 discuss the use and effects of delayed consequences in behavior change programs.
14. Malott and Shane (2014) refer to these two operations as "stimulus addition" and "stimulus subtraction."
15. For examples of inaccurate representations of behaviorism and behavior analysis and their implications for training practitioners and serving clients, see Cooke (1984); Heward (2005); Heward and Cooper (1992); Morris (2009); Schlinger (2018); and Todd and Morris (1983, 1992).
16. Foxx (1982) introduced the terms *Type I punishment* and *Type II punishment* for positive punishment and negative punishment, respectively. Some behavior analysts and practitioners continue to use Foxx's terminology. Malott and Shane (2014) refer to negative punishment as a *penalty contingency*.
17. Michael (1975) and Baron and Galizio (2005) present cogent arguments that positive and negative reinforcement are examples of the same fundamental operant relation. This issue is discussed further in Chapter 12.
18. Some authors use the modifiers *primary* or *unlearned* to identify *unconditioned reinforcers* and *unconditioned punishers*.
19. In addition to using *aversive stimulus* as a synonym for a *negative reinforcer*, Skinner (1953) used the term to refer to stimuli whose onset or presentation functions as punishment, a practice continued by many behavior analysts (e.g., Alberto & Troutman, 2013; Malott & Shane, 2014; Miltenberger, 2016). The term *aversive stimulus* (and *aversive control* when speaking of behavior change techniques involving such stimuli) is used widely in the behavior analysis literature to refer to one or more of three different behavioral functions: An aversive stimulus may be (a) a negative reinforcer if its termination increases behavior, (b) a punisher if its presentation decreases behavior, and/or (c) a motivating operation if its presentation increases the current frequency of behaviors that have terminated it in the past (see Chapter 16). When speaking or writing technically, behavior analysts must be careful that their use of omnibus terms such as *aversive* does not imply unintended functions (Michael, 1995).
20. Some authors use the modifiers *secondary or learned* to identify *conditioned reinforcers* and *conditioned punishers*.
21. Contingency diagrams, such as those shown in Figure 2.3, are an effective way to illustrate temporal and functional relations between behavior and environmental events. Examples of other types of contingency diagrams and suggestions for using them to teach and learn about behavior analysis can be found in Goldwater and Acker (1995); Malott and Shane (2014); Mattaini (1995); and Toogood (2012). State notation is another means for visualizing complex contingency relations and experimental procedures (Mechner, 1959; Michael & Shafer, 1995).
22. The phrase *to make reinforcement contingent* describes the behavior of the researcher or practitioner: delivering the reinforcer only after the target behavior has occurred.
23. Like all scientific findings, these facts are subject to revision and even replacement should future research reveal more useful data.
24. In *shaping*, a new behavior is gradually acquired through reinforcement of successive approximations to a final form (see Chapter 22). Because the natural environment seldom (if ever) truly shapes new behavior, *contingency-selected behavior* may be a better term than *contingency-shaped behavior*.
25. This example was adapted from Sidener (2006). More examples of joint control are presented in Chapter 18, Verbal Behavior.

PART 2

Selecting, Defining, and Measuring Behavior

Because applied behavior analysts must achieve and document behavior changes that improve people's quality of life, the careful selection and systematic measurement of behavior form the operational foundation of applied behavior analysis. Chapter 3 describes the role of assessment in behavior analysis, principal assessment methods used by behavior analysts, how to identify and assess the social significance of potential target behaviors, how to prioritize target behaviors, and how to define the selected behaviors to enable accurate and reliable measurement, and discusses options for setting criteria for behavior change. Chapter 4 explains the role of measurement in applied behavior analysis, defines measurable dimensions of behavior, describes procedures and tools for measuring behavior, and suggests guidelines for selecting a measurement system. Chapter 5 identifies indicators of trustworthy measurement; elucidates common threats to the validity, accuracy, and reliability of behavioral measurement; recommends strategies for combating those threats; and describes methods for assessing the accuracy and quality of behavioral measurement.

CHAPTER 3

Selecting and Defining Target Behaviors

LEARNING OBJECTIVES

- Understand and explain the role of assessment in applied behavior analysis.
- Identify the ethical and professional standards of professional applied behavior analysis.
- State target intervention outcomes in observable and measurable terms.
- Describe the four major methods for obtaining assessment information.
- Explain the importance of social validity in regard to selecting target behavior.
- Describe procedures for assessing the social significance of potential target behaviors.
- Discuss criteria for prioritizing target behaviors.
- Define behavior in observable and measurable terms.
- Explain the process for setting criteria for behavior change.

Applied behavior analysis is concerned with producing predictable and replicable improvements in behavior. However, not just any behavior will do: Applied behavior analysts improve *socially significant behaviors* that have immediate and long-lasting effects for the person and for those who interact with that person. Such behaviors include language, social, motor, and academic skills.

An important preliminary and universally accepted first step involves choosing the *right* behaviors to target for assessment, measurement, and change (Lerman, Iwata, & Hanley, 2013). Lerman et al. (2013) state: "Specific target behaviors are usually selected because they will improve a person's quality of life in the short and the long term by allowing the person access to new reinforcers and additional reinforcing contexts" (p. 86).

This chapter describes the role of assessment in applied behavior analysis, three principal behavioral assessment methods, how to assess and prioritize the social significance of potential target behaviors, and how to apply criteria for defining target behaviors.

ROLE OF ASSESSMENT IN APPLIED BEHAVIOR ANALYSIS

Assessment has long been considered the first of four phases in any systematic model of instruction that includes: assessment, planning, implementation, and evaluation (Stephens, 1976). A comprehensive behavioral assessment informs planning, provides guidance for implementation, and assists with evaluation.

Definition and Purpose of Behavioral Assessment

Traditional psychological and educational assessments typically involve a series of norm-referenced, criterion-referenced, or curriculum-based assessments supplemented by observations, anecdotal reports, and historical data to determine the learner's strengths and weaknesses within cognitive, academic, social, and/or psychomotor domains.

Conversely, **behavioral assessment** includes indirect and direct procedures such as interviews, checklists, and tests to identify and define the specific target behavior. In addition to identifying behavior(s) to change, comprehensive behavioral assessment can uncover functional relations between variables; it provides context on the resources, assets, significant others, competing contingencies, maintenance and generalization factors, and reinforcers (or punishers) that can be combined to improve the efficiency of an intervention (Brown, McDonnell, & Snell, 2016).[1]

Wacker, Berg, Harding, and Cooper-Brown (2011) indicated that the principal goal of behavioral assessment is "to identify environmental variables that are related to increases or decreases in target behavior" (p. 165). Linehan (1977) offered a succinct description of the purpose of behavioral assessment: "To figure out what the client's problem is and how to change it for the better" (p. 31). Implicit in the definitions of both Wacker et al. and Linehan is the concept that behavioral assessment is more than an exercise in describing and classifying behavioral abilities and deficiencies. In short, behavioral assessment goes beyond trying to obtain a psychometric score, grade equivalent data, or rating measure, as worthy as such findings might be for other purposes. Behavioral assessment discovers the *function* that behavior serves in the person's environment (e.g., obtaining social attention, escaping or avoiding a task). A well-constructed and thorough assessment identifies the key variables controlling the behavior, and guides the practitioner to manipulate these variables to the benefit of the learner. Consequently, subsequent interventions can be targeted and have a much better chance of success. As Bourret, Vollmer, and Rapp (2004) pointed out: "The critical test of . . . assessment is the degree to which it differentially indicates an effective teaching strategy" (p. 140).

Phases of Behavioral Assessment

Hawkins's (1979) conceptualization of behavioral assessment embraces five phases: (a) screening, (b) defining and quantifying problems and establishing outcome criteria, (c) pinpointing the target behavior(s), (d) monitoring progress, and (e) following up. Although the five phases form a general chronological sequence, overlap often occurs. Part III of this book, "Evaluating and Analyzing Behavior Change," describes the monitoring and follow-up stages of assessment. This chapter is concerned primarily with the preintervention functions of assessment, the selection and definition of a **target behavior**—the specific behavior selected for change.

To serve competently, applied behavior analysts must know what constitutes socially important behavior, have the technical skills to use appropriate assessment methods and instruments, analyze the data, and be able to match assessment data with an intervention strategy. For instance, the remedial reading specialist must understand the critical behaviors of a competent reader; be able to determine the learner's progress across a continuum of recognition, decoding, and comprehension skills; and deliver appropriate and effective instruction. In short, the analyst must be knowledgeable about the full scope and sequence of the target behavior.

Preassessment Considerations

Before conducting an informal or formal behavioral assessment for the purpose of pinpointing a target behavior, the analyst must address two fundamental questions. First, who has the authority, permission, resources, and skills to complete an assessment and intervene with the client? If a practitioner does not have authority or permission, then the analyst's role in assessment and intervention is restricted. For example, suppose that a behavior analyst is standing in a checkout line where a nearby parent is attempting to manage an extremely disruptive child. Does the behavior analyst have the authority to conduct an on-the-spot assessment of the problem or to suggest an intervention to the parent? No. However, if the same episode occurred during an *in situ* "coaching session" with the parent who had requested assistance beforehand, the analyst would be able to offer an assessment and recommend an intervention.

The second question asks: What records, resources, or data currently exist that shed light on what has been done in the past to identify, treat, and evaluate the target behavior? Minimally, the behavior analyst should examine and review relevant medical, educational, or historical data. Clearly, all medical reasons for suspected unusual behavior should be ruled out. A child with serious, but as yet undetected, eye (amblyopia), ear (otitis media), or prenatal conditions (fetal alcohol syndrome) may exhibit behavior problems, which, if treated solely by behavioral measures, will miss the mark. Pretreating these causal factors medically allows for better focus in later educational and/or behavioral interventions.

Likewise, the practitioner should conduct an analysis of prior educational and behavioral interventions. Through examining narrative reports, analyzing data-based graphs or charts, and interviewing caretakers, a skilled analyst can form a picture about the nature of the target behavior, its developmental scope and sequence, and the reinforcers and punishers that appear to sustain the behavior. Further, a judgment can be made about treatment integrity with prior interventions. It's possible that a past intervention (e.g., extinction) was employed to reduce calling out in class, but it was abandoned prematurely because the caretakers misinterpreted the *gradual* decrease in call outs as failure. Alternatively, misbehaviors that were addressed successfully in a training environment (e.g., special education classroom, developmental center) might surface in an untrained setting (home, community setting) because of a past failure to program for generalization.

In effect, applied behavior analysts must not only recognize the role of assessment in the four-stage assessment-planning-implementation-evaluation continuum, but also recognize all the personal, social, and environmental factors that affect behavior. Only then can they use their behavior analytic skills to assess and ultimately change behavior.[2] Figure 3.1 outlines the four cornerstones of professional assessment.

Figure 3.1 Four cornerstones of professional assessment.

1. *Recognize professional limitations.*	• Secure authority to assess the problem or suggest an intervention. • Do not test beyond professional training or license capability. • Decline to assess under poor conditions (e.g., the learner is ill, the environment is distracting, the analyst is rushed for time).
2. *Assume responsibility for your work.*	• Be careful, be thorough, be conservative with interpretations. • Recognize the assumptions for referral and testing (i.e., change of placement, generate intervention strategies).
3. *Maintain confidentiality.*	• Hold assessment information in confidence. Obtain a signed and dated Release of Information (ROI). • Ensure that assessment results are shared only with those who are eligible to receive them. • Seek guidance in situations where confidentiality is in question (e.g., life-threatening situations).
4. *Adhere to professional, administration, and ethical standards.*	• Use technically reliable and valid measures and procedures to assess. • Follow appropriate protocols. • Examine and analyze all relevant medical, educational, and historical data. • Recommend the strongest, but least intrusive interventions.

ASSESSMENT METHODS USED BY BEHAVIOR ANALYSTS

Behavior analysts use a variety of assessment methods to identify which behavior(s) to target for change. A comprehensive behavioral assessment often includes both indirect and direct methods.[3]

Indirect Assessment

Interviews, checklists, and rating scales are *indirect assessment approaches* because the data obtained from these methods are derived from recollections, reconstructions, and/or subjective, ordinal-scale ratings of events. Interviews, checklists, and rating scales can be conducted with the client and/or with people who come into regular contact with the individual (e.g., teachers, parents, care providers).

Indirect assessments include open- and closed-ended formats (Fryling & Baires, 2016). *Open-ended indirect assessments* encourage the informant to comment freely and without restriction on the number, rate, intensity, and duration of target behaviors and stimuli and conditions that surround the occurrence of these behaviors (*How often does Mario engage in self-injurious behavior?*). The informant's narrative across a range of questions often leads to follow-up questions that provide more context and substance on the possible variables controlling the behavior (*Does Mario's self-injurious behavior occur more often when he is at home or at school?*).

Closed-ended indirect assessments require the informant to use a Likert scale to rate a series of questions, with a total summary score being generated that provides direction on possible variables controlling the behavior (e.g., *Rate the occurrences of Mario's self-injurious behavior using this scale:* 5 = *frequently*; 3 = *sometimes*; 1 = *rarely*). Figure 3.2 compares the relative strengths and limitations of closed- and open-ended indirect assessments.

The following sections describe the roles of the client, significant others, and checklists and rating scales with respect to conducting indirect assessments.

Interviewing the Client

A behavioral interview is often a first and important step in identifying potential target behaviors, which can be verified, or rejected, by subsequent direct observation or empirical analysis. A behavioral interview differs from a traditional interview by the type of questions asked and the level of information sought. Behavior analysts rely primarily on *what* and *when* questions, which tend to focus on the environmental conditions that exist before, during, and after a behavioral episode. Identifying environmental events that correlate with the behavior provides valuable information for formulating hypotheses about the controlling function of these variables and for planning interventions. Hypothesis generation leads to experimental manipulation and the discovery of functional relations (see Chapter 26).

Figure 3.3 provides examples of the appropriate kinds of *what* and *when* questions. This sequence of questions was developed by a behavioral consultant in response to a teacher who wanted to reduce the frequency of her own negative reactions to acting out and disruptive students. Similar questions could be generated to address situations in homes or community settings (Sugai & Tindal, 1993).

Interviewing Significant Others

Sometimes either the behavior analyst cannot interview the client personally or the analyst needs information from others who are important in the client's life (e.g., parents, teachers, coworkers). In such cases, the analyst will interview one or more of these significant others. When asked to describe a behavioral problem or deficit, significant others often begin with general terms or labels that do not identify specific behaviors to change and often imply causal factors thought to be intrinsic to the client (e.g., fearful, aggressive, unmotivated, lazy, withdrawn). By asking structured questions, the behavior analyst helps significant others describe the problem in terms of specific behaviors, environmental conditions, and events associated with those behaviors. For example, when interviewing parents, the following questions help to target instances of "noncompliant" and "immature" behaviors.

- What does Derek do that leads you to characterize his behavior as immature or noncompliant?
- During what time of day does Derek seem most immature (or noncompliant)?

Figure 3.2 Strengths and limitations of closed- versus open-ended indirect assessments.

	Closed-ended indirect assessments	Open-ended indirect assessments
Strengths	-Assures information about common controlling variables with some populations. -Quick and easy to administer. -Few particular skills are required to administer and interpret.	-Information about a wide range of contextual variables may be obtained. -Opportunity to develop rapport with the informant and to listen to his or her experiences.
Limitations	-Only asks questions about pre-determined variables. -May suggest a non-function (i.e., false-positives). -May be misused by individuals without training in ABA. -Little opportunity to develop rapport with informants.	-Takes longer than closed-ended indirect assessments. -May include information that is not relevant to the function. -Interpretation requires behavior analytic skills. -Requires clinical interviewing skills to obtain information and develop rapport.

- Are there certain situations or places where Derek is noncompliant or acts immature? If so, where, and what does he do?
- How many different ways does Derek act immature (or noncompliant)?
- What's the most frequent noncompliant behavior that Derek has?
- How do you and other family members respond when Derek exhibits these behaviors?
- If Derek were to be more mature and independent as you would like, what would he do differently than he does now?

Figure 3.4 is a form with which parents, caregivers, and significant others can identify possible target behaviors.

Figure 3.3 Sample behavioral interview questions.

Problem Identification Interview Form

Reason for referral: The teacher requested help reducing her negative attention to acting out and disruptive students who were yelling and noncompliant.

1. In your own words, can you define the problem behaviors that prompted your request?
2. Are there any other teacher-based behaviors that concern you at this time?
3. When you engage in negative teacher attention (i.e., when you attend to yelling or noncompliant behavior), what usually happens *immediately before* the negative teacher attention occurs?
4. What usually happens *after* the negative teacher attention occurs?
5. What are the students' reactions when you yell or attend to their noncompliant behavior?
6. What behaviors would the students need to perform so that you would be less likely to attend to them in a negative way?
7. Have you tried other interventions? What has been their effect?

Figure 3.4 Form for generating possible target behaviors.

The 5 + 5 Behavior List

Child's name: ______________________________

Person completing this list: ______________________________

Listmaker's relationship to child: ______________________________

5 good things _______ does now	5 things I'd like to see _______ learn to do more (or less) often
1. ______________________	1. ______________________
2. ______________________	2. ______________________
3. ______________________	3. ______________________
4. ______________________	4. ______________________
5. ______________________	5. ______________________

Directions: Begin by listing in the left-hand column 5 desirable behaviors your child (or student) does regularly now; things that you want him or her to continue doing. Next, list in the right-hand column 5 behaviors you would like to see your child do more often (things that your child does sometimes but should do with more regularity) and/or undesirable behaviors that you want him or her to do less often (or not at all). You may list more than 5 behaviors in either column, but try to identify at least 5 in each.

In addition to seeking help from significant others to identify target behaviors and possible controlling variables, the behavior analyst can sometimes use the interview to determine the extent to which significant others are willing and able to help implement a subsequent intervention. Without the assistance of parents, siblings, teacher aides, and staff, it is difficult for behavior change programs to succeed, or be sustained, with any degree of treatment integrity after the initial intervention.

As an outgrowth of being interviewed, some clients, or their significant others, may be asked to complete a questionnaire or so-called *needs assessment survey*. Questionnaires and needs assessment surveys have been developed in multiple human services areas to refine or extend the interview process (Altschuld & Witkin, 2000). Results from such assessments can be useful in selecting and defining target behaviors further, or in determining possible interventions. For example, a client seeking behavioral treatment to quit smoking might respond to a questionnaire or survey by indicating the number of cigarettes smoked each day and the conditions under which smoking occurs (e.g., morning coffee break, after dinner, stuck in a traffic jam). These client-collected data may shed light on antecedent conditions correlated with the target behavior.

Checklists and Rating Scales

Behavior checklists and rating scales can be used alone or in combination with interviews to identify potential target behaviors (Kelley, LaRue, Roane & Gadaire, 2011). A **behavior checklist** provides a description of specific behaviors and the conditions under which each behavior occurs (i.e., antecedent and consequence events that may affect the frequency, intensity, or duration of behaviors). Situation- or program-specific checklists can be created to assess one particular behavior (e.g., tooth brushing) or a specific skill area (e.g., social skills).

A rating scale using a Likert system (e.g., a range of numbers from 1 to 5 or 1 to 10) attempts to more precisely describe and quantify the target behavior of interest by using an ordinal scale. When a numerically based scale is employed, sometimes a total score is generated to provide further guidance on the significance of the target behavior. The *Functional Assessment Checklist for Teachers and Staff* (March et al., 2000) combines checklist and rating scale components to help specify the target behavior and the conditions under which it occurs (see Figure 3.5). Still, whenever an ordinal scale is used, and data interpretation is involved, behavior analysts are advised to heed Merbitz, Morris, and Grip's (1989) sage advice:

> Ordinal level scales are widely used in rehabilitation. Such scales provide a rank order characterization of phenomena when the direction of an underlying dimension (such as consciousness) can be described and units of measurement cannot. Unfortunately, the information produced by these scales is difficult to interpret and easy to misuse. (p. 308)

Direct Assessment

Tests and direct observations are *direct assessment* approaches because the results from these procedures provide measurable and validated information about the learner's behavior. Standardized tests and observations are two principal methods of direct assessment.

Standardized Tests

Literally thousands of standardized tests have been developed to assess behavior (cf. Carlson, Geisinger, & Jonson, 2017). Each time a *standardized test* is administered, the same questions and tasks are presented using specified procedures and the same scoring criteria are applied. Some standardized tests yield norm-referenced scores, meaning that during the test's development it was administered to a large sample of people selected to represent the population for whom the test is designed, and scoring tables and charts are produced that can later be referenced to plot, chart, or calculate results. Scores are charted on a normalized curve. See Box 3.1: "Primer on Norm-referenced Test Scores".

The majority of standardized tests on the market, however, are not conducive to behavioral assessment because the results cannot be translated directly into target behaviors for instruction or treatment. For example, results from standardized tests commonly used in the schools, such as the *Iowa Tests of Basic Skills* (Hoover, Dunbar, & Frisbie, 2007), the *Peabody Individual Achievement Test–R/NU* (Markwardt, 2005), and the *Wide Range Achievement Test—5* (WRAT-5) (Wilkinson & Robertson, 2017), might indicate that a fourth-grader is performing at the third-grade level in mathematics and at the first-grade level in reading. Such information is useful in determining how the student performs with these subjects compared to students in general, but it indicates neither the specific math nor reading skills the student has mastered. Further, it does not provide sufficient direction with which to launch a remedial, intervention, or enrichment program.

Finally, and from a practical perspective, behavior analysts may not be able to administer a given standardized test because of licensing requirements. For instance, only a licensed psychologist can administer some types of intelligence and personality inventories.

Tests are most useful as behavioral assessment devices when they provide a specific measure of the person's performance of the behaviors of interest. Practitioners often use criterion-referenced and curriculum-based assessments to help target behaviors to change.

Criterion-referenced Assessment

A criterion-referenced assessment (CRA) measures a child's skill performance across recognized and commonly accepted "developmental milestones." For instance, most 12-month-old toddlers can sit with trunk stability, stand independently, walk a few steps, reach across their midline, and roll a ball with an adult. In scoring CRAs, teachers might indicate a plus (+), minus (−), or (E) for each associated skill measured to signify that the skill was present, not present, or emerging, respectively.

Curriculum-based Assessment

A curriculum-based assessment (CBA), by contrast, is especially useful because the data that are obtained bear uniquely on the

Figure 3.5 The Functional Assessment Checklist for Teachers and Staff.

Functional Assessment Checklist for Teachers and Staff (FACTS-Part A)

Step 1 Student/Grade: ______________________ Date: ______________________
Interviewer: ______________________ Respondent(s): ______________________

Step 2 **Student Profile:** Please identify at least three strengths or contributions the student brings to school.
____

Step 3 **Problem Behavior(s): Identify problem behaviors**

____ Tardy	____ Fight/physical Aggression	____ Disruptive	____ Theft
____ Unresponsive	____ Inappropriate Language	____ Insubordination	____ Vandalism
____ Withdrawn	____ Verbal Harassment	____ Work not done	____ Other ________
	____ Verbally Inappropriate	____ Self-injury	

Describe problem behavior: ____

Step 4 **Identifying Routines: Where, when and with whom problem behaviors are most likely**

Schedule (Times)	**Activity**	**Likelihood of Problem Behavior**						**Specific Problem Behavior**
	Before School	Low 1	2	3	4	5	High 6	
	Math	1	2	3	4	5	6	
	Transition	1	2	3	4	5	6	
	Language Arts	1	2	3	4	5	6	
	Recess	1	2	3	4	5	6	
	Reading	1	2	3	4	5	6	
	Lunch	1	2	3	4	5	6	
	Science	1	2	3	4	5	6	
	Transition	1	2	3	4	5	6	
	Block Studies	1	2	3	4	5	6	
	Art	1	2	3	4	5	6	

Step 5 **Select 1–3 routines for further assessment: Select routines based on (a) similarity of activities (conditions) with ratings of 4, 5 or 6 and (b) similarity of problem behavior(s). Complete the FACTS-Part B for each routine identified.**

Functional Assessment Checklist for Teachers & Staff (FACTS-Part B)

Step 1 Student/Grade: ______________________ Date: ______________________
Interviewer: ______________________ Respondent(s): ______________________

Step 2 **Routine/Activities/Context:** Which routine (only one) from the FACTS-Part A is assessed?

Routine/Activities/Context	**Problem Behavior(s)**

(continued)

Figure 3.5 (continued)

Step 3 **Provide more detail about the problem behavior(s):**

What does the problem behavior(s) look like?

How often does the problem behavior(s) occur?

How long does the problem behavior(s) last when it does occur?

What is the intensity/level of danger of the problem behavior(s)?

Step 4 **What are the events that predict when the problem behavior(s) will occur? (Predictors)**

Related Issues (setting events)		**Environmental Features**	
____ illness	Other: ____________	____ reprimand/correction	____ structured activity
____ drug use	____________	____ physical demands	____ unstructured time
____ negative social	____________	____ socially isolated	____ tasks too boring
____ conflict at home	____________	____ with peers	____ activity too long
____ academic failure	____________	____ Other	____ tasks too difficult
		____________	

Step 5 **What consequences appear most likely to maintain the problem behavior(s)?**

Things that are Obtained		**Things Avoided or Escaped From**	
____ adult attention	Other: ____________	____ hard tasks	Other: ____________
____ peer attention	____________	____ reprimands	____________
____ preferred activity	____________	____ peer negatives	____________
____ money/things	____________	____ physical effort	____________
		____ adult attention	____________

SUMMARY OF BEHAVIOR

Step 6 **Identify the summary that will be used to build a plan of behavior support.**

Setting Events & Predictors	**Problem Behavior(s)**	**Maintaining Consequence(s)**

Step 7 **How confident are you that the Summary of Behavior is accurate?**

Not very confident					**Very confident**
1	2	3	4	5	6

Step 8 **What current efforts have been used to control the problem behavior?**

Strategies for preventing problem behavior		**Strategies for responding to problem behavior**	
____ schedule change	None: ____ Other ____	____ reprimand	None: ____ Other ____
____ seating change	____________	____ office referral	____________
____ curriculum change	____________	____ detention	____________

BOX 3.1

Primer on Norm-Referenced Test Scores

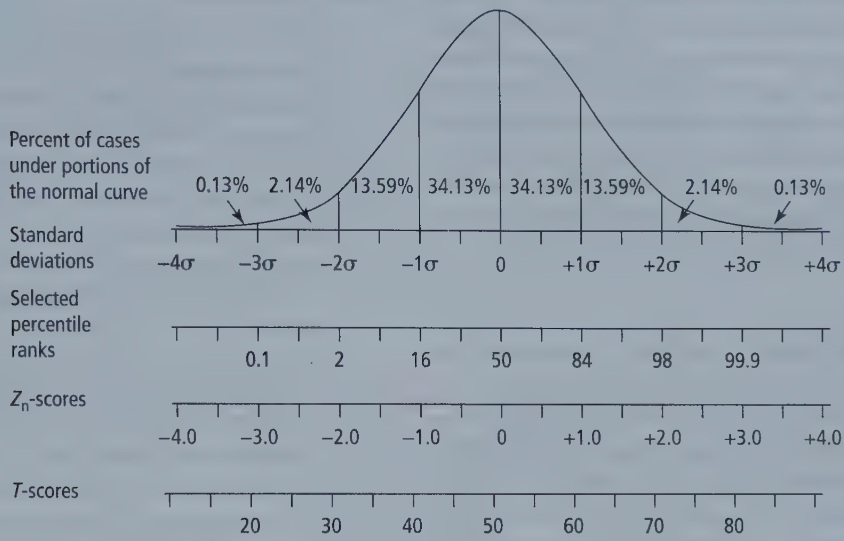

Figure A Relationship among percentile scores, *z*-scores, and *t*-scores in a normal distribution.

From *Educational Assessment of Students*, 8th ed., p. 391, by S. M. Brookhart and A. J. Nitko, 2019, Upper Saddle River, NJ: Pearson. Reprinted by permission.

Norm-referenced tests compare an individual's performance with a comparable norm group. These tests provide a number of metrics that practitioners use to make decisions. Three widely used and reported norm-referenced scores are percentiles, *z*-scores, and *t*-scores. Figure A shows the relationships of these and other norm-referenced scores within a normal distribution

Standardized tests yield a number of metrics that practitioners use to make decisions. Plotted beneath this "normal curve" are key measures that can be used to compare an individual's performance with that of a comparable norm group. Test scores of most interest are percentile ranks, *z*-scores, and *t*-scores.

Percentile Ranks

A percentile rank aligns a score with a standard deviation. An average score is the 50th percentile, located in the middle of the distribution. A score of 84 means that the tester's score was equal to or better than the scores of 84% of the individuals who took the standardized test and equates with 1 standard deviation above the mean.

Z-scores

A *z*-score represents the number of standard deviations that a score appears below, at, or above the mean of the population who completed the assessment. A *z*-score of +1.0 equates to 1 standard deviation, and also the 84th percentile.

T-scores

A *t*-score is a standard score with an average of 50 and a standard deviation of 10. In our highlighted example, a *t*-score of 50, located in the middle of the distribution, equates to a percentile score of 50 (read the percentile scale above).

Two other derived scores of interest are the grade equivalent score and the age equivalent (not shown on the normal curve).

Grade Equivalent Score

A grade equivalent score—say, a GES of 5.5—means that the learner's raw score (the number of total items answered correctly on the test) equaled the average number raw score by learners midway through fifth grade in the norm group. This score does not provide information on the specific skills the individual possesses or lacks.

Age Equivalent Score

An age equivalent score—say, 4.6—means that the learner's raw score (the number of total items answered correctly on the test) equaled the average number of raw score points earned by learners midway through age 4 in the norm group. This score does not provide information on the specific skills the individual possesses or lacks.

To learn more about standardized testing and interpreting norm-referenced scores, see assessment texts such as those by Brookhart and Nitko (2019) and Salvia, Ysseldyke, and Bolt (2013).

daily or weekly tasks the learner performs in response to planned lessons (i.e., the curriculum) (Overton, 2006). A learner taking a spelling test at the end of the week based on a 5-day list of words, or a middle school student taking a science quiz on a chapter from the text, serves as a prime example of curriculum-based assessments. CBA data can be collected on a formative basis (e.g., to note error patterns or relative progress) or on a summative schedule (e.g., yearly) across motor (gross and fine), language (receptive and expressive), self-help, or cognition areas. Teachers would record aggregate scores or, depending on the learner's developmental level, mark associated tasks within the skill area as occurring independently, semi-independently, or not at all.

Direct Observations

Direct and repeated observations of the client's behavior in the natural environment are useful for determining behaviors to assess and ultimately to select as a target behavior. Practitioners, however, should be advised that observations could produce limited and skewed information. For instance, if data are collected only during morning sessions, at home, or with a specific caretaker, the "target" behavior may be masked in the afternoon, at school, or with different caretakers. Expanding the direct observations to include a wider range of settings, persons, or behaviors is likely to improve the overall quality of direct assessment, but until the manipulation of variables occurs, it will fall short of being a complete analysis (Thompson & Borrero, 2011).

One basic form of direct continuous observation, first described by Bijou, Peterson, and Ault (1968), is called ABC, or **anecdotal observation**, recording. With **ABC recording**, the observer records a descriptive, temporally sequenced account of all behaviors of interest and the antecedent conditions and consequences for those behaviors as those events occur in the client's natural environment (Cooper, 1981). This technique produces behavioral assessment data that can be used to identify potential target behaviors.[4]

Anecdotal observation yields an overall description of a client's behavior patterns. This detailed record of the client's behavior within its natural context provides accountability to the individual and to others involved in the behavior change plan and is extremely helpful in designing interventions.

Accurately describing behavioral episodes as they occur in real time is aided by using a form to record relevant antecedents, behaviors, and consequences in temporal sequence. For example, Lo (2003) used the form shown in Figure 3.6 to record anecdotal observations of a fourth-grade special education student whose teacher had complained that the boy's frequent talk-outs and out-of-seat behavior were impairing his learning and often disrupted the entire class. ABC observations can also be recorded on a checklist of specific antecedents, behaviors, and consequent events individually created for the client based on information from interviews and/or initial observations (see Figure 27.3).

ABC recording requires the observer to commit full attention to the person being observed for upwards of 20 to 30 minutes. Hence, a classroom teacher, for example, could not easily use this assessment procedure while engaging in other activities, such as managing a reading group, demonstrating a mathematics problem on the chalkboard, or conducting a classwide peer tutoring session. Following are some additional guidelines and suggestions for conducting anecdotal direct observations:

- Record everything the client does and says and everything that happens to the client.
- Use homemade shorthand or abbreviations to make recording more efficient, but be sure the notes can be and are accurately expanded immediately after the observation session.
- Record only actions that are seen or heard, not interpretations of those actions.
- Record the temporal sequence of each response of interest by writing down what happened just before and just after it.
- Record the estimated duration of each instance of the client's behavior. Mark the beginning and ending time of each behavioral episode.
- Be aware that continuous anecdotal observation is often an obtrusive recording method. Most people behave differently when they see someone with a pencil and clipboard staring at them. Knowing this, observers should be as unobtrusive as possible (e.g., stay a reasonable distance away from the subject, avoid eye contact).
- Carry out the observations over a period of several days so that the novelty of having someone observe the client will lessen and the repeated observations can produce a valid picture of day-to-day behavior.

Ecological Assessment

Behavior analysts understand that human behavior is a function of multiple events and that many events have multiple effects on behavior (cf. Michael, 1995). An ecological approach to assessment recognizes the complex interrelationships between environment and behavior. In an **ecological assessment** a great deal of information is gathered about the person and the various environments in which that person lives and works. Among the many factors that can affect a person's behavior are physiological conditions, physical aspects of the environment (e.g., lighting, seating arrangements, noise level), interactions with others, home environment, and past reinforcement history. Each of these factors represents a potential area for assessment.

Although a thorough ecological assessment will provide a tremendous amount of descriptive data, the basic purpose of assessment—to identify the most pressing behavior problem and possible ways to alleviate it—should not be forgotten. It is easy to go overboard with the ecological approach, gathering far more information than necessary. Ecological assessment can be costly in terms of professional and client time, and it may raise ethical and perhaps legal questions regarding confidentiality (Koocher & Keith-Spiegel, 1998). Ultimately, good judgment must be used in determining how much assessment information is necessary. Writing about the role of ecological assessment for special education teachers, Heron and Heward (1988) suggested that

> The key to using an ecological assessment is to know when to use it. . . . Educators must strive to become keen discriminators of: (1) situations in which a

Figure 3.6 Example of an anecdotal ABC recording form.

Student: Student 4 Date: 3/10/03 Setting: SED resource room (math period)

Observer: Experimenter Starting time: 2:40 P.M. Ending time: 3:00 P.M.

Time	Antecedents (A)	Behavior (B)	Consequences (C)
2:40	T tells students to work quietly on their math worksheets	Walks around the room and looks at other students	T says, "Everyone is working, but you. I don't need to tell you what to do."
	✓	Sits down, makes funny noises with mouth	A female peer says: "Would you please be quiet?"
	✓	Says to the peer, "What? Me?" Stops making noises	Peer continues to work
2:41	Math worksheet	Sits in his seat and works quietly	No one pays attention to him
	Math worksheet	Pounds on desk with hands	SED aide asks him to stop
2:45	Math worksheet	Makes vocal noises	Ignored by others
	Math worksheet	Yells-out T's name three times and walks to her with his worksheet	T helps him with the questions
2:47	Everyone is working quietly	Gets up and leaves his seat	T asks him to sit down and work
	✓	Sits down and works	Ignored by others
	Everyone is working quietly	Gets up and talks to a peer	T asks him to sit down and work
	✓	Comes back to his seat and works	Ignored by others
2:55	Math worksheet, no one is attending to him	Hand grabs a male peer and asks him to help on the worksheet	Peer refuses
	✓	Asks another male peer to help him	Peer helps him
2:58	✓	Tells T he's finished the work and it's his turn to work on computer	T asks him to turn in his work and tells him that it's not his turn on the computer
	✓	Whines about why it's not his turn	T explains to him that other students are still working on the computer and he needs to find a book to read
	✓	Stands behind a peer who is playing computer and watches him play the game	Ignored by T

Adapted from *Functional Assessment and Individualized Intervention Plans: Increasing the Behavior Adjustment of Urban Learners in General and Special Education Settings* (p. 317) by Y. Lo. Unpublished doctoral dissertation. Columbus, OH: The Ohio State University. Used by permission.

planned intervention has the potential for affecting student behaviors other than the behavior of concern; and (2) situations in which an intervention, estimated to be effective if the target behavior were viewed in isolation, may be ineffective because other ecological variables come into play. (p. 231)

Reactive Effects of Assessment

Reactivity refers to the effects that an assessment has on the behavior being assessed. Reactivity is most likely when observation is *obtrusive*—that is, the person being observed is aware of the observer's presence and purpose (Kazdin, 2010). Studies have demonstrated that the presence of observers in

applied settings can influence a subject's behavior (Mercatoris & Craighead, 1974; White, 1977). Perhaps the most obtrusive assessment procedures are those that require the participant to monitor and record her own behavior. Research on self-monitoring shows that the procedure commonly affects the behavior under assessment (Kirby, Fowler, & Baer, 1991).[5]

Research suggests, however, that even when the presence of an observer alters the behavior of the person being observed, the reactive effects are temporary (e.g., Kazdin, 1982). Nevertheless, behavior analysts mitigate reactivity when they make observations as unobtrusive as possible, repeat observations until apparent reactive effects subside, and take possible reactive effects into account when interpreting the results of observations.

Choosing an Assessment Method

In addition to selecting assessment methods and tools for identifying target behaviors, behavior analysts conduct assessments to guide the design of effective interventions. These require the experimental manipulation of variables and are described elsewhere in this text: preference and reinforcer assessment (Chapter 11), punisher assessment (Chapter 14), and functional behavior analysis (Chapter 27).

Given that multiple possibilities exist across assessment methods, how might a behavior analyst proceed when trying to weigh the cost-benefit of delaying an intervention in favor of gathering more "assessment" data versus launching an intervention prematurely? Kelley and colleagues (2011) provide a guideline:

> Ultimately, best practice is likely to include an assessment package that contains a structured interview, at least one rating scale, direct observation, and experimental manipulation of environmental variables. A combination of these assessment methods is likely to produce . . . a desirable outcome. (p. 189)

We restate a key point: Assuming the assessment tools have reasonable reliability and validity, and are conducted according to professional standards, the most important element of the assessment process is not so much the gathering of the data as it is the *analysis* of that data. If the analysis should prove not to produce a desirable outcome as Kelley et al. (2011) project, practitioners should not be dismayed. Instead, they should try again "based on the original failure and previous ineffective analysis. . . . Failure is always informative in the logic of behavior analysis" (Baer, 2005, p. 8).

ASSESSING THE SOCIAL SIGNIFICANCE OF POTENTIAL TARGET BEHAVIORS

In the past, few questions were asked when a teacher, therapist, or other human services professional determined that a client's behavior should be assessed. For a well-trained behavior analyst, this is not the case. Because behavior analysts possess an effective technology to change behavior, accountability must be served. Both the goals and the rationale supporting assessment and intervention programs must be open to critical examination by the consumers (i.e., clients and their families) and by others who may be affected (i.e., society). In selecting target behaviors, practitioners should first consider *whose* behavior is being assessed—and changed—and why.

Target behaviors should not be selected solely for the primary benefit of others (e.g., "Be still, be quiet, be docile," in Winett & Winkler, 1972), to simply maintain the status quo (Budd & Baer, 1976; Holland, 1978), or because they pique the interest of someone in a position to change the behaviors. For instance, assume that a newly hired director of an early childhood developmental daycare center announces an annual goal that all the children learn to talk, when in fact, it would be a more appropriate option to assess (and later intervene) on a fuller range of communication options (e.g., signing, picture exchange communication). Selecting "speaking" as a target goal for all children stands in stark contrast to the more fundamental and laudable goal of providing specialized services to meet the individual needs of the children.

Admittedly, judgments about which behaviors to change are difficult to make. Still, practitioners are not without direction when choosing target behaviors. Numerous authors have suggested guidelines and criteria for selecting target behaviors (e.g., Bailey & Lessen, 1984; Bosch & Fuqua, 2001; Hawkins, 1984; Komaki, 1998; Rosales-Ruiz & Baer, 1997). Overall, these guidelines revolve around this central question: To what extent will the proposed behavior change improve the person's life experience? A key answer to this question rests squarely on the concept of habilitation.

Habilitation Defined

Hawkins (1984) suggested that the potential meaningfulness of any behavior change should be considered within the context of **habilitation**, which he defined as "the degree to which the person's repertoire maximizes short- and long-term reinforcers for that individual and for others, and minimizes short- and long-term punishers." (p. 284)

Hawkins (1986) cited several advantages of the definition in that it (a) is conceptually familiar to behavior analysts, (b) defines treatment using measurable outcomes, (c) is applicable to a wide range of habilitative activities, (d) deals with individual and societal needs nonjudgmentally, (e) treats adjustment along a non-deficit-driven, adaptive continuum, and (f) is culturally and situationally relative.

It is difficult to make a priori decisions about how a particular behavior change will contribute to a person's overall habilitation (adjustment, competence). We simply do not know beforehand how useful or functional a given behavior change will prove to be in the future (Baer, 1981, 1982), even when its short-term utility can be predicted. Applied behavior analysts, however, must place the highest importance on the selection of target behaviors that are truly useful and habilitative (Hawkins, 1991). In effect, if a potential target behavior meets the habilitation standard, then the individual is much more likely to (a) acquire additional reinforcers in the future and (b) avoid potential punishers.

From ethical and pragmatic perspectives, any target behavior must benefit the person either directly or indirectly. Examining prospective target behaviors according to the 10 key questions described in the following sections should help clarify their relative social significance and habilitative value.

Figure 3.7 Worksheet for evaluating the social significance of potential target behaviors.

Client's/Student's Name: ________________________ Date: ____________

Person Completing Worksheet: ________________________

Rater's Relationship to Client/Student: ________________________

Behavior: ________________________

Considerations	Assessment	Rationale/Comments
Is this behavior likely to produce reinforcement in the client's natural environment after intervention ends?	Yes No Not Sure	
Is this behavior a necessary prerequisite for a more complex and functional skill?	Yes No Not Sure	
Will this behavior increase the client's access to environments where other important behaviors can be acquired and used?	Yes No Not Sure	
Will changing this behavior predispose others to interact with the client in a more appropriate and supportive manner?	Yes No Not Sure	
Is this behavior a pivotal behavior or behavioral cusp?	Yes No Not Sure	
Is this an age-appropriate behavior?	Yes No Not Sure	
If this behavior is to be reduced or eliminated from the client's repertoire, has an adaptive and functional behavior been selected to replace it?	Yes No Not Sure	
Does this behavior represent the actual problem/goal, or is it only indirectly related?	Yes No Not Sure	
Is this "just talk," or is it the real behavior of interest?	Yes No Not Sure	
Is the goal itself is not a specific behavior (e.g., losing 20 lb), will this behavior help achieve it?	Yes No Not Sure	

Summary notes/comments: ________________________

Figure 3.7 consolidates these questions in a worksheet that can be used to evaluate the social significance of target behaviors.

Will This Behavior Produce Reinforcement in the Client's Natural Environment After Treatment Ends?

To determine whether a particular target behavior is functional for the client, the behavior analyst, significant others, and, whenever possible, the client should ask whether the proposed behavior change will be reinforced in the person's daily life. Ayllon and Azrin (1968) called this the **relevance of behavior rule**; it means that a target behavior should be selected only when it can be determined that the behavior is likely to produce reinforcement in the person's natural environment. The likelihood that a new behavior will result in reinforcement after the behavior change program is terminated is the primary determinant of whether the new behavior will be maintained, thereby having the possibility of long-term benefits for that person.

Judging whether occurrences of the target behavior will be reinforced in the absence of intervention can also help to clarify whether the proposed behavior change is primarily for the individual's benefit or for someone else's. For instance, despite parental wishes or pressure, it would be of little value to try to teach math skills to a student with severe developmental disabilities with pervasive deficits in communication and social skills. Teaching communication skills that would enable the student to have more effective interactions in her *current* environment should take precedence over skills that she might be able to use in the *future* (e.g., making change in the grocery store). Sometimes target behaviors are selected appropriately not because of their direct benefit to the person, but because of an important indirect benefit. Indirect benefits can occur in several different ways, as described by the questions that follow.

Is This Behavior a Necessary Prerequisite for a Useful Skill?

Some behaviors that, in and of themselves, are not important are targeted for instruction because they are necessary prerequisites to learning other functional behaviors. For example, advances in reading research have demonstrated that teaching phonemic awareness skills has positive effects on the acquisition of reading skills (e.g., initial, medial, and final isolated and blended sound combinations) (National Reading Panel, 2000).[6]

Will This Behavior Increase the Client's Access to Environments Where Other Important Behaviors Can Be Learned and Used?

Hawkins (1986) described the targeting of "access behaviors" as a means of producing indirect benefits to clients. For example, students in special education are taught to complete their assignments, interact politely and appropriately with the teacher and their peers, and follow teacher instructions because these behaviors not only will help their personal progress in their current setting but also will likely increase their acceptance and adaptation into a general education classroom.

Will Changing This Behavior Predispose Others to Interact with the Client in a More Appropriate and Supportive Manner?

Another type of indirect benefit occurs when a behavior change is of primary interest to a significant other in the person's life. The behavior change may enable the significant other to behave in a manner more beneficial to the person. For example, suppose a teacher wants the parents of his students to implement a home-based instruction program, believing that the students' language skills would improve considerably if their parents spent just 10 minutes per night playing a vocabulary game with them. In meeting with one student's parents, however, the teacher realizes that although the parents are also concerned about poor language skills, they have other and, in their opinion, more pressing needs—the parents want their child to clean her room and help with the dinner dishes. Even though the teacher believes that straightening up a bedroom and washing dishes are not as important to the child's ultimate welfare as language development, these tasks may be important target behaviors if a sloppy room and a sink full of dirty dishes impede positive parent–child interactions (including playing the teacher's vocabulary-building games). In this case, the daily chores might be selected as the target behaviors for the direct, immediate benefit of the parents, with the expectation that the parents will be more likely to help their daughter with school-related activities if they are happier with her because she straightens her bedroom and helps with the dishes.

Is This Behavior a Behavioral Cusp or a Pivotal Behavior?

Behavior analysts often use a building block method to develop repertoires for clients. For example, in teaching a complex skill (e.g., two-digit multiplication), simpler and more easily attainable skills are taught first (e.g., addition, regrouping, single-digit multiplication), or with shoe tying, crossing laces, making bows, and tying knots are taught systematically. As skill elements are mastered, they combine into increasingly complex behaviors. At any point along this developmental skill continuum when the person performs the skill to criterion, reinforcement follows, and the practitioner makes the determination to advance to the next skill level. As systematic and methodical as this approach has proven to be, behavior analysts are researching ways to improve the efficiency of developing new behavior (see Chapters 19 through 23). Choosing target behaviors that are behavioral cusps and pivotal behaviors may improve this effort.

Behavioral Cusps

A **behavioral cusp** occurs when a learner performs a new behavior that sets the occasion to access reinforcers that otherwise would not have been available. Stated in different terms, a behavioral cusp can be claimed when what has been learned exposes the individual to an array of contingencies that go beyond the reinforcers that would have been delivered had only the target behavior, or a series of behaviors, occurred.

Rosales-Ruiz and Baer (1997) defined a behavioral cusp as:

> [A] behavior that has consequences beyond the change itself, some of which may be considered important. . . . What makes a behavior change a cusp is that it exposes the individual's repertoire to new environments, especially new reinforcers and punishers, new contingencies, new responses, new stimulus controls, and new communities of maintaining or destructive contingencies. When some or all of those events happen, the individual's repertoire expands; it encounters a differentially selective maintenance of the new as well as some old repertoires, and perhaps that leads to some further cusps. (p. 534)

Rosales-Ruiz and Baer (1997) cited crawling, reading, and generalized imitation as examples of behavioral cusp behaviors because the occurrence of such behaviors "*suddenly open* the child's world to new contingencies that will develop many new, important behaviors" (p. 535, italics added for emphasis).

Cusps differ from component or prerequisite behaviors in that cusps ultimately occasion new behaviors in novel environments that bring the learner under different social, sensory, or personal stimulus control (Lerman et al., 2013; Twyman, 2011). For an infant, specific arm, head, leg, or positional movements would be component behaviors for crawling. Crawling is the cusp because it enables the infant to contact new stimuli as sources of reinforcement (e.g., toys, parents), which, in turn, open a host of contingencies that can shape and select other adaptive behaviors. These novel contingencies become available for the learner *and* the significant others in the learner's community.

Rosales-Ruiz and Baer (1997) distinguish between a learner performing a series of tasks in a task analysis and receiving the associated reinforcer for completing each step, and a behavioral cusp that exposes the learner to a host of new contingencies of reinforcement altogether. In plain language, a cusp might be akin to tree branches shooting off the trunk, and providing the possibility of still more offshoots from that "cusp" branch.

Rosales-Ruiz & Baer (1997) sum up the role of identifying cusps as target behaviors by stating:

> The importance of cusps is judged by (a) the extent of the behavior changes they systematically enable, (b) whether they systematically expose behavior to new cusps, and (c) the audience's view of whether these changes are important for the organism, which in turn is often controlled by societal norms and expectations of what behaviors should develop in children and when that development should happen. (p. 537)

By identifying and assessing target behaviors based on their cusp potential, practitioners provide "added value" to their programming. Bosch and Hixson (2004) proposed a series of actions behavior analysts can take and questions to determine behavioral cusps (see Figure 3.8). If the answer is "yes" to the majority of these questions in the right-hand column, a good case can be made that the behavior is a cusp.

Finally, Twyman (2011) sheds much-needed light on how present or future technologies can assist practitioners with developing and refining behavioral cusps. Whether it be through websites, smartphones, iPad/tablet applications, social media, simulations, virtual learning applications, or access to on-line instruction, behavior analysts can further explore programming cusp behaviors to enhance the learning of those they serve.

Pivotal Behavior

A **pivotal behavior** is a behavior that, once learned, produces corresponding modifications or covariations in other adaptive untrained behaviors. For instance, Koegel, Carter, and Koegel (2003) indicated that teaching children with autism to "self-initiate" (e.g., approach others) may be a pivotal behavior. Choice making, self-management, and functional communication training may also be considered pivotal behaviors in that once these behaviors are learned, they are likely to produce adaptive variations in untrained settings.

Koegel and Koegel (2018) and their colleagues have examined pivotal behavior assessment and treatment approaches across a wide range of areas (e.g., social skills, communication, academic performance disruptive behavior) (Koegel, Bradshaw, Ashbaugh, & Koegel, 2014; Koegel, Koegel, Green-Hopkins,

Figure 3.8 Actions and questions to determine behavioral cusps.

Information Needed	Behavioral Cusp Determination
List the direct reinforcers for that target behavior: Social, automatic, conditioned, unconditioned.	Will the behavior contact new reinforcers?
List and describe the environments that the new target behavior will access.	Will the behavior allow access to new selective environments?
List school personnel or familial beliefs and expectations that may strengthen or weaken the value of the behavior change.	Does the behavior meet the demands of the social community of which the person is a member?
List the audience reactions, such as smiles, laughter, etc.	Is the behavior a reinforcer for the audience?
List the inappropriate behaviors and their severity, including frequency, duration, strength, etc. and the effects on the environment.	Is the behavior interfering with or replacing inappropriate behaviors?
List the behaviors/repertoires subsequently affected.	Is the behavior facilitating subsequent learning by being either a prerequisite or a component of more complex responses?
Approximate number of people physically or emotionally affected over time.	Is the behavior impacting a large number of people?
Give a dollar amount by estimating the cost of physical/property damage, health care, lawsuits, etc. over time.	Is the failure to establish this behavior costly?

From "The Final Piece to a Complete Science of Behavior: Behavior Development and Behavioral Cusps," by S. Bosch and M. D. Hixson, *The Behavior Analyst Today*, 5(2), 2004, pp. 244–254.

& Barnes, 2010; Koegel, Koegel, & Schreibman, 1991). The "longitudinal outcome data from children with autism suggest that the presence of pivotal initiation behaviors may be a prognostic indicator of more favorable long-term outcomes and therefore may be 'pivotal' in that they appear to result in widespread positive changes in a number of areas" (Koegel, Carter, & Koegel, 2003, p. 134). Improvement in self-initiations may be critical for the emergence of untrained response classes, such as asking questions and increased production and diversity of talking.

Assessing and targeting pivotal behaviors can be advantageous for the practitioner and the client. From the practitioner's perspective, it might be possible to assess and then train pivotal behaviors within relatively few sessions that would later be emitted in untrained settings or across untrained responses (Koegel et al., 2003). From the client's perspective, learning a pivotal behavior would shorten intervention, provide the person with a new repertoire with which to interact with his environment, improve the efficiency of learning, and increase the chances of coming into contact with reinforcers. As Koegel and colleagues concluded: "The use of procedures that teach the child with disabilities to evoke language learning opportunities in the natural environment may be particularly useful for speech and language specialists or other special educators who desire ongoing learning outside of language teaching sessions" (p. 143).

Is This an Age-Appropriate Behavior?

A number of years ago it was common to see adults with developmental disabilities being taught behaviors that an adult without disabilities would seldom, if ever, do. It was thought—perhaps as a by-product of the concept of mental age—that a 35-year-old woman with the verbal skills of a 10-year-old should play with dolls. Not only is the selection of such target behaviors demeaning, but their occurrence reduces the probability that other people in the person's environment will set the occasion for and reinforce more desirable, adaptive behaviors, leading to a more normal and rewarding life.

The principle of **normalization** refers to the use of progressively more typical environments, expectations, and procedures "to establish and/or maintain personal behaviors which are as culturally normal as possible" (Wolfensberger, 1972, p. 28). Normalization is not a single technique, but a philosophical position that holds the goal of achieving the greatest possible physical and social integration of people with disabilities into the mainstream of society.

In addition to the philosophical and ethical reasons for selecting age- and setting-appropriate target behaviors, it should be re-emphasized that adaptive, independent, and social behaviors that come into contact with reinforcement are more likely to be maintained than are behaviors that do not. For example, instruction in leisure-time skills such as sports, hobbies, and music-related activities would be more functional for a 17-year-old boy than teaching him to play with toy trucks and building blocks. An adolescent with those behaviors—even in an adapted way—has a better chance of interacting in a typical fashion with his peer group, which may help to ensure the maintenance of his newly learned skills and provide opportunities for learning other adaptive behaviors.

If the Proposed Target Behavior Is to Be Reduced or Eliminated, What Adaptive Behavior Will Replace It?

A practitioner should never plan to reduce or eliminate a behavior from a person's repertoire without first (a) determining an adaptive behavior that will take its place (also known as the *fair pair rule*) and (b) designing the intervention plan to ensure that the replacement behavior is learned. Teachers and other human services professionals should be in the business of building positive, adaptive repertoires, not merely reacting to and eliminating behaviors they find troublesome (Brown et al., 2016). Even though a child's maladaptive behaviors may be exceedingly annoying to others, or even damaging physically, those undesirable responses have proven functional for the child. That is, the maladaptive behavior has worked for the child in the past by producing reinforcers and/or helping the child avoid or escape punishers. A program that only denies that avenue of reinforcement is a nonconstructive approach. It does not teach adaptive behaviors to replace the inappropriate behavior.

Some of the most effective and recommended methods for eliminating unwanted behavior focus primarily on the development of desirable replacement behaviors. Goldiamond (1997) recommended that a "constructional" approach—as opposed to an eliminative approach—be used for the analysis of and intervention into behavioral problems. Under the constructional approach the "solution to problems is the construction of repertoires (or their reinstatement or transfer to new situations) rather than the elimination of repertoires" (Goldiamond, 1974, p. 14). Finally, using the "fair pair" rule helps to ensure that maladaptive behaviors are replaced with incompatible, adaptive behaviors.

If a strong case cannot be made for specific, positive replacement behaviors, then a compelling case has not been made for eliminating the undesirable target behavior. The classroom teacher, for example, who wants a behavior change program to maintain students staying in their seats during reading period must go beyond the simple notion that "they need to be in their seats to do the work." The teacher must select materials and design contingencies that facilitate that goal and motivate the students to accomplish their work.

Does This Behavior Represent the Actual Problem or Goal, or Is It Only Indirectly Related?

An all-too-common error in education is teaching a related behavior, not the behavior of interest. Numerous behavior change programs have been designed to increase on-task behaviors when the primary objective should have been to increase production or work output. On-task behaviors are chosen because people who are productive also tend to be on task. However, as *on task* is typically defined, it is possible for a student to be on task (e.g., in her seat, quiet, and oriented toward or handling academic materials) yet produce little or no work.

Targeting needed prerequisite skills should not be confused with selecting target behaviors that do not directly represent or fulfill the primary reasons for the behavior analysis effort. Prerequisite skills are not taught as terminal behaviors for their own sake, but as necessary elements of the desired terminal behavior. Related, but indirect, behaviors are not necessary to perform the true objective of the program, nor are they really

intended outcomes of the program by themselves. In attempting to detect indirectness, behavior analysts should ask two questions: Is this behavior a necessary prerequisite to the intended terminal behavior? Is this behavior what the instructional program is really all about? If either question can be answered affirmatively, the behavior is eligible for target behavior status.

Is This Just Talk, or Is It the Real Behavior of Interest?

A characteristic of nonbehavioral therapies is that they rely heavily on what people *say* about what they do and why they do it. The client's verbal behavior is considered important because it is believed to reflect the client's inner state and the mental processes that govern the client's behavior. Therefore, getting a person to talk differently about himself (e.g., in a more healthful, positive, and less self-effacing way) is viewed as a significant step in solving the person's problem. This change in attitude is considered by some to be the primary goal of therapy.

Behavior analysts, in contrast, distinguish between what people say and what they do (Skinner, 1953). Knowing and doing are not the same. Getting someone to understand his maladaptive behavior by being able to talk logically about it does not necessarily mean that his behavior will change in more constructive directions. The gambler may know that compulsive betting is ruining his life and that his losses would cease if he simply stopped placing bets. He may even be able to verbalize these facts to a therapist and state convincingly that he will not gamble in the future. Still, he may continue to bet.

Because verbal behavior can be descriptive of what people do, it is sometimes confused with the performance itself. A teacher at a school for juvenile offenders introduced a new math program that included instructional games, group drills, timed tests, and self-graphing. The students responded with negative comments: "This is stupid," "Man, I'm not writin' down what I do," "I'm not even going to try on these tests." If the teacher had attended only to the students' talk about the program, it would probably have been discarded on the first day. But the teacher was aware that negative comments about school and work were expected in the peer group of adolescent delinquents and that her students' negative remarks had enabled them in the past to avoid tasks they thought they would not enjoy. Consequently, the teacher ignored the negative comments and attended to and rewarded her students for accuracy and rate of math computation when they participated in the program. In 1 week, the negative talk had virtually ceased, and the students' math production was at an all-time high.

There are, of course, situations in which the behavior of interest *is* what the client says. Helping a person reduce the number of self-effacing comments he makes and increase the frequency of positive self-descriptions is an example of a program in which talk should be the target behavior—not because the self-effacing comments are indicative of a poor self-concept, but because the client's verbal behavior is the problem.

In every case, a determination must be made of exactly which behavior is the desired functional outcome of the program: Is it a skill or motor performance, or is it verbal behavior? In some instances, doing and talking behaviors might be important. A trainee applying for a lawn mower repair position may be more likely to get a job if he describes verbally how he would fix a cranky starter on a mower. However, once hired, he will hold his job if he is skilled and efficient in repairing mowers. It is highly unlikely that a person will last long on the job if he talks about how he would fix a lawn mower but not be able to do so. Target behaviors must be functional.

What if the Goal of the Behavior Change Program Is Not a Behavior?

Some of the important changes people want to make in their lives are not behaviors, but are instead the result or product of certain other behaviors. Weight loss is an example. On the surface, it appears that target behavior selection is obvious and straightforward—losing weight. The number of pounds can be measured accurately; but weight, or, more precisely, losing weight, is not a behavior. Losing weight is not a specific response that can be defined and performed; it is the product or result of other behaviors—notably reduced food consumption and/or increased exercise. Eating and exercise are definable, observable behaviors that can be measured in precise units.

Some otherwise well-designed weight loss programs have not been successful because behavior change contingencies were placed on the goal—reduced weight—and not on the behaviors necessary to produce the goal. Target behaviors in a weight loss program should be measures of food consumption and exercise level, with intervention strategies designed to address those behaviors (e.g., De Luca & Holborn, 1992; McGuire, Wing, Klem, & Hill, 1999). Weight should be measured and charted during a weight loss program, not because it is the target behavior of interest, but because weight loss shows the positive effects of increased exercise or decreased food consumption.

There are numerous other examples of important goals that are not behaviors, but are the end products of other behaviors. Earning higher grades, for example, is a goal accomplished by practicing skills longer, complying with feedback on practiced performance, joining groups that perform even higher than the learner and imitating that performance, and so forth. Behavior analysts help clients achieve their goals by selecting target behaviors that are the most directly and functionally related to those goals.

Some goals expressed by and for clients are not the direct product of a specific target behavior, but are broader, more general goals: To be more successful, to have more friends, to be creative, to learn good sportsmanship, to develop an improved self-concept. Clearly, none of these goals are defined by specific behaviors, and all are more complex in terms of their behavioral components than losing weight or earning a higher grade. Goals such as being successful represent a class of related behaviors or a general pattern of responding. They are labels that are used to describe people who behave in certain ways. Selecting target behaviors that will help clients or students attain these kinds of goals is even more difficult than their complexity suggests because the goals themselves often mean different things to different people. Being a success entails a wide variety of behaviors. One person may view success in terms of income and job title. For another, success means job satisfaction and ample leisure time. An important role of the behavior analyst during assessment and target behavior identification is to help the client select and define personal behaviors, the sum of which will result in a better quality of life for the client and others evaluating her repertoire in the intended fashion.

PRIORITIZING TARGET BEHAVIORS

Once a "pool" of eligible target behaviors has been identified, decisions must be made about their relative priority. Sometimes the information obtained from behavioral assessment points to one particular aspect of the person's repertoire in need of improvement more so than another. More often, though, assessment reveals a constellation of related, and sometimes not-so-related, behaviors in need of change. Direct observations, along with a behavioral interview and needs assessment, may produce a long list of important behaviors to change. When more than one eligible target behavior remains after careful evaluation of the considerations described in the previous section, the question becomes, Which behavior should be changed first? Judging each potential target behavior in light of the following nine questions may help determine which behavior deserves attention first, and the relative order in which the remaining behaviors will be addressed.

1. *Does this behavior pose any danger to the client or to others?* Behaviors that cause harm or pose a serious threat to the client's or to others' personal safety or health must receive first priority.
2. *How many opportunities will the person have to use this new behavior?* or *How often does this problem behavior occur?* A student who consistently writes reversed letters presents more of a problem than does a child who reverses letters only occasionally. If the choice is between first teaching a prevocational student to pack his lunch or to learn how to plan his 2-week vacation each year, the former skill takes precedence because the employee-to-be may need to pack his lunch every workday.
3. *How long-standing is the problem or skill deficit?* A chronic behavior problem (e.g., bullying) or skill deficit (e.g., lack of social interaction skills) should take precedence over problems that appear sporadically or that have just recently surfaced.
4. *Will changing this behavior produce higher rates of reinforcement for the person?* If all other considerations are equal, a behavior that results in higher, sustained levels of reinforcement should take precedence over a behavior that produces little additional reinforcement for the client.
5. *What will be the relative importance of this target behavior to future skill development and independent functioning?* Each target behavior should be judged in terms of its relation (i.e., prerequisite or supportive) to other critical behaviors needed for optimal learning and development and maximum levels of independent functioning in the future.
6. *Will changing this behavior reduce negative or unwanted attention from others?* Some behaviors are not maladaptive because of anything inherent in the behavior itself, but because of the unnecessary problems the behavior causes the client. Some people with developmental and motoric disabilities may have difficulty at mealtimes with using utensils and napkins appropriately, thus reducing opportunities for positive interaction in public. Granted, public education and awareness are warranted as well, but it would be naive not to consider the negative effects of public reaction. Also, not teaching more appropriate mealtime skills may be a disservice to the person. Idiosyncratic public displays or mannerisms may be high-priority target behaviors if their modification is likely to provide access to more normalized settings or important learning environments.
7. *Will this new behavior produce reinforcement for significant others?* Even though a person's behavior should seldom, if ever, be changed simply for the convenience of others or for maintaining the status quo, neither should the effect of a person's behavior change on the significant others in his life be overlooked. This question is answered best by the significant others themselves because people not directly involved in the person's life would often have

   > no idea how rewarding it is to see your 19-year-old with severe intellectual disabilities acquire the skill of toilet flushing on command or pointing to food when she wants a second helping. I suspect that the average taxpayer would not consider it "meaningful" to him or her for Karrie to acquire such skills. And, although we cannot readily say how much Karrie's being able to flush the toilet enhances her personal reinforcement/punishment ratio, I can testify that it enhances mine as a parent. (Hawkins, 1984, p. 285)

8. *How likely is success in changing this target behavior?* Some behaviors are more difficult to change than others. At least four sources of information help assess the level of difficulty or, more precisely, predict the ease or degree of success in changing a particular behavior. First, what does the literature say about attempts to change this behavior? Many of the target behaviors that confront applied behavior analysts have been studied. Practitioners should stay abreast of published research reports in their areas of application. Not only is such knowledge likely to improve the selection of proven and efficient techniques for behavior change, but also it may help to predict the level of difficulty or chance of success.

   Second, how experienced is the practitioner? The practitioner's own competencies and experiences with the target behavior in question should be considered. A teacher who has worked successfully with acting-out, aggressive children may have an array of effective behavior management strategies to employ. However, that same teacher may believe that he is less able to improve significant deficits in a student's written language skills.

   Third, to what extent can important variables in the client's environment be controlled effectively? Whether a certain behavior *can* be changed is not the question. In an applied setting, however, identifying and then consistently manipulating the controlling variables for a given target behavior will determine whether the behavior *will* be changed.

   Fourth, are the resources available to implement and maintain the intervention at a level of fidelity and intensity that is long enough to achieve the desired outcomes? No matter how expertly designed a treatment plan, implementing it without the personnel and other resources needed to carry out the intervention properly is likely to yield disappointing results.
9. *How much will it cost to change this behavior?* Cost should be considered before implementing any systematic behavior change program. However, a cost–benefit analysis of several potential target behaviors does not mean that if

a teaching program is expensive, it should not be implemented. Major courts have ruled that the lack of public funds may not be used as an excuse for not providing an appropriate education to all children regardless of the severity of their disability (cf., Yell & Drasgow, 2000). The cost of a behavior change program cannot be determined by simply adding aggregate expenditures for equipment, materials, transportation, staff salaries, and the like. Consideration should also be given to how much of the client's time the behavior change program will demand. If, for example, teaching a fine motor skill to a child with severe disabilities consumes so much of the child's day that there is little time for her to learn communication, leisure, or self-help skills, the fine motor skill objective may be too costly.

Developing and Using a Target Behavior Ranking Matrix

Assigning a numerical rating to each of a list of potential target behaviors produces a priority ranking of those behaviors. One such ranking matrix is shown in Figure 3.9; it is an adaptation of a system described by Dardig and Heward (1981) for prioritizing

Figure 3.9 Worksheet for prioritizing potential target behaviors.

Client's/Student's Name: ______________________ Date: __________

Person Completing Worksheet: ______________________

Rater's Relationship to Client/Student: ______________________

Directions: Use the key below to rank each potential target behavior by the extent to which it meets or fulfills each prioritizations criteria. Add each team member's ranking of each potential target behavior. The behavior(s) with the highest total scores would presumably be the highest priority for intervention. Other criteria relevant to a particular program or individual's situation can be added, and the criteria can be differentially weighted.

Key: 0 = No/Never; 1 = Rarely; 2 = Maybe/Sometimes; 3 = Probably/Usually; 4 = Yes/Always

	Potential Target Behaviors			
Prioritization Criteria	**(1)** _______	**(2)** _______	**(3)** _______	**(4)** _______
Does this behavior pose danger to the individual or to others?	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4
How many opportunities will the individual have to use this new skill in the natural environment? or How often does problem behavior occur?	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4
How long-standing is the problem or skill deficit?	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4
Will changing this behavior produce a higher rate of reinforcement for the individual?	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4
What is the relative importance of this target behavior to future skill development and independent functioning?	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4
Will changing this behavior reduce negative or unwanted attention from others?	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4
Will changing this behavior produce reinforcement for significant others?	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4
How likely it success in changing this behavior?	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4
How much will it cost to change this behavior?	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4	0 1 2 3 4

and selecting learning goals for students with disabilities. Each behavior is given a number representing the behavior's value on each of the prioritizing variables (e.g., 0 to 4, with 0 representing no value or contribution and 4 representing maximum value or benefit).

Professionals planning behavior change programs for senior citizens would probably insist that target behaviors with immediate benefits receive high priority. Educators serving secondary students with disabilities would likely advocate for behaviors that focus on skill development and independent functioning.

At times, the behavior analyst, the client, and/or significant others have conflicting goals. Parents may want their adolescent daughter in the house by 10:30 PM on weekends, but the daughter may want to stay out until midnight. The school may want a behavior analyst to develop a program to increase students' adherence to an unpopular dress code. The behavior analyst may believe that elements of the dress codes are negotiable, but not to the point that the administration wants the code enforced. Who decides what is best for whom?

One way to minimize conflicts is to obtain client, parent, and staff/administration participation in the goal determination process. For example, the active participation of parents and students, when possible, in the selection of short- and long-term goals is desirable. Such participation by all of the significant parties can avoid and resolve goal conflicts, not to mention the invaluable information the participants can provide relative to other aspects of program planning (e.g., identification of likely reinforcers). Reviewing the results of assessment efforts and allowing each participant to provide input on the relative merits of each proposed goal or target behavior can often produce consensus on the best direction. Program planners should not commit *a priori* that whatever behavior is ranked first will necessarily be considered the highest priority target behavior. However, if the important people involved in a person's life go through a ranking process such as the one shown in Figure 3.9, they are likely to identify areas of agreement and disagreement, which leads to further discussions of target behavior selection and concentration on the critical concerns of those involved.

DEFINING TARGET BEHAVIORS

Before a behavior undergoes analysis, it must be defined in a clear, objective, and concise manner. In constructing target behavior definitions, applied behavior analysts must consider the functional and topographical implications of their definitions.

Role and Importance of Target Behavior Definitions in Applied Behavior Analysis

Applied behavior analysis derives its validity from its systematic approach to seeking and organizing knowledge about human behavior. Validity of scientific knowledge in its most basic form implies replication. When predicted behavioral effects can be reproduced, principles of behavior are confirmed and methods of practice developed. If applied behavior analysts employ definitions of behavior not available to other scientists, replication is less likely. Without replication, the usefulness or meaningfulness of data cannot be determined beyond the specific participants themselves, thereby limiting the orderly development of the discipline as a useful technology (Baer, Wolf, & Risley, 1968). Without explicit, well-written definitions of target behaviors, researchers would be unable to accurately and reliably measure the same response classes within and across studies; or to aggregate, compare, and interpret their data.[7]

Explicit, well-written definitions of target behavior are also necessary for the practitioner, who may not be so concerned with replication by others or development of the field. Most behavior analysis programs are not conducted primarily for the advancement of the field; they are implemented by educators, clinicians, and other human services professionals to improve the lives of their clients. However, implicit in the application of behavior analysis is an accurate, ongoing evaluation of the target behavior, for which an explicit definition of behavior is a must.

A practitioner concerned only with evaluating his efforts to provide optimum service to his clients might ask, "As long as I know what I mean by [name of target behavior], why must I write down a specific definition?" First, a good behavioral definition is operational. It provides the opportunity to obtain complete information about the behavior's occurrence and nonoccurrence, and it enables the practitioner to apply procedures in a consistently accurate and timely fashion. Second, a good definition increases the likelihood of an accurate and believable evaluation of the program's effectiveness. Not only does an evaluation need to be accurate to guide ongoing program decisions, but also the data must be believable to those with a vested interest in the program's effectiveness. Thus, even though the practitioner may not be interested in demonstrating an analysis to the field at large, he must always be concerned with demonstrating effectiveness (i.e., accountability) to clients, parents, and administrators.

Two Types of Target Behavior Definitions

Target behaviors can be defined functionally or topographically.

Function-based Definitions

A **function-based definition** designates responses as members of the targeted response class solely by their common effect on the environment. For example, Irvin, Thompson, Turner, and Williams (1998) defined hand mouthing as any behavior that resulted in "contact of the fingers, hand, or wrist with the mouth, lips, or tongue" (p. 377). Figure 3.10 shows several examples of function-based definitions.

Applied behavior analysts should use function-based definitions of target behaviors whenever possible for the following reasons:

- A function-based definition encompasses all relevant forms of the response class. However, target behavior definitions based on a list of specific topographies might omit some relevant members of the response class and/or include irrelevant response topographies. For example, defining children's offers to play with peers in terms of specific things the children say and do might omit

Figure 3.10 Function-based definitions of various target behaviors.

Creativity In Children's Blockbuilding

The child behaviors of blockbuilding were defined according to their products, *block forms*. The researchers created a list of 20 arbitrary, but frequently seen forms, including:

Arch—any placement of a block atop two lower blocks not in contiguity.

Ramp—a block leaned against another, or a triangular block placed contiguous to another, to simulate a ramp.

Story—two or more blocks placed one atop another, the upper block(s) resting solely upon the lower.

Tower—any story of two or more blocks in which the lowest block is at least twice as tall as it is wide. (Goetz & Baer, 1973, pp. 210–211).

Exercise by Obese Boys

Riding a stationary bicycle—each wheel revolution constituted a response, which was automatically recorded by magnetic counters (DeLuca & Holborn, 1992, p. 672).

Compliance at Stop Signs by Motorists

Coming to a complete stop—observers scored a vehicle as coming to a complete stop if the tires stopped rolling prior to the vehicle entering the intersection (Van Houten & Retting, 2001, p. 187).

Recycling by Office Employees

Recycling office paper—number of pounds and ounces of recyclable office paper found in recycling and trash containers. All types of paper accepted as recyclable were identified as well as examples of nonrecyclable paper (Brothers, Krantz, & McClannahan, 1994, p. 155).

Safety Skills to Prevent Gun Play by Children

Touching the firearm—the child making contact with the firearm with any part of his or her body or with any object (e.g., a toy) resulting in the displacement of the firearm.

Leaving the area—the child removing himself or herself from the room in which the firearm was located within 10 seconds of seeing the firearm (Himle, Miltenberger, Flessner, & Gatheridge, 2004, p. 3).

responses to which peers respond with reciprocal play and/or include behaviors that peers reject.

- The outcome, or function, of behavior is most important. This holds true even for target behaviors for which form or aesthetics is central to their being valued as socially significant. For example, the flowing strokes of the calligrapher's pen and the gymnast's elegant movements during a floor routine are important (i.e., have been selected) because of their effects or function on others (e.g., praise from the calligraphy teacher, high scores from gymnastics judges).
- Functional definitions are often simpler and more concise than topography-based definitions, which leads to easier and more accurate and reliable measurement and sets the occasion for the consistent application of intervention. For example, in their study on skill execution by college football players, Ward and Carnes (2002) recorded a correct tackle according to the clear and simple definition, "if the offensive ball carrier was stopped" (p. 3).

Function-based definitions can also be used in some situations in which the behavior analyst does not have direct and reliable access to the natural outcome of the target behavior, or cannot use the natural outcome of the target behavior for ethical or safety reasons. In such cases, a *function-based definition by proxy* can be considered. For example, the natural outcome of elopement (i.e., running or walking away from a caregiver without consent) is a lost child. By defining elopement as "any movement away from the therapist more than 1.5 m without permission" (p. 240), Tarbox, Wallace, and Williams (2003) were able to measure and treat this socially significant target behavior in a safe and meaningful manner.

Topography-based Definitions

A **topography-based definition** identifies instances of the target behavior by the shape or form of the behavior. Topography-based definitions should be used when the behavior analyst (a) does not have direct, reliable, or easy access to the functional outcome of the target behavior and/or (b) cannot rely on the function of the behavior because each instance of the target behavior does not produce the relevant outcome in the natural environment or the outcome might be produced by other events. For example, Silvestri (2004) defined and measured two classes of positive teacher statements according to the words that made up the statements, not according to whether the comments produced specific outcomes (see Figure 3.11).

Figure 3.11 Topography-based definitions for two types of teacher statements.

Generic Positive Statements

Generic positive statements were defined as audible statements by the teacher that referred to one or more student's behavior or work products as desirable or commendable (e.g., "I'm proud of you!", "Great job, everyone."). Statements made to other adults in the room were recorded if they were loud enough to be heard by the students and made direct reference to student behavior or work products (e.g., "Aren't you impressed at how quietly my students are working today?"). A series of positive comments that specified neither student names nor behaviors with less than 2 seconds between comments was recorded as one statement. For example, if the teacher said, "Good, good, good. I'm so impressed" when reviewing three or four students' work, it was recorded as one statement.

Teacher utterances not recorded as generic positive statements included (a) statements that referred to specific behavior or student names. (b) neutral statements indicating only that an academic response was correct (e.g., "Okay", "Correct"), (c) positive statements not related to student behavior (e.g., saying "Thanks for dropping off my attendance forms" to a colleague), and (d) incomprehensible or inaudible statements.

Behavior-Specific Positive Statements

Behavior-specific positive statements made explicit reference to an observable behavior (e.g., "Thank you for putting your pencil away"). Specific positive statements could refer to general classroom behavior (e.g., "You did a great job walking back to your seat quietly") or academic performance (e.g., "That was a super smart answer!"). To be recorded as separate responses, specific positive statements were separated from one another by 2 seconds or by differentiation of the behavior praised. In other words, if a teacher named a desirable behavior and then listed multiple students who were demonstrating the behavior, this would be recorded as one statement (e.g., "Marissa, Tony, and Mark, you did a great job of returning your materials when you were finished with them"). However, a teacher's positive comment noting several different behaviors would be recorded as multiple statements regardless of the Interval between the end of one comment and the start of the next. For example, "Jade, you did a great job *cleaning up* so quickly; Charles, thanks for *putting the workbooks away*; and class, I appreciate that you *lined up quietly*" would be recorded as three positive statements.

Adapted from *The Effects of Self-Scoring on Teachers' Positive Statements during Classroom Instruction* (pp. 48–49) by S. M. Silvestri. Unpublished doctoral dissertation. Columbus, OH: The Ohio State University. Used by permission.

Topography-based definitions can also be used for target behaviors for which the relevant outcome is sometimes produced in the natural environment by undesirable variations of the response class. For example, because a duffer's very poor swing of a golf club sometimes produces a good outcome (i.e., the ball lands on the green), it is better to define a correct swing by the position and movement of the golf club and the golfer's feet, hips, head, and hands.

A topography-based definition should encompass all response forms that would typically produce the relevant outcome in the natural environment. Although topography provides an important element for *defining* target behaviors, the applied behavior analyst must be especially careful not to *select* target behaviors solely on the basis of topography (see Box 3.2).

Writing Target Behavior Definitions

A good definition of a target behavior provides an accurate, complete, and concise description of the behavior to be changed (and therefore measured). It also states what is not included in the behavioral definition. Asking aloud to be excused from the dinner table is an observable and measurable behavior that can be counted. By comparison, "exercising good manners" is not a description of any particular behavior; it merely implies a general response class of polite and socially acceptable behaviors. Hawkins and Dobes (1977) described three characteristics of a good target behavior definition that are as valid and useful today as they were when published more than 40 years ago:

1. The definition should be *objective*, referring only to observable characteristics of the behavior (and environment, if needed) or translating any inferential terms (such as "expressing hostile feelings," "intended to help," or "showing interest in") into more objective ones.
2. The definition should be *clear* in that it should be readable and unambiguous so that experienced observers could read it and readily paraphrase it accurately.
3. The definition should be *complete*, delineating the "boundaries" of what is to be included as an instance of the response and what is to be excluded, thereby directing the observers in all situations that are likely to occur and leaving little to their judgment. (p. 169)

Stated succinctly, first, a good definition must be objective, ensuring that specific instances of the defined target behavior are observed and recorded reliably. An objective definition increases the likelihood of an accurate and believable evaluation of program effectiveness. Second, a clear definition is technological, meaning that it enables others to use and replicate it (Baer et al., 1968). A clear definition therefore becomes operational for present and future purposes. Finally, a complete definition discriminates between what is and what is not an instance of the target behavior. A complete definition allows others to record an occurrence of a target behavior, but

BOX 3.2

How Serious Are These Behavior Problems?

Suppose you are a behavior analyst in a position to design and help implement an intervention to change the following four behaviors:

1. A child repeatedly raises her arm, extending and retracting her fingers toward her palm in a gripping/releasing type of motion.
2. An adult with developmental disabilities pushes his hand hard against his eye, making a fist and rubbing his eye rapidly with his knuckles.
3. Several times each day a high school student rhythmically drums her fingers up and down, sometimes in bursts of 10 to 15 minutes in duration.
4. A person repeatedly grabs at and squeezes another person's arms and legs so hard that the other person winces and says "Ouch!"

How much of a problem does the behavior pose for the person or for others who share his or her current and future environments? Would you rate each behavior as a mild, moderate, or serious problem? How important do you think it would be to target each of these behaviors for reduction or elimination from the repertoires of the four individuals?

Appropriate answers to these questions cannot be found in topographical descriptions alone. The meaning and relative importance of any operant behavior can be determined only in the context of the environmental antecedents and consequences that define the behavior. Here is what each of the four people in the previous examples were actually doing:

1. An infant learning to wave "bye-bye."
2. A man with allergies rubbing his eye to relieve the itching.
3. A student typing unpredictable text to increase her keyboarding fluency and endurance.
4. A massage therapist giving a relaxing, deep-muscle massage to a grateful and happy customer.

Applied behavior analysts must remember that the meaning of any behavior is determined by its function, not its form. Behaviors should not be targeted for change on the basis of topography alone.

Note: Examples 1 and 2 are adapted from Meyer and Evans. 1989. p. 53.

not record instances of nonoccurrence, in a standard fashion. A complete definition is a precise and concise description of the behavior of interest. Note how the target behavior definitions in Figures 3.10 and 3.11 meet the standard for being objective, clear, and complete.

Morris (1985) suggested testing the definition of a target behavior by asking three questions:

1. Can you count the number of times that the behavior occurs in, for example, a 15-minute period, a 1-hour period, or 1 day? Or, can you count the number of minutes that it takes for the child to perform the behavior? That is, can you tell someone that the behavior occurred "x" number of times or "x" number of minutes today? (Your answer should be "yes.")
2. Will a stranger know exactly what to look for when you tell him or her the target behavior you are planning to modify? That is, can you actually see the child performing the behavior when it occurs? (Your answer should be "yes.")
3. Can you break down the target behavior into smaller behavioral components, each of which is more specific and observable than the original target behavior? (Your answer should be "no.")

In responding to the suggestion that perhaps a sourcebook of standard target behavior definitions be developed because it would increase the likelihood of exact replications among applied researchers and would save the considerable time spent in developing and testing situation-specific definitions, Baer (1985) offered the following perspectives. Applied behavior analysis programs are implemented because someone (e.g., teacher, parent, individual himself) has "complained" that a behavior needs to be changed. A behavioral definition has validity in applied behavior analysis only if it enables observers to capture every aspect of the behavior that the complainer is concerned with and none other. Thus, to be valid from an applied perspective, definitions of target behaviors should be situation specific. Attempts to standardize behavior definitions assume an unlikely similarity across all situations.

SETTING CRITERIA FOR BEHAVIOR CHANGE

Target behaviors are selected for study in applied behavior analysis because of their importance to the people involved. Applied behavior analysts attempt to increase, maintain, and generalize adaptive, desirable behaviors and decrease the occurrence of maladaptive, undesirable behaviors. Behavior analysis efforts that not only target important behaviors but also change those behaviors in a positive and meaningful way are said to have **social validity**.[8] But how much does a target behavior need to change before it makes a meaningful difference in the person's life?

Van Houten (1979) made a case for specifying the desired outcome criteria before efforts to modify the target behavior begin.

> This step [specifying outcome criteria] becomes as important as the previous step [selecting socially important target behaviors] if one considers that for most behaviors there exists a range of responding within which performance is

> most adaptive. When the limits of this range are unknown for a particular behavior, it is possible to terminate treatment when performance is above or below these limits. Hence, the behavior would not be occurring within its optimal range. . . .
>
> In order to know when to initiate and terminate a treatment, practitioners require socially validated standards for which they can aim. (pp. 582, 583)

Van Houten (1979) suggested two basic approaches to determining socially valid goals: (a) assess the performance of people judged to be highly competent and (b) experimentally manipulate different levels of performance to determine empirically which produces optimal results.

Regardless of the method used, specifying treatment goals before intervention begins provides a guideline for continuing or terminating a treatment. Further, setting objective, predetermined goals helps to eliminate disagreements or biases among those involved in evaluating a program's effectiveness.

SUMMARY

Role of Assessment in Applied Behavior Analysis

1. Behavioral assessment involves using indirect, direct, and empirical methods to identify, define, and determine the function of target behaviors.
2. Behavioral assessment consists of five phases or functions: (a) screening, (b) defining and quantifying problems or goals, (c) pinpointing the target behavior(s) to be treated, (d) monitoring progress, and (e) following up.
3. Before conducting a behavioral assessment, the behavior analyst must determine whether she has the authority and permission, resources, and skills to assess and change the behavior. Past and current records related to medical, educational, and historical events should be examined and analyzed as part of a complete behavioral assessment.

Assessment Methods Used by Behavior Analysts

4. Subsumed under the three major methods for assessment information—indirect, direct, and empirical—are (a) interviews, checklists/rating scales, (b) tests and direct observations, and (c) functional behavior analysis and reinforcer/punishment preference assessment methods, respectively.
5. The client interview is used to determine the client's description of problem behaviors or achievement goals. *What, when*, and *where* questions are emphasized, focusing on the actual behavior of the client and the responses of significant others to that behavior.
6. Questionnaires and needs assessment surveys are sometimes completed by the client to supplement the information gathered in the interview.
7. Clients are sometimes asked to self-monitor certain situations or behaviors. Self-collected data may be useful in selecting and defining target behaviors.
8. Significant others can also be interviewed to gather assessment information and, in some cases, to find out whether they will be willing and able to assist in an intervention.
9. Direct observation with a behavior checklist that contains specific descriptions of various skills can indicate possible target behaviors.
10. Anecdotal observation, also called ABC recording, yields a descriptive, temporally sequenced account of all behaviors of interest and the antecedent conditions and consequences for those behaviors as those events occur in the client's natural environment.
11. Ecological assessment entails gathering a large amount of information about the person and the environments in which that person lives and works (e.g., physiological conditions, physical aspects of the environment, interactions with others, past reinforcement history). A complete ecological assessment is neither necessary nor warranted for most applied behavior analysis programs.
12. Reactivity refers to the effects that an assessment procedure has on the behavior being assessed. Behavior analysts should use assessment methods that are as unobtrusive as possible, repeat observations until apparent reactive effects subside, and take possible reactive effects into account when interpreting the results of observations.
13. Choose assessment methods that produce reliable and valid results, conduct assessments according to professional standards, and apply conservative analyses when interpreting results.

Assessing the Social Significance of Potential Target Behaviors

14. Target behaviors in applied behavior analysis must be socially significant behaviors that will increase a person's habilitation (adjustment, competence, and quality of life).
15. The relative social significance and habilitative value of a potential target behavior can be clarified by viewing it in light of the following considerations:
    - Will the behavior be reinforced in the person's daily life? The relevance of behavior rule requires that a target behavior produce reinforcement for the person in the postintervention environment.

- Is the behavior a necessary prerequisite for a useful skill?
- Will the behavior increase the person's access to environments in which other important behaviors can be learned or used?
- Will the behavior predispose others to interact with the person in a more appropriate and supportive manner?
- Is the behavior a cusp or pivotal behavior? Behavioral cusps have sudden and dramatic consequences that extend well beyond the idiosyncratic change itself because they expose the person to new environments, reinforcers, contingencies, responses, and stimulus controls. Learning a pivotal behavior produces corresponding modifications or covariations in other untrained behaviors.
- Is the behavior age appropriate?
- Whenever a behavior is targeted for reduction or elimination, a desirable, adaptive behavior must be selected to replace it.
- Does the behavior represent the actual problem or achievement goal, or is it only indirectly related?
- A person's verbal behavior should not be confused with the actual behavior of interest. However, in some situations the client's verbal behavior should be selected as the target behavior because it is the behavior of interest.
- If a person's goal is not a specific behavior, a target behavior(s) must be selected that will produce the desired results or state.

Prioritizing Target Behaviors

16. Assessment often reveals more than one possible behavior or skill area for targeting. Prioritization can be accomplished by rating potential target behavior against key questions related to their relative danger, frequency, long-standing existence, potential for reinforcement, relevance for future skill development and independent functioning, reduced negative attention from others, likelihood of success, and cost.
17. Participation by the person whose behavior is to be changed, parents and/or other important family members, staff, and administration in identifying and prioritizing target behaviors can help reduce goal conflicts.

Defining Target Behaviors

18. Explicit, well-written target behavior definitions are necessary for researchers to accurately and reliably measure the same response classes within and across studies or to aggregate, compare, and interpret their data.
19. Good target behaviors definitions are necessary for practitioners to collect accurate and believable data to guide ongoing program decisions, apply procedures consistently, and provide accountability to clients, parents, and administrators.
20. Function-based definitions designate responses as members of the targeted response class solely by their common effect on the environment.
21. Topography-based definitions define instances of the targeted response class behavior by the shape or form of the behavior.
22. A good definition must be objective, clear, and complete, and must discriminate between what is and what is not an instance of the target behavior.
23. A target behavior definition is valid if it enables observers to capture every aspect of the behavior that the "complainer" is concerned with and none other.

Setting Criteria for Behavior Change

24. A behavior change has social validity if it changes some aspect of the person's life in an important way.
25. Outcome criteria specifying the extent of behavior change desired or needed should be determined before efforts to modify the target behavior begin.
26. Two approaches to determining socially validated performance criteria are (a) assessing the performance of people judged to be highly competent and (b) experimentally manipulating different levels of performance to determine which produces optimal results.

MULTIPLE-CHOICE QUESTIONS

1. All of the following are assessment methods used in applied behavior analysis except:
   a. Direct observation
   b. Interview
   c. Medical evaluations
   d. Checklists

   Hint: (See "Role of Assessment in Applied Behavior Analysis")

2. Behavior assessment seeks to determine the ______ of a behavior.
   a. Function
   b. Replacement
   c. Importance
   d. Structure

   Hint: (See "Role of Assessment in Applied Behavior Analysis")

3. All of the following are competencies of a behavior analyst except:
   a. Knowledge of socially important behavior
   b. Technical skills
   c. Ability to conduct statistical analyses of data
   d. Ability to match assessment data with intervention strategies

   Hint: (See "Phases of Behavioral Assessment")

4. Potential target behaviors should not be selected if the primary reason for selection is the:
   a. Benefit of others
   b. Safety of the person
   c. Safety of family members
   d. Potential to increase independence

   Hint: (See "Assessing the Social Significance of Potential Target Behaviors")

5. Interview questions should avoid "why" questions because these tend to encourage _______ explanations of behavior.
   a. Defensive
   b. Mentalistic
   c. Lengthy
   d. Direct

   Hint: (See "Interviewing the Client")

6. A descriptive and temporally sequenced account of behavior in the natural environment is called a(n):
   a. Anecdotal observation
   b. Behavioral assessment
   c. Ecological assessment
   d. Real time observation

   Hint: (See "Direct Observations")

7. The ________ of behavior rule states that a target behavior should only be selected when it can be determined that the behavior will produce natural reinforcement.
   a. Functionality
   b. Validity
   c. Relevance
   d. Importance

   Hint: (See "Will This Behavior Likely to Produce Reinforcement in the Client's Natural Environment after Treatment Ends?")

8. The principle of ________ determines the degree to which a person's behavior repertoire maximizes short and long-term reinforcers for that individual and for others, and minimizes short and long-term punishers.
   a. Normalization
   b. Habilitation
   c. Functionality
   d. Justification

   Hint: (See "Assessing the Social Significance of Potential Target Behaviors")

9. Behavior that exposes an individual to new contingencies, reinforcers, and stimulus controls is called:
   a. Pivotal behavior
   b. Access behavior
   c. Behavior cusp
   d. Contingent behavior

   Hint: (See "Is This Behavior a Behavioral Cusp or a Pivotal Behavior?")

10. When a problem behavior has been targeted for reduction or elimination, the behavior analyst must always include a(n) ________ in the intervention plan.
    a. Replacement behavior
    b. Appropriate response
    c. Pivotal behavior
    d. Performance criterion

    Hint: (See "If the Proposed Target Behavior is to be Reduced or Eliminated, What Adaptive Behavior Will Replace It?")

11. Juan is a six-year-old boy with a developmental disability who attends an integrated kindergarten class. Assessments have identified four target behaviors. Which behavior should be the first target for intervention?
    a. Flicking his fingers in front of his eyes
    b. Bolting from the playground
    c. Toilet training
    d. Humming loudly during group activities

    Hint: (See "Prioritizing Target Behaviors")

12. In determining the likelihood of success in changing a behavior, all of the following should be considered except:

a. Research on changing this behavior

b. Experience of the behavior analyst

c. Social validity of the behavior

d. Available resources

Hint: (See "Prioritizing Target Behaviors")

13. Explicit behavior definitions are important in research of applied behavior analysis for all of the following except:

a. Replication by other scientists

b. Accurate and reliable measurement of behavior

c. Comparison of data across studies

d. Agreement between assessment and intervention data

Hint: (See "Defining Target Behaviors")

14. A(n) ________ definition designates responses in terms of their effect on the environment.

a. Observable

b. Function-based

c. Topography-based

d. Ecological

Hint: (See "Defining Target Behaviors")

15. A behaviors has ________ if it changes some aspect of the person's life in an important way.

a. Social validity

b. Functional application

c. Observable benefit

d. Normalized outcomes

Hint: (See "Setting Criteria for Behavior Change")

16. Outcome criteria should be established before intervention commences for all of the following reasons except:

a. To establish the target performance level

b. To know when to terminate intervention

c. To ensure accurate data collection

d. To ensure agreement on outcomes among stakeholders

Hint: (See "Setting Criteria for Behavior Change")

ESSAY-TYPE QUESTIONS

1. How does behavioral assessment differ from educational or psychological assessment?

Hint: (See "Role of Assessment in Applied Behavior Analysis")

2. Describe one of the competencies of an applied behavior analyst.

Hint: (See "Phases of Behavioral Assessment")

3. Describe one of the four major assessment methods used in behavior analysis.

Hint: (See "Assessment Methods Used by Behavior Analysts")

4. Identify one reason social validity has become a major focus of applied behavior analysis.

Hint: (See "Assessing the Social Significance of Potential Target Behavior")

5. Describe the relevance of behavior rule and briefly explain how it can be used to identify socially significant behavior.

Hint: (See "Habilitation Defined")

6. What is the first question to ask when prioritizing potential target behaviors and why should it be asked first?

Hint: (See "Prioritizing Target Behaviors")

7. Explain one research benefit of explicit, well-written definitions in applied behavior analysis.

Hint: (See "Defining Target Behaviors")

8. What are two features of a function-based behavior definition?

Hint: (See "Two Types of Target Behavior Definitions")

9. Describe one benefit to setting the criteria for behavior change prior to initiating intervention.

Hint: (See "Setting Criteria for Behavior Change")

NOTES

1. Problem behaviors can be assessed empirically using a three-step process called *functional behavior assessment* that is designed to identify and systematically manipulate antecedents and/or consequences that may control the occurrence of the problem behavior(s). Chapter 27 describes this process in detail.
2. Chapter 31, "Ethical and Professional Responsibilities of Applied Behavior Analysts," examines this important issue in detail.
3. Behavior analysts use other forms of assessment to guide the design of effective interventions. Those assessment methods are described elsewhere in this text: preference assessment and reinforcer assessment (Chapter 11), punisher assessment (Chapter 14), and functional behavior assessment (Chapter 27).
4. ABC recording is discussed further in Chapter 27, "Functional Behavior Assessment."
5. Reactive effects of assessment are not necessarily negative. Self-monitoring has become as much a treatment procedure as it is an assessment procedure; see Chapter 29.
6. A target behavior's indirect benefit as a necessary prerequisite for another important behavior should not be confused with indirect teaching. Indirect teaching involves selecting a target behavior different from the true purpose of the behavior because of a belief that they are related (e.g., having a student with poor reading skills practice shape discrimination or balance beam walking). The importance of directness in target behavior selection is discussed later in this section.
7. Procedures for measuring behavior accurately and reliably are discussed in Chapter 4.
8. A third component of social validity concerns the social acceptability of the procedures used to change the behavior. Chapter 10 describes procedures for assessing the social validity of behavior change.

CHAPTER 4

Measuring Behavior

LEARNING OBJECTIVES

- Describe the functions of measurement in applied behavior analysis.
- Identify the measurable dimensions of behavior.
- Describe the different procedures for measuring behavior.
- State the advantages and disadvantages of using continuous measurement procedures and sampling procedures.
- Explain the procedure for measuring behavior by permanent products.
- Explain computer-assisted measurement of behavior.
- Select the appropriate measurement procedure given the dimensions of the behavior and the logistics of observing and recording.

When I awoke this morning, I looked at the clock to see how many hours I slept. (Do I stay in bed or get up? I got up.) I showered, shaved, brushed my teeth, and then stepped onto the bathroom scale to check my weight. (Did I weigh the same, less, or more than yesterday? I gained two pounds.) I started thinking about how much we humans use measurement in our everyday activities, and for the most part we are completely oblivious of the behavioral measurement.

For breakfast I made coffee (4 scoops of coffee, with 4½ cups of water) and placed an English muffin in the toaster (set the toaster to the correct temperature for toasting the muffin). I had breakfast and then I was off to the community rec center for morning exercise.

I got in the car, and the speedometer told me how many miles per hour I was driving. (I stayed within the speed limit.) The gas gauge told me how much gas was in the tank. (Enough to drive to the rec center, return home, and then some.)

At the rec center, I observed people walking or running on the track. One walker recorded the number of laps on a hand-held tally counter, a runner glanced at the clock after each lap, and several walkers and runners wore digital step counters on their wrists. In other places in the rec center, people counted and recorded the number of repetitions they completed with free weights and strength-building machines.

And on and on it goes throughout the day. Measurement makes up a large portion of our everyday lives. It greatly improves the quality of our interaction with our environment. Just as measurement is so important in our environment, it is the foundation of all activity in applied behavior analysis.

Measurement provides the basis for all scientific discoveries and for the development and successful application of technologies derived from those discoveries. Direct and frequent measurement constitutes the foundation for applied behavior analysis. Applied behavior analysts use measurement to detect and compare the effects of various environmental arrangements on the acquisition, maintenance, and generalization of socially significant behaviors.

What is it about behavior that applied behavior analysts can and should measure? How should those measures be obtained? And, what should we do with these measures once we have obtained them? This chapter identifies the dimensions by which behavior can be measured and describes the measurement methods behavior analysts commonly use. First, we examine the definition and functions of measurement in applied behavior analysis.

DEFINITION AND FUNCTIONS OF MEASUREMENT IN APPLIED BEHAVIOR ANALYSIS

Measurement is the process of applying quantitative labels to describe and differentiate objects and natural events. "[It] involves attaching a number representing the observed extent of a dimensional quantity to an appropriate unit. The number

and the unit together constitute the measure of the object or event" (Johnston & Pennypacker, 1993a, p. 95). Measurement in applied behavior analysis entails three steps: (a) identifying the behavior to be measured, (b) defining the behavior in observable terms, and (c) selecting an appropriate observation and data-recording method (Gast, 2014). Chapter 3 covered selecting and defining target behavior; this chapter details measurement methods.

Bloom, Fischer, and Orme (2003)—who described measurement as the act or process of applying quantitative or qualitative labels to events, phenomena, or observed properties using a standard set of consensus-based rules by which to apply labels to those occurrences—pointed out that the concept of measurement includes the characteristics of what is being measured, the quality and appropriateness of the measurement tools, the technical skill of the measurer, and how the measures obtained are used. In the end, measurement gives researchers, practitioners, and consumers a common means for describing and comparing behavior with a set of labels that convey a common meaning.

Researchers Need Measurement

> *Dr. Watson: "What do you imagine that means?"*
> *Sherlock Holmes: "I have no data yet. It is a capital mistake to theorize before one has data. Insensibly one begins to twist facts to suit theories, instead of theories to suit facts."*
> —from A Scandal in Bohemia by Arthur Conan Doyle

Measurement is how scientists operationalize empiricism. Objective measurement enables (indeed, it requires) scientists to describe the phenomena they observe in precise, consistent, and publicly verifiable ways. Without measurement, all three levels of scientific knowledge—description, prediction, and control—would be relegated to guesswork subject to the "individual prejudices, tastes, and private opinions of the scientist" (Zuriff, 1985, p. 9). We would live in a world in which the alchemist's suppositions about a life-prolonging elixir would prevail over the chemist's formulated compounds derived from experimentation.

Behavior analysts measure behavior to answer questions about the existence and nature of functional relations between socially significant behavior and environmental variables. Measurement enables comparisons of a person's behavior within and between different environmental conditions, thereby affording the possibility of drawing empirically based conclusions about the effects of those conditions on behavior. For example, Dunlap and colleagues (1994) measured students' task engagement and disruptive behaviors during choice and no-choice conditions. Measurement revealed the level of both target behaviors during each condition, whether and how much the behaviors changed when choice was introduced or withdrawn, and how variable or stable the behaviors were during each condition.

The researcher's ability to achieve a scientific understanding of behavior change depends on her ability to measure it. Measurement makes possible the detection and verification of virtually everything that has been discovered about the effects of the environment on behavior. The empirical databases of the basic and applied branches of behavior analysis consist of organized collections of behavioral measurements. Virtually every graph in the *Journal of Applied Behavior Analysis* and *Journal of the Experimental Analysis of Behavior* displays an ongoing record or summary of behavioral measurement. In short, measurement provides the very basis for learning and talking about behavior in scientifically meaningful ways.[1]

Practitioners Need Measurement

Behavioral practitioners are dedicated to improving their clients' lives by changing socially significant behaviors. Practitioners measure behavior initially to determine the current level of a target behavior and whether that level merits intervention. If intervention is warranted, the practitioner measures the extent to which his efforts are successful. Practitioners measure behavior to find out whether and when it has changed; the extent and duration of behavior changes; the variability or stability of behavior before, during, and after treatment; and whether important behavior changes have occurred in other settings or situations and spread to other behaviors.

Frequent measures of behavior during treatment (*formative assessment*) enable dynamic, data-based decision making concerning the continuation, modification, or termination of treatment. Practitioners also compare measurements of the target behavior before and after treatment (sometimes including pre- and post-treatment measures obtained in nontreatment settings or situations) to evaluate the overall effects of behavior change programs (*summative evaluation*).

The practitioner who does not obtain and attend to frequent measures of the target behavior is vulnerable to committing mistakes: (a) continuing an ineffective treatment when no real behavior change has occurred or (b) discontinuing an effective treatment because subjective judgment detects no improvement (e.g., without measurement, a teacher would be unlikely to know that a student's oral reading rate has increased from 70 to 80 words per minute). Direct and frequent measurement enables practitioners to detect their successes and, equally important, their failures so they can make changes to transform failure into success (Bushell & Baer, 1994; Greenwood & Maheady, 1997; Gast, 2014).

> Our technology of behavior change is also a technology of behavior measurement and of experimental design; it developed as that package, and as long as it stays in that package, it is a self-evaluating enterprise. Its successes are successes of known magnitude; its failures are almost immediately detected as failures; and whatever its outcomes, they are attributable to known inputs and procedures rather than to chance events or coincidences. (D. M. Baer, October 21, 1982)

In addition to enabling ongoing program monitoring and data-based decision making, frequent measurement

provides other important benefits to practitioners and the clients they serve:

- *Measurement helps practitioners optimize their effectiveness.* To be optimally effective, a practitioner must maximize behavior change efficiency in terms of time and resources. Only by maintaining close, continual contact with relevant outcome data can a practitioner hope to achieve optimal effectiveness and efficiency (Bushell & Baer, 1994). Commenting on the critical role of direct and frequent measurement in maximizing the effectiveness of classroom practice, Sidman (2000) noted that teachers "must remain attuned to the pupil's messages and be ready to try and to evaluate modifications [in instructional methods]. Teaching, then, is not just a matter of changing the behavior of pupils; it is an interactive social process" (p. 23, words in brackets added). Direct and frequent measurement is the process by which practitioners hear their clients' messages.
- *Measurement enables practitioners to verify the legitimacy of treatments touted as "evidence based."* Practitioners are increasingly expected, and in some fields mandated by law, to use evidence-based interventions. An evidence-based practice is a treatment or intervention that has been shown to be effective by a substantial body of high-quality, peer-reviewed scientific research. When implementing any treatment, regardless of the type or amount of research evidence to support it, practitioners can and should verify its effectiveness with the students or clients they serve by direct and frequent measurement.
- *Measurement helps practitioners identify and terminate treatments based on pseudoscience, fad, fashion, or ideology.* Many controversial treatments and proposed cures for people with developmental disabilities and autism (e.g., facilitated communication, holding therapy, megadoses of vitamins, strange diets, weighted vests, dolphin-assisted therapy) have been promoted in the absence of sound scientific evidence of effectiveness (Foxx & Mulick, 2016). The use of so-called breakthrough therapies has led to disappointment and loss of precious instructional or therapeutic time and, in some cases, to disastrous consequences (Maurice, 1993; Todd, 2012). Even though well-controlled studies have shown many of these methods to be ineffective, and even though these programs are not justified because they lacked sound scientific evidence of effects, risks, and benefits, parents and practitioners are still bombarded with sincere and well-meaning testimonials. Measurement is the practitioner's best ally in the quest to find and verify effective treatments, and to root out those whose strongest support consists of testimonials and slick Internet ads. Practitioners should maintain a healthy skepticism regarding claims for effectiveness. See Box 31.5 for further discussion on this topic.

  Using Plato's Allegory of the Cave as a metaphor for teachers and other practitioners who use untested and pseudo-instructional ideas, Heron, Tincani, Peterson, and Miller (2005) argued that practitioners would be better served by casting aside pseudo-educational theories and philosophies and adopting a scientific approach. Practitioners who directly and frequently measure the effects of their intervention and treatment programs have empirical support to defend against political or social pressures to adopt unproven treatments. In a real sense they arm themselves with what Carl Sagan (1996) called a "baloney detection kit."
- *Measurement helps practitioners be accountable to clients, consumers, employers, and society.* Practitioners should use direct and frequent measurement of behavior to answer parent and caregiver questions about the development of their children or clients.
- *Measurement helps practitioners achieve ethical standards.* Ethical codes of conduct for behavior analytic practitioners require direct and frequent measurement of client behavior (Behavior Analyst Certification Board, 2018; Chapter 31 this text). Determining whether a client's right to effective treatment is being honored requires measurement of the behavior(s) for which treatment was sought or intended. Failing to measure the nature and extent of relevant behavior changes of clients borders on malpractice. Kauffman (2005) offered this perspective on the relationship between measurement and ethical practice in education:

  > [T]he teacher who cannot or will not pinpoint and measure the relevant behaviors of the students he or she is teaching is probably not going to be very effective. . . . Not to define precisely and to measure these behavioral excesses and deficiencies, then, is a fundamental error; it is akin to the malpractice of a nurse who decides not to measure vital signs (heart rate, respiration rate, temperature, and blood pressure), perhaps arguing that he or she is too busy, that subjective estimates of vital signs are quite adequate, that vital signs are only superficial estimates of the patient's health, or that vital signs do not signify the nature of the underlying pathology. The teaching profession is dedicated to the task of changing behavior—changing behavior demonstrably for the better. What can one say, then, of educational practice that does not include precise definition and reliable measurement of the behavioral change induced by the teacher's methodology? It is indefensible. (p. 439)

MEASURABLE DIMENSIONS OF BEHAVIOR

If a friend asked you to measure a coffee table, you would probably ask why he wants the table measured. In other words, what does he want measurement to tell him about the table? Does he need to know its height, width, and depth? Does he want to know how much the table weighs? Perhaps he is interested in the color of the table? Each of these reasons for measuring the table requires measuring a different dimensional quantity of the table (e.g., length, mass, light reflection).

Behavior, like coffee tables and all entities in the physical world, also has features that can be measured. Because behavior

occurs within and across time, it has three fundamental and measurable *dimensional quantities*. Johnston and Pennypacker (2009) described these dimensional quantities as:

- **Repeatability** (also called *countability*): Instances of a behavior can occur repeatedly through time (i.e., behavior can be counted).
- **Temporal extent**: Every instance of behavior occurs during some amount of time (i.e., the duration of behavior can be measured).
- **Temporal locus**: Every instance of behavior occurs at a certain point in time with respect to other events (i.e., when behavior occurs can be measured).

Figure 4.1 shows a schematic representation of repeatability, temporal extent, and temporal locus. Alone and in combination, these dimensional quantities provide the basic and derivative measures used by applied behavior analysts. In the following pages these and two other measurable dimensions of behavior—its form and strength—will be discussed.

Measures Based on Repeatability

Count

Count is a simple tally of the number of occurrences of a behavior. Although how often a behavior occurs is often of primary interest, measures of count alone may not provide enough information to allow behavior analysts to make useful program decisions or analyses. For example, data showing that Katie wrote correct answers to 5, 10, and 15 long division problems over three consecutive math class periods suggests improving performance. However, if the three measures of count were obtained in observation periods of 5 minutes, 20 minutes, and 60 minutes, respectively, a much different interpretation of Katie's performance is suggested. Therefore, the observation period, or counting time, should always be noted when reporting measures of count.

Rate

Combining count and observation time yields rate, one of the most widely used measures in behavior analysis. Skinner (1953) considered rate of response the basic measurement for behavioral research. He invented the cumulative recorder, a device that automatically produced a graphic record of operant response rates by his experimental subjects (see Figure 1.1).

Rate is defined as the number of responses per unit of time.[2] A rate measure is a ratio consisting of the dimensional quantity of count (number of responses) and time (observation period in which the count was obtained). Converting count to rate of response makes measurement more meaningful. For example, knowing that Yumi read 95 words correctly and 4 words incorrectly in 1 minute, that Lee wrote 250 words in 10 minutes, and that Joan's self-injurious behavior occurred 17 times in 1 hour provides important information and context. Expressing the previously reported counts of Katie's performance in math class as rate reveals that she correctly answered long division problems at rates of 1.0, 0.5, and 0.25 per minute over three consecutive class periods.

Rate is often reported as a count per 30 seconds, count per minute, count per hour, count per day—or occasionally, count per week, count per month, or count per year. As long as the unit of time is standard within or across experiments, rate measures can be compared. For example, a student who, over four daily class activities of different durations, had 12 talk-outs in 20 minutes, 8 talk-outs in 12 minutes, 9 talk-outs in 15 minutes, and 12 talk-outs in 18 minutes had response rates of 0.60, 0.67, 0.60, and 0.67 per minute.

The six rules and guidelines that follow will help researchers and practitioners obtain, describe, and interpret count and rate data most appropriately.

Reference the Counting Time. Behavior analysts use two methods to calculate rate of response: (a) total observation time and (b) total interresponse time (IRT) (Johnston & Pennypacker, 2009). Applied behavior analysts most often use the total observation time to calculate rate. To calculate total IRT, the analysts first measure the IRT for each response (i.e., the amount of time that elapses between two consecutive instances of a behavior) and then calculate the sum of the IRTs. (See the section on IRT later in this chapter.)

When using rate of response, behavior analysts must include the duration of the observation time. Comparing rate measures without reference to the counting time can lead to faulty interpretations of data. Consider, for example, that Sally and Lillian each ran at a rate of 7 minutes per mile. We cannot compare their performances without reference to the distances they ran. Running 1 mile at a rate of 7 minutes per mile is a different class of behavior than running a marathon (26.2 miles) at a rate of 7 minutes per mile.

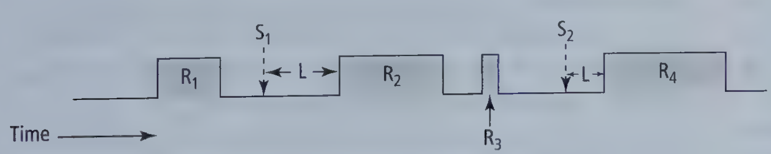

Figure 4.1 Schematic representation of the dimensional quantities of repeatability, temporal extent, and temporal locus. *Repeatability* is shown by a count of four instances of a given response class (R_1, R_2, R_3, and R_4) within the observation period. The *temporal extent* (i.e., duration) of each response is represented by the raised and shaded portions of the time line. One aspect of the *temporal locus* (response latency) of two responses (R_2 and R_4) is represented by the elapsed time (←L→) between the onset of two antecedent stimulus events (S_1 and S_2) and the initiation of the responses that follow.

The counting time used for each session needs to accompany each rate measure when the counting time changes from session to session. For instance, rather than having a set counting time to answer arithmetic facts (e.g., a 1-minute timing), the teacher records the total time required for the student to complete an assigned set of arithmetic problems during each class session. In this situation, the teacher could report the student's correct and incorrect answers per minute for each session, and also report the counting times for each session because they changed from session to session.

Calculate Correct and Incorrect Rates of Response When Assessing Skill Development. When a participant has an opportunity to make correct and incorrect responses, a rate of response for each behavior should be reported. Calculating rates of correct and incorrect responses is crucial for evaluating skill development because knowing only the correct rate does not allow the behavior analyst or participant to assess an improving performance. The rate of correct responses alone could show an improving performance, but if the rate of incorrect responding is also increasing, the improvement may be illusionary. Correct and incorrect rate measures together provide important information to help the teacher evaluate how well the student is progressing. Ideally, the correct response rate accelerates toward a performance criterion, while the incorrect response rate decelerates to a performance criterion. Also, reporting rate correct and rate incorrect enables an assessment of proportional accuracy while maintaining the dimensional quantities of the measurement (e.g., 20 correct and 5 incorrect responses per minute = 80% accuracy, or a multiple of ×4 proportional accuracy).

Correct and incorrect response rates provide essential data for assessing fluent performance (i.e., proficiency) (Kubina, 2005). The assessment of fluency requires measuring the number of correct and incorrect responses per unit of time (i.e., proportional accuracy). Fluency cannot be evaluated using correct rate only because fluent performance must be accurate also.

Consider the Varied Complexity of Responses. Rate of responding is a sensitive and appropriate measure of skill acquisition and the development of fluent performances only when the level of difficulty and complexity from one response to the next remains constant within and across observations. The rates of response previously discussed have been with whole units in which the response requirements are essentially the same from one response to the next. Many important behaviors, however, are composites of two or more component behaviors, and different situations call for varied sequences or combinations of the component behaviors.

One method for measuring rate of responding that takes varied complexity into account for multiple-component behaviors is to count the operations required to achieve a correct response. For example, in measuring students' math calculation performance, instead of counting answers to a two-digit plus three-digit addition problem with regrouping as correct or incorrect, a behavior analyst might consider the number of steps that were completed in correct sequence within each problem. Helwig (1973) used the number of operations needed to produce the answers to mathematics problems to calculate response rates. Each session, students were given 20 multiplication and division problems selected at random from a set of 120 problems. The teacher recorded the duration of time for each session. All the problems were of two types: $a \times b = c$ and $a \div b = c$. For each problem, the students were asked to find one of the factors: the product, the dividend, the divisor, or the quotient. Depending on the problem, finding the missing factor required from one to five operations. For example, writing the answer 275 in response to the problem $55 \times 5 = ?$ would be scored as four correct responses because finding the missing factor requires four operations:

1. Multiply the ones: $5 \times 5 = 25$.
2. Record the 5 ones and carry the 2 tens.
3. Multiply the tens: $5 \times 5(0) = 25(0)$.
4. Add the 2 tens carried and record the sum (27).

If multiple ways to find the answer were possible, the mean number of operations was counted. For example, the answer to the problem $4 \times ? = 164$ can be obtained by two operations with multiplication and by four operations with division. The mean number of operations is three. Helwig counted the number of operations completed correctly and incorrectly per set of 20 problems and reported correct and incorrect rates of response.

Use Rate to Measure Free Operants. Rate of response is a useful measure for all behaviors characterized as free operants. The term **free operant** refers to behaviors that have discrete onsets and offsets, do not depend on discriminative stimuli, involve minimal displacement of the organism in time and space (upon completion of one response, the organism is immediately ready to emit another response in the class), and can be emitted over a wide range of response rates. Skinner (1966) used rate of response of free operants as the primary dependent variable when developing the experimental analysis of behavior. The bar press by rats and key peck by pigeons are typical free operant responses used in nonhuman animal laboratory studies. Many socially significant behaviors meet the definition of free operants: words read during a 1-minute counting period, head slaps per minute, letter strokes written in 3 minutes.

Rate of response is a preferred measurement for free operants because it is sensitive to changes in behavior values (e.g., oral reading may occur at rates ranging from 0 to 250 or more correct words per minute) and because it offers clarity and precision by defining a count per unit of time.

Do Not Use Rate to Measure Behaviors That Occur Within Discrete Trials. Rate of response is an inappropriate measure for behaviors that can occur only within limited or restricted situations. For example, response rates of behaviors that occur within **discrete trials** are controlled by a given opportunity to emit the response. Typical discrete trials used in nonhuman animal laboratory studies include moving from one end of a maze

or shuttle box to another. Applied examples of discrete trials include responding to teacher-presented flash cards; answering a question prompted by the teacher; and, when presented with a sample color, pointing to a color from an array of three colors that matches the sample color. In each of these examples, rate of response is controlled by the presentation of a discriminative stimulus. Because behaviors that occur within discrete trials are opportunity bound, measures such as percentage of response opportunities in which a response was emitted or trials-to-criterion should be used.

Do Not Use Rate to Measure Continuous Behaviors That Occur for Extended Periods. Rate is also a poor measure for continuous behaviors that occur for extended periods, such as participating in a playground game or being on task during a classroom activity. Such behaviors are best measured by whether they are "on" or "off" at any given time, yielding data on duration or estimates of duration obtained by interval recording.

Celeration

Just like a car that goes faster when the driver presses the gas pedal and slows down when the driver releases the pedal or steps on the brake, rates of response accelerate and decelerate. **Celeration**, the root word of acceleration and deceleration, is a measure of how rates of response change over time. Rate accelerates when a participant responds faster over successive counting periods and decelerates when responding slows over successive observations. Applied behavior analysts should use the terms *acceleration* or *deceleration* when describing increasing or decreasing rates of response.

Celeration is a measure of count per unit time/per unit of time; or expressed another way, rate/per unit of time (Graf & Lindsley, 2002; Kubina, 2005). Celeration—changes in rate—is a direct measure of dynamic patterns of behavior change, such as transitions from one steady state of responding to another and the acquisition of fluent levels of performance (Cooper, 2005). The Standard Celeration Chart provides a standard format for displaying measures of celeration. There are four Standard Celeration Charts, showing rate as count (a) per day, (b) per week, (c) per month, and (d) per year. These four charts provide different levels of magnification for viewing and interpreting celeration. Methods for plotting and interpreting celeration data on the Standard Celeration Chart are described in Chapter 6.

Measures Based on Temporal Extent

Duration

Duration, the amount of time from the onset to the end point of a response, is the basic measure of temporal extent. Applied behavior analysts measure duration in standard units of time (e.g., Enrique worked cooperatively with his peer tutor for 6 minutes and 24 seconds today).

Duration is important when measuring the amount of time a person engages in a target behavior. Applied behavior analysts measure the duration of target behaviors that a person has been engaging in for too long or for too short of a time period, such as a child with developmental disabilities who has tantrums for more than an hour at a time, or a student who sticks with an academic task for no more than 30 seconds.

Duration is also an appropriate measure for behaviors that occur at very high rates (e.g., rocking, rapid jerks of the head, hands, legs) or task-oriented continuous behaviors that occur for an extended time (e.g., cooperative play, on-task behavior, off-task behavior).

Behavioral researchers and practitioners commonly measure one or both of two kinds of duration measures: *total duration* per session or observation period and *duration per occurrence*.

Total Duration per Session. Total duration is a measure of the cumulative time a person engages in the target behavior. Applied behavior analysts use two procedures to measure and report total duration. One method involves recording the cumulative amount of time a target behavior occurs during an observation period. An observer measuring the total time a child engages in solitary play during free-play periods activates a stopwatch when the child begins to play alone. The moment solitary play ceases, the observer stops the stopwatch but does not reset it. When the child drifts into solitary play again, the observer restarts the stopwatch. The observer continues to start and stop the stopwatch, matching the child's starting and ending bouts of solitary play. If the duration of the observation periods remains constant (e.g., 10 minutes), total duration per session data can be reported in standard units of time (e.g., 6 min and 30 sec of free play). If the duration of observation periods varies, total duration per session data must be converted to a percentage of total time observed (e.g., 6 min and 30 sec of solitary play in a 10-min session = 65%).

Zhou, Iwata, Goff, and Shore (2001) used total duration measurement to assess leisure-item preferences of people with profound developmental disabilities. They used a stopwatch to record physical engagement with an item (i.e., contact between both hands and the item) during 2-minute trials. They reported total contact in seconds by summing the duration values across three 2-minute trials of each assessment. McCord, Iwata, Galensky, Ellingson, and Thomson (2001) measured the total duration in seconds that two adults with severe or profound intellectual disabilities engaged in problem behavior (see Figure 6.6).

The other measure of total duration recording is the amount of time a person spends completing a specific task, without specifying a minimum or maximum observation period—for example, the number of minutes a person takes getting washed and dressed for work, after arising in the morning, or the time needed to complete a flat tire repair by a high school student enrolled in a work-study program.

Duration per Occurrence. Duration per occurrence is a measure of the duration of time that each instance of the target behavior occurs. For example, Greene, Bailey, and Barber (1981) used a sound-recording device to automatically record (a) the number of times noisy disruptions by children on a school bus exceeded a specified sound threshold and (b) the duration in seconds that each disruption remained above that

threshold. The researchers used the mean duration per occurrence of noisy disruptions as one measure for evaluating the intervention's effects.

Selecting and Combining Measures of Count and Duration. Measurements of count, total duration, and duration per occurrence provide different views of behavior. Count and duration measure different dimensional quantities of behavior, and these differences provide the basis for selecting which dimension(s) to measure. Count measures repeatability, whereas duration recording measures temporal extent. For instance, a teacher concerned about a student who is out of her seat "too much" could tally each time the student leaves her seat. The behavior is discrete and is unlikely to occur at such a high rate that counting the number of occurrences would be difficult. Because any instance of out-of-seat behavior has the potential to occur for an extended time and the total time the student is out of her seat is a socially significant aspect of the behavior, the teacher could also use total duration recording.

Using count to measure out-of-seat behavior provides the number of times the student left her seat. A measure of total duration will indicate the amount and proportion of time that the student was out of her seat during the observation period. Because of the relevance of temporal extent in this case, duration would be a better measure than count. The teacher might observe that the student left her seat once in a 30-minute observation period. One occurrence in 30 minutes might not be viewed as a problem. However, if the student left her seat at minute 1 of the observation period and did not return for the remainder of the period, a very different view of the behavior is obtained.

In this situation, duration per occurrence would make a better measurement selection than count or total duration recording because duration per occurrence measures repeatability (i.e., the rate of response) *and* the temporal extent of the behavior. A duration-per-occurrence measure will give the behavior analyst information on the number of times the student was out of her seat and the duration of each occurrence. Duration per occurrence is often preferable to total duration because rate is sensitive to the number of instances and duration of the target behavior. Further, if a total duration measure is useful for other purposes, the individual durations of each of the counted and timed occurrences can be summed. However, if behavior endurance (e.g., academic responding, motor movements) is the major consideration, then total duration recording may be sufficient (e.g., 5 minutes of oral reading, 10 minutes of free writing).

Measures Based on Temporal Locus

Temporal locus refers to (a) when a behavior occurs with respect to other events of interest (e.g., the latency between the onset of an antecedent event and the occurrence of the behavior) and (b) the amount of time that elapses between two consecutive instances of a response class. These two points of reference provide the context for measuring response latency and interresponse time (IRT), the two measures of temporal locus most frequently reported in the behavior analysis literature.

Latency

Latency is a measure of the elapsed time between the onset of a stimulus and a subsequent response.[3] Latency is an appropriate measure when the applied behavior analyst is interested in how much time occurs between the opportunities to emit a behavior and when the subject initiates the target behavior. For example, Edwards, La Londe, Cox, Weetjens, and Poling (2016) researched the effects of schedules of reinforcement (see Chapter 13) on rats' search for living people trapped under rubble. "Rats were exposed to 10 trials each day. For each trial, the release point for rats and the location of the two human targets, who assumed seated positions within the rubble, were selected from random lists" (p. 200). The researchers recorded (a) the latency from the rat's search-area release point to finding and placing both front paws on a prepositioned human target under simulated rubble and (b) after an initiation buzzer sounded, a second latency measure from the target back to the release point. This significant research emphasized the importance of quickly locating and providing treatment to living people who have been trapped under rubble.

Interest can also focus on latencies that are too short. A student may answer incorrectly because she does not wait for the teacher to complete the questions. An adolescent who, at the slightest provocation from a peer, immediately retaliates has no time to consider alternative behaviors that could defuse the situation and lead to improved interactions.

Behavior analysts typically report response latency data as the mean, median, and range of individual latency measures per observation period. For example, Lerman, Kelley, Vorndran, Kuhn, and LaRue (2002) used a latency measure to assess the effects of different reinforcer magnitudes (i.e., 20 seconds, 60 seconds, or 300 seconds of access to a reinforcer) on post-reinforcement pause—the absence of responding for a period following reinforcement. The researchers measured the number of seconds from the end of each reinforcer-access interval to the first instance of the target behavior (a communication response). They then calculated and graphed the mean, median, and range of response latencies measured during each session (see Lerman et al., 2002, p. 41).

Interresponse Time

Interresponse time (IRT) is a measure of the amount of time that elapses between two consecutive instances of a behavior. Like response latency, IRT is a measure of temporal locus because it identifies *when* a specific instance of behavior occurs with respect to another event (i.e., the previous response). Figure 4.2 shows a schematic representation of interresponse time.

Although a direct measure of temporal locus, IRT is functionally related to rate of response. Shorter IRTs coexist with higher rates of response, and longer IRTs occur within lower response rates. Applied behavior analysts measure IRT when the time between instances of a response class is important. IRT provides a basic measure for implementing and evaluating interventions using differential reinforcement of low and high rates (DRL & DRH), a procedure for using reinforcement to reduce (i.e., DRL) or increase (i.e., DRH) the rate of

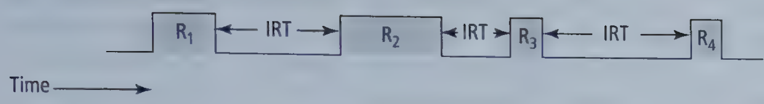

Figure 4.2 Schematic representation of three interresponse times (IRT). IRT, the elapsed time between the termination of one response and the initiation of the next response, is a commonly used measure of temporal locus.

responding (see Chapter 25). Like latency data, IRT measures are typically reported and displayed graphically by mean (or median) and range per observation period.

IRT measures appear frequently in basic behavior analysis experiments examining the effects of schedules of reinforcement (Tanno, Silberberg, & Sakagami, 2009) and variables related to conditioned reinforcement (Bejarano & Hackenberg, 2007), delayed reinforcement (Lattal & Ziegler, 1982), and punishment (Galbicka & Platt, 1984). In one of the few applied studies featuring IRT measures, Lennox, Miltenberger, and Donnelly (1987) reduced rapid eating by three adults with profound intellectual disabilities. The intervention combined differential reinforcement of low rate responding (DRL; see Chapter 25) (an IRT of 15 sec was required before an eating response was permitted), response interruption (blockage of eating responses before 15 seconds had elapsed since the previous response), and prompting participants to engage in an incompatible behavior (putting their forks down and hands in their laps) during the 15-second interval.

Derivative Measures

Behavior analysts frequently use *percentage* and *trials-to-criterion*, two forms of data derived from direct measures of dimensional quantities of behavior.

Percentage

Percentage is a ratio (i.e., a proportion) formed by combining the same dimensional quantities, such as count (i.e., a tally divided by a tally) or time (i.e., a duration divided by a duration; a latency divided by a latency). Percentage expresses the proportional quantity of some event in terms of the number of times the event occurred per 100 opportunities that the event could have occurred. For example, if a student correctly answered 39 of 50 exam items, an accuracy percentage would be calculated by dividing the number of correct answers by the total number of items and multiplying that product by 100 ($39 \div 50 = 0.78 \times 100 = 78\%$).

Percentage is frequently used in applied behavior analysis to report participants' response accuracy. For example, Ward and Carnes (2002) used a percentage-of-correct-performances measure in their study evaluating the effects of goal setting and public posting on skill execution of three defensive skills by linebackers on a college football team. The researchers recorded counts of correct and incorrect reads, drops, and tackles by each player and calculated accuracy percentages based on the number of opportunities for each type of play. (Data from this study are shown in Figure 9.3.) Petursdottir and Aguilar (2016) reported percentage correct data on three kindergarten boys' acquisition of receptive identification tasks as a function of the order of stimulus presentation in matching-to-sample trials.

Applied behavior analysts often use percentage to report the proportion of observation intervals in which the target behavior occurred. These measures are typically reported as a percentage of intervals within a session (e.g., see Figures 6.4 and 12.7). Percentage can also be calculated for an entire observation session. In a study analyzing the differential effects of reinforcer quality, immediacy, and response effort on the impulsive behavior of students with attention-deficit/hyperactivity disorder, Neef, Bicard, and Endo (2001) reported the percentage of time each student allocated to two sets of concurrently available math problems (e.g., time allocated to math problems yielding high-quality delayed reinforcers ÷ total time possible × 100 = %).

Percentages are used widely in education, psychology, and the popular media, and most people understand proportional relationships expressed as percentages. However, percentages are often used improperly. Accordingly, we offer several notes of caution on the use and interpretation of percentages.

Percentages most accurately reflect the level of and changes in behavior when calculated with a divisor (or denominator) of 100 or more. However, most percentages used by behavior analysts are calculated with divisors much smaller than 100. Percentage measures based on small divisors are unduly affected by small changes in behavior. For example, a change in count of just 1 response per 10 opportunities changes the percentage by 10%. Guilford (1965) cautioned that it is unwise to compute percentages with divisors smaller than 20. For research purposes, we recommend that whenever possible, applied behavior analysts design measurement systems in which resultant percentages are based on no fewer than 30 response opportunities or observation intervals.

Changes in percentage may erroneously suggest improving performance. For example, an accuracy percentage could increase even though the occurrence of incorrect responses remains the same or worsens. Consider a student whose accuracy in answering math problems on Monday is 50% (5 of 10 problems answered correctly) and on Tuesday is 60% (12 of 20 problems answered correctly). Even with the improved proportional accuracy, the number of errors increased (from 5 on Monday to 8 on Tuesday).

Although no other measure communicates proportional relationships better than percentage, its use as a behavioral quantity is limited because a percentage has no dimensional quantities.[4] For example, percentage cannot be used to assess the development of proficient or fluent behavior because an assessment of proficiency must reference count and time. Percentage can, however, show the proportional accuracy of a targeted behavior during the development of proficiency.

Another limitation of percentage as a measure of behavior change is that it imposes lower and upper limits on the data. For example, using percent correct to assess a student's

reading performance establishes an artificial ceiling on the measurement of performance. A learner who correctly reads 100% of the words she is presented cannot improve according to the measure used.

Different percentages can be reported from the same data set, with each percentage suggesting significantly different interpretations. For example, consider a student who scores 4 correct (20%) on a 20-item pretest and 16 correct (80%) when the same 20 items are given as a posttest. The most straightforward description of the student's improvement from pretest to posttest (60%) compares the two measures using the original basis or divisor (20 items). Because the student scored 12 more items correct on the posttest than he did on the pretest, his performance on the posttest could be reported as an increase (gain score) over his pretest performance of 60%. And given that the student's posttest score represented a fourfold improvement in correct responses, some might report the posttest score as a 300% improvement of the pretest—a completely different interpretation from an improvement of 40%.

Although percentages greater than 100% are sometimes reported, strictly speaking, doing so is incorrect. Although a behavior change greater than 100% may seem impressive, it is a mathematical impossibility. A percentage is a *proportional* measure of a total set, where *x* (the proportion) of *y* (the total) is expressed as 1 part in 100. A proportion of something cannot exceed the total of that something or be less than zero (i.e., there is no such thing as a negative percentage). Every coach's favorite athlete who "always gives 110%" simply does not exist.[5]

Trials-to-Criterion

Trials-to-criterion is a measure of the number of response opportunities needed to achieve a predetermined level of performance. What constitutes a trial depends on the nature of the target behavior, the relevant setting variables and antecedent stimuli, and the desired performance level. For a skill such as shoe tying, each opportunity to tie a shoe could be considered a trial, and trials-to-criterion data are reported as the number of trials required for the learner to tie a shoe correctly without prompts or assistance. For behaviors involving problem solving or discriminations that must be applied across a large number of examples to be useful, a trial might consist of a block, or series of response opportunities, in which each response opportunity involves the presentation of a different exemplar of the problem or discrimination. For example, a trial for discriminating between the short and long vowel sounds of the letter *o* could be a block of 10 consecutive opportunities to respond, in which each response opportunity is the presentation of a word containing the letter *o*, with short-vowel and long-vowel *o* words (e.g., *hot, boat*) presented in random order. Trials-to-criterion data could be reported as the number of blocks of 10 trials required for the learner to correctly pronounce the *o* sound in all 10 words. Count would be the basic measure from which the trials-to-criterion data would be derived.

Behavior analysts can also use other basic measures as trials-to-criterion data (i.e., rate, duration, latency). For example, a trials-to-criterion measure for solving two-digit minus two-digit subtraction problems requiring borrowing could be the number of practice sheets of 20 randomly generated and sequenced problems a learner completes before she is able to solve all 20 problems on a single sheet in 3 minutes or less.

Trials-to-criterion data are often calculated and reported as an ex post facto measure of one important aspect of the "cost" of a treatment or instructional method. For example, Trask-Tyler, Grossi, and Heward (1994) reported the number of instructional trials needed by each of three students with visual impairments and developmental disabilities to prepare three recipes without assistance on two consecutive times over two sessions. Each recipe entailed from 10 to 21 task-analyzed steps.

Trials-to-criterion data are used frequently to compare the relative efficiency of two or more treatments or instructional methods. For example, by comparing the number of practice trials needed for a student to master weekly sets of spelling words practiced in two different ways, a teacher could determine whether the student learns spelling words more efficiently with one method than with another. Sometimes trials-to-criterion data are supplemented by information on the number of minutes of instruction needed to reach predetermined performance criteria (e.g., Holcombe, Wolery, Werts, & Hrenkevich 1993; Repp, Karsh, Johnson, & Van Laarhoven, 1994).

Trials-to-criterion measures can also be collected and analyzed as a dependent variable throughout a study. For example, R. Baer (1987) recorded and graphed trials-to-criterion on a paired-associates memory task as a dependent variable in a study assessing the effects of caffeine on the behavior of preschool children.

Trials-to-criterion data can also be useful for assessing a learner's increasing competence in acquiring a related class of concepts. For instance, teaching a concept such as the color red to a child could consist of presenting "red" and "not red" items to the child and differentially reinforcing correct responses. Trials-to-criterion data could consist of the number of "red" and "not red" exemplars required before the child achieves a specified level of performance with the discrimination. The same instructional and data collection procedures could then be used in teaching other colors to the child. Data showing that the child achieves mastery of each newly introduced color in fewer instructional trials than required to learn previous colors might be evidence of the child's increasing agility in learning color concepts.

Definitional Measures

In addition to the basic and derived dimensions already discussed, behavior can also be defined and measured by its form and intensity. Neither form (i.e., topography) nor intensity (i.e., magnitude) of responding is a fundamental dimensional quantity of behavior, but each is an important parameter for defining and verifying the occurrence of many response classes. Behavior analysts measure the topography or magnitude of a response to determine whether the response represents an occurrence of the target behavior. Occurrences of the target behavior verified on the basis of topography or magnitude are then measured by one or more aspects of count, temporal extent, or temporal locus. In other words, measuring topography or magnitude is sometimes necessary to determine whether instances of the targeted

response class have occurred, but the subsequent quantification of those responses is recorded, reported, and analyzed in terms of the fundamental and derivative measures of count, rate, duration, latency, IRT, percentage, and trials-to-criterion.

Topography

Topography, the physical form or shape of a behavior, is a measurable and malleable dimension of behavior. Topography is a measurable dimension of behavior because responses of varying form can be detected from one another. That topography is a malleable aspect of behavior is evidenced by the fact that responses of varying form are shaped and selected by their consequences.

A group of responses with widely different topographies may serve the same function (i.e., form a response class). For example, each of the different ways of writing the word *topography* shown in Figure 4.3 would produce the same effect on most readers. Membership in some response classes, however, is limited to responses within a narrow range of topographies. Although each of the response topographies in Figure 4.3 would meet the functional requirements of most written communications, none would meet the standards required of an advanced calligraphy student.

Topography is of obvious and primary importance in activities in which form, style, or artfulness of behavior is valued in its own right (e.g., painting, sculpting, dancing, gymnastics). Measuring and providing differential consequences for responses of varied topographies is also important when the functional outcomes of the behavior correlate highly with specific topographies. A student who sits with good posture and looks at the teacher is more likely to receive positive attention and opportunities to participate academically than is a student who slouches, with her head on the desk (Schwarz & Hawkins, 1970). Basketball players who execute foul shots with a certain form make a higher percentage of shots than when they shoot idiosyncratically (Kladopoulos & McComas, 2001; see Figure 6.3).

Trap, Milner-Davis, Joseph, and Cooper (1978) measured the topography of cursive handwriting by first-grade students. Plastic transparent overlays were used to detect deviations from model letters in lower- and uppercase letters written by the children (see Figure 4.4). The researchers counted the number of correct letter strokes—those that met all of the specified topographical criteria (e.g., all letter strokes contained within the 2-mm parameters of the overlay, connected, complete, sufficient length)—and used the percentage correct of all strokes

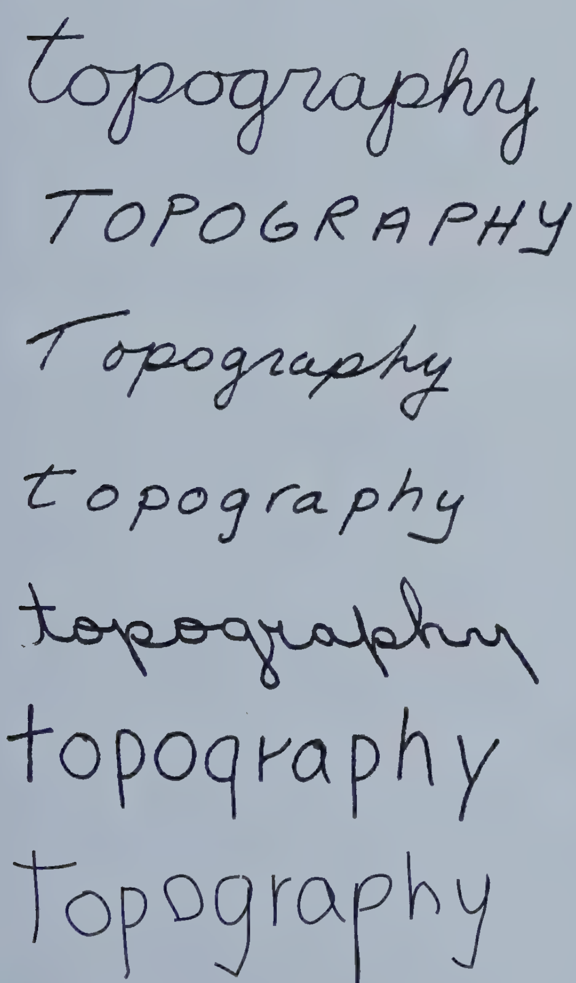

Figure 4.3 Topography, the physical form or shape of behavior, is a measurable dimension of behavior.

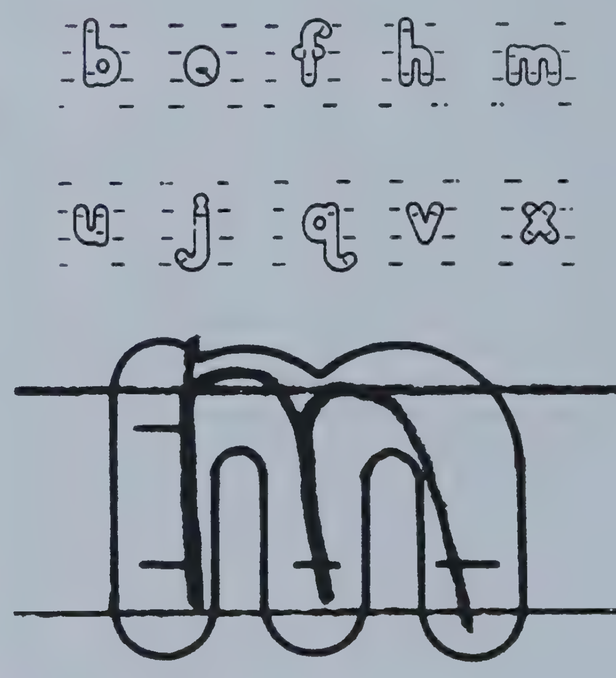

Figure 4.4 Examples of outlines on a transparent overlay used to measure inside and outside boundaries of manuscript letters and an illustration of using the transparent overlay to measure the letter *m*. Because the vertical stroke of the letter *m* extends beyond the outline boundary, it did not meet the topographical criteria for a correct response.

From "The Measurement of Manuscript Letter Strokes" by J. J. Helwig, J. C. Johns, J. E. Norman, J. O. Cooper, 1976. *Journal of Applied Behavior Analysis, 9*, p. 231. Copyright 1976 by the Society for the Experimental Analysis of Behavior, Inc. Used by permission.

written by each student to assess the effects of visual and verbal feedback and a certificate of achievement on the children's acquisition of cursive handwriting skills.

Magnitude

Magnitude refers to the force or intensity of a response. The desired outcomes of some behaviors are contingent on responding at or above (or below) a certain intensity or force. A screwdriver must be turned with sufficient force to insert or remove screws; a pencil must be applied to paper with enough force to leave legible marks. In contrast, applying too much torque to a misaligned screw or bolt is likely to strip the threads, and pushing too hard with a pencil will break its point.

Several studies have measured the magnitude of speech or other vocalizations that were considered too loud or too soft (Koegel & Frea, 1993). Schwarz and Hawkins (1970) measured the voice loudness of Karen, a sixth-grade girl who spoke so softly in class that her voice was usually inaudible to others. Karen's voice was recorded on videotape during two class periods each day. (The videotape was also used to obtain data on two other behaviors: face touching and the amount of time Karen sat in a slouched position). The researchers then played the videotape into an audiotape recorder with a loudness indicator and counted the number of times the needle went above a specified level on the loudness meter. Schwarz and Hawkins used the number (proportion) of needle inflections per 100 words spoken by Karen as the primary measure for evaluating the effects of an intervention on increasing her voice volume during class.

Edgerton and Wine (2017) used a digital tablet and app (Voice Meter Pro™) to measure the voice volume of a boy with autism who frequently spoke below conversational volume. The app displayed a thermometer gauge that rose and fell with the surrounding sound level and signaled changes in voice volume with different background colors, an animated figure, and text prompts ("Speak up, I can't hear you!", "That's better", and "That's too loud!"). The investigators calibrated the app to detect three levels of magnitude (too soft, conversational, and too loud) and recorded the number of times the boy's responses to questions were spoken at conversational volume.

Greene, Bailey, and Barber (1981) measured the magnitude of noisy disruptions by middle school students on a school bus with an automated sound-recording device. The recording device could be adjusted so that only sound levels above a predetermined threshold activated it. The device automatically recorded both the number of times outbursts of sound exceeded a specified threshold (93 dB) and the total duration in seconds that the sound remained above that threshold. When the noise level exceeded the specified threshold, a light on a panel that all students could see was activated automatically. When the light was off, students listened to music during the bus ride; when the number of noisy disruptions was below a criterion, they participated in a raffle for prizes. This intervention drastically reduced the outbursts and other problem behaviors as well. Greene and colleagues reported both the number and the mean duration per occurrence of noisy disruptions as measures of evaluating the intervention's effects.[6] Table 4.1 summarizes the measurable dimensions of behavior and considerations for their use.

METHODS FOR MEASURING BEHAVIOR

Methods for measuring behavior used most often by applied behavior analysts involve one or a combination of the following: event recording, timing, and various time sampling methods.

Event Recording

Event recording encompasses a wide variety of procedures for detecting and recording the number of times a behavior of interest occurs. For example, Cuvo, Lerch, Leurquin, Gaffaney, and Poppen (1998) used event recording to measure the effects of work requirements and reinforcement schedules on the choice behavior of adults with intellectual disabilities and preschool children while they were engaged in age-appropriate tasks (e.g., adults sorting silverware, children tossing beanbags or jumping hurdles). The researchers recorded each piece of silverware sorted, each beanbag tossed, and each hurdle jumped.

Event recording is also used to measure discrete trial behaviors, in which the count for each trial or opportunity to respond is either 1 or 0, representing the occurrence or nonoccurrence of the target behavior. Figure 4.5 shows a form used to record the occurrence of imitation responses by a preschooler with disabilities and his typically developing peer partner within a series of instructional trials embedded into ongoing classroom activities (Valk, 2003). For each trial, the observer recorded the occurrence of a correct response, no response, an approximation, or an inappropriate response by the target child and the peer by circling or marking a slash through letters representing each behavior. The form also allowed the observer to record whether the teacher prompted or praised the target child's imitative behavior.

Considerations for Event Recording. Many applied behavior analysts in practice use non-automated event recording. It is easy to do. Most people can tally discrete behaviors accurately, often on the first attempt. If the response rate is not too high, non-automated event recording may not interfere with other activities. For example, a teacher can continue with instruction while tallying occurrences of the target behavior. Event recording provides useful data for most behaviors. However, each instance of the target behavior must have discrete beginning and ending points. Event recording is applicable for target behaviors such as students' oral responses to questions, students' written answers to math problems, and a parent praising a son or daughter's behavior. Behaviors such as humming are hard to measure with event recording because an observer would have difficulty determining when one hum ends and another begins. Event recording is difficult for behaviors defined without specific discrete action or object relations, such as engagement with materials during free-play activity. Because engagement with materials does not present a specific discrete action or object relation, an observer may

TABLE 4.1 Fundamental, derived, and definitional dimensions by which behavior can be measured and described.

Fundamental measures	How calculated	Considerations
Count: The number of responses emitted.	Simple tally of the number of responses observed. • Judah contributed 5 comments to the class discussion.	• Used in calculating rate, celeration, percentage, and trials-to-criterion.
Rate: A ratio of count per observation time; often expressed as count per standard unit of time (e.g., per minute, per hour, per day).	Report number of responses recorded per unit of time in which observations were conducted. • If Judah's comments were counted during a 10-minute class discussion, his rate of responding would be 5 comments per 10 minutes. Often calculated by dividing the number of responses recorded by the number of standard units of time in which observations were conducted. • Judah commented at a rate of 0.5 per minute.	• Minimize faulty interpretations by reporting counting time. • Evaluating skill development and fluency requires measurement of correct and incorrect response rates. • Account for varied complexity and difficulty when calculating response rates. • Rate is the most sensitive measure of changes in repeatability. • Preferred measure for free operants. • Poor measure for behaviors that occur within discrete trials or for behaviors that occur for extended durations. • Most sensitive measure of behavior repeatability.
Celeration: The change (acceleration or deceleration) in rate of responding over time.	Based on count per unit of time (rate)/per unit of time expressed as the factor by which responding is accelerating/decelerating (multiplying or dividing). • A trend line connecting Judah's mean rates of commenting over 4 weeks of 0.1, 0.2, 0.4, and 0.8 comment per minute, respectively, would show an acceleration of ×2 per week.	• Reveals dynamic patterns of behavior change, such as transitions from one steady state to another and acquisition of fluency. • Displayed with a trend line on a Standard Celeration Chart (see Chapter 6). • Minimum of seven measures of rate recommended for calculating.
Duration: The amount of time from the onset to the end point of a response.	*Total duration:* Two methods: (a) Add the individual amounts of time for each response during an observation period; or (b) record the total time the individual is engaged in an activity, or needs to complete a task, without a minimum or maximum observation period. • Judah commented for 1.5 minutes in class today. *Duration per occurrence:* Record duration of time for each instance of the behavior; often reported by mean or median and range of durations per session. • Judah's 5 comments today had a mean duration of 11 seconds, with a range of 3 to 24 seconds.	• Important measure when target behavior is problematic because it occurs for durations that are too long or too short. • Useful measure for behaviors that occur at very high rates and for which accurate event recording is difficult (e.g., finger flicking). • Useful measure for behaviors that do not have discrete beginnings and for which event recording is difficult (e.g., humming). • Useful measure for task-oriented or continuous behaviors (e.g., cooperative play). • Duration per occurrence often preferred over total duration because it includes data on count and total duration.

(continued)

TABLE 4.1 (continued)

Fundamental measures	How calculated	Considerations
		• Use total duration when increasing the endurance of behavior is the goal. • Measuring duration per occurrence entails counting responses, which can be used to calculate rate of responding.
Latency: The elapsed time between the onset of stimulus and the initiation of a subsequent response.	Record time elapsed from the onset of the antecedent stimulus event and the beginning of the response; often reported by mean or median and range of latencies per session. • Judah's comments today had a mean latency of 30 seconds following a peers' comment (range, 5 to 90 seconds).	• Important measure when target behavior is a problem because it is emitted with latencies that are too long or too short. • Decreasing latencies may reveal increasing mastery of some skills.
Interresponse time (IRT): The amount of time that elapses between two consecutive instances of a response class.	Record time elapsed from the end of previous response and the beginning of next response; often reported by mean or median and range of IRTs per session. • Judah's comments today had a median IRT of 2 minutes and a range of 10 seconds to 5 minutes.	• Important measure when the time between responses, or pacing of behavior, is a concern. • Although a measure of temporal locus, IRT is correlated with rate of responding. • An important measure when implementing and evaluating DRL (see Chapter 23).

Derived measures	How calculated	Considerations
Percentage: A proportion, expressed as a number of parts per 100; typically a ratio of the number of responses of a certain type per total number of responses (or opportunities or intervals in which such a response could have occurred).	Divide number of responses meeting specified criteria (e.g., correct responses, responses with minimum IRT, responses of particular topography) by the total number of responses emitted (or response opportunities) and multiply by 100. • 70% of Judah's comments today were relevant to the discussion topic.	• Percentages based on divisors smaller than 20 are unduly influenced by small changes in behavior. Minimum of 30 observation intervals or response opportunities recommended for research. • Change in percentage may erroneously suggest improved performance. • Always report the divisor on which percentage measures are based. • Cannot be used to assess proficiency or fluency. • Imposes upper and lower limits on performance (i.e., cannot exceed 100% or fall below 0%). • Widely different percentages can be reported from the same data set.

TABLE 4.1 (continued)

Fundamental measures	How calculated	Considerations
		• To calculate an overall percentage from percentages based on different denominators (e.g., 90% [9/10], 87.5% [7/8], 33% [1/3], 100% [1/1], divide the total numerators of the component percentages (e.g., 18) by the total denominators (e.g., 18 / 22 = 81.8%). A mean of the percentages themselves yields a different outcome (e.g., 90% + 87.5% + 33% + 100% / 4 = 77.6%).
Trials-to-criterion: Number of responses, instructional trials, or practice opportunities needed to reach a predetermined performance criterion.	Add number of responses or practice trials necessary for learner to achieve specified criterion. • Judah needed 14 blocks of 10 opportunities to comment to achieve the criterion of 8 on-topic comments per 10 opportunities for 2 consecutive sessions.	• Provides an ex post facto description of the "cost" of a treatment or instructional method. • Useful for comparing relative efficiency of different methods of instruction or training. • Useful in assessing changes in the rate at which a learner masters new skills (agility).

Definitional measures	How calculated	Considerations
Topography: The form or shape of behavior.	Used to determine whether responses meet topographical criteria; responses meeting those criteria are measured and reported by one or more fundamental or derivative measures (e.g., percentage of responses meeting topographical criteria). • The plane of the golf club remained within plus or minus 2 degrees from backswing to follow-through on 85% of Amanda's swings.	• Important measure when desired outcomes of behavior are contingent on responses meeting certain topographies. • Important measure for performance areas in which form, style, or artfulness is valued.
Magnitude: The strength, intensity, or force of behavior.	Used to determine whether responses meet magnitude criteria; responses meeting those criteria are measured and reported by one or more fundamental or derivative measures (e.g., count of responses meeting magnitude criteria). • Jill bench pressed 60 pounds 20 times.	• Important measure when desired outcomes of behavior are contingent on responses within a certain range of magnitudes.

have difficulty judging when one engagement starts and ends, and then another engagement begins.

Another consideration with non-automated event recording is that the target behaviors should not occur at such high rates that an observer would have difficulty counting each discrete occurrence accurately. High-rate behaviors that may be difficult to measure with event recording include rapid talking, body rocks, and tapping objects.

Also, event recording does not produce accurate measures for target behaviors that occur for extended time periods, such as staying on task, listening, playing quietly alone, being out of one's seat, or thumb sucking. Task-oriented or continuous behaviors (e.g., being "on task") are examples of target behaviors for which event recording would not be indicated. Classes of continuous behaviors occurring across time are usually not a prime concern of applied behavior analysts. For example, reading per se is of less concern than the number of words read correctly and incorrectly, or the number of reading comprehension questions answered correctly and incorrectly. Similarly, behaviors that demonstrate understanding are more important to measure than "listening behavior," and the number of academic responses a student emits during an independent seatwork period is more important than being on task.

Timing

Behavior analysts use a variety of timing devices and procedures to measure duration, response latency, and IRT.

Timing Duration

Researchers often use semi-automated computer-driven systems for recording durations. Practitioners, however, will most likely use non-automated instruments for recording duration. The most precise non-automated instrument is a digital stopwatch. Practitioners can use wristwatches and wall clocks to measure duration, but the measures obtained will be less precise than those obtained with a stopwatch.

The procedure for recording the total duration of a target behavior per session with a stopwatch is to (a) activate the stopwatch when the behavior starts and (b) stop the watch at the end of the episode. Then, without resetting the stopwatch, the observer starts the stopwatch again at the beginning of the second occurrence of the behavior and stops the watch at the end of the second episode. The observer continues to accumulate the durations of time in this fashion until the end of the observation period, and then transfers the total duration of time showing on the stopwatch to a data sheet.

Timing Latency and IRT

Procedures for measuring latency and IRT are similar to those used to measure duration. Measuring latency requires the precise detection and recording of the time that elapses from the onset of each occurrence of the antecedent stimulus event of interest to the onset of the target behavior. Measuring IRTs requires recording the precise time that elapses from the termination of each occurrence of the target behavior to the onset of the next response.

Time Sampling

Time sampling refers to a variety of methods for observing and recording behavior during intervals or at specific moments in time. The basic procedure involves dividing the observation period into time intervals and then recording the presence or absence of behavior within or at the end of each interval.

Ethologists originally developed time sampling to study the behavior of animals in the field (Altmann, 1974). Because it was not possible or feasible to observe the animals continuously, these scientists arranged systematic schedules of relatively brief but frequent observation intervals. The measures obtained from these "samples" are considered representative of the behavior during the total time period from which they were collected. For example, much of our knowledge about the behavior of chimpanzees and other primates is based on data collected with time sampling observation methods by researchers such as Jane Goodall (1991).

Applied behavior analysts use three forms of time sampling—whole-interval recording, partial-interval recording, and momentary time sampling.[7]

Whole-Interval Recording

Whole-interval recording is often used to measure continuous behaviors (e.g., cooperative play) and behaviors that occur at such high rates that observers have difficulty distinguishing one response from another (e.g., rocking, humming) but can detect whether the behavior is occurring at any given time. The observation period for **whole-interval recording** is divided into a series of brief time intervals (e.g., 5 to 10 seconds). At the end of each interval, the observer records whether the target behavior occurred *throughout* the interval. Data obtained with whole-interval recording usually underestimate the overall percentage of the observation period in which the behavior actually occurred. The longer the observation intervals, the greater the degree to which whole-interval recording may underestimate the actual occurrence of the behavior.

Data collected with whole-interval recording are reported as the percentage of total intervals in which the target behavior was recorded as occurring. Because whole-interval recording represents the proportion of the entire observation period that the person was engaged in the target behavior, whole-interval recording data yield an estimate of total duration. For example, assume a whole-interval observation period consisted of six 10-second intervals (a 1-minute time frame). If the target behavior occurred for four of these 10-second whole intervals and did not occur for the remaining two intervals, the whole-interval recording would yield a total duration estimate of 40 seconds.

Figure 4.6 shows an example of a whole-interval recording form used to measure the on-task behavior of four students during academic seatwork time (Ludwig, 2004). Each minute was divided into four 10-second observation intervals; each observation interval was followed by 5 seconds in which the observer recorded the occurrence or nonoccurrence of target behavior during the preceding 10 seconds. The observer first watched Student 1 continuously for 10 seconds, and then she looked away during the next 5 seconds and recorded whether Student 1 had been on task throughout the previous 10 seconds by circling YES or NO on the recording form. After the 5-second interval for recording Student 1's behavior, the observer looked up and watched Student 2 continuously for 10 seconds, after which she recorded Student 2's behavior on the form. The same procedure for observing and recording was used for Students 3 and 4. In this way, the on-task behavior of each student was observed and recorded for one 10-second interval per minute.

Continuing the sequence of observation and recording intervals over a 30-minute observation period provided thirty 10-second measures (i.e., samples) of each student's on-task behavior. The data in Figure 4.6 show that the observer judged the four students to have been on task during Session 17 for 87%, 93%, 60%, and 73% of the intervals, respectively. Although the data are intended to represent the level of each student's behavior throughout the observation period, it is important to remember that each student was observed for a total of only 5 of the observation period's 30 minutes.

Observers using any form of time sampling should always make a recording response of some sort in every interval. For example, an observer using a form such as the one in Figure 4.6 would record the occurrence or nonoccurrence of the target behavior in each interval by circling YES or NO. Leaving unmarked intervals increases the likelihood of losing one's place on the recording form and marking the result of an observation in the wrong interval space.

All time sampling methods require a timing device to signal the beginning and end of each observation and recording interval. Observers using pencil, paper, clipboard, and timers for interval measurement will often attach a stopwatch to a clipboard. However, observing and recording behavior while having to look simultaneously at a stopwatch is likely to have a negative impact on the accuracy of measurement. As an effective solution to this problem, the observer can listen by earphone to prerecorded audio cues signaling the observation and recording intervals. For example, observers using a whole-interval recording procedure like the one just described could listen to an audio recording with a sequence of prerecorded statements such as the following: "Observe Student 1"; 10 seconds later, "Record Student 1"; 5 seconds later, "Observe Student 2"; 10 seconds later, "Record Student 2"; and so on.

Tactile prompting devices can also be used to signal observation intervals. For example, the *Gentle Reminder* (dan@gentlereminder.com) and *MotivAider* (www.habitchange.com) are small timing instruments that vibrate at the time intervals programmed by the user.

L. Ludwig, 2004, p. 101. Unpublished master's thesis, The Ohio State University. Used by permission.

Partial-Interval Recording

When using **partial-interval recording**, the observer records whether the behavior occurred *at any time* during the interval. Partial-interval time sampling is not concerned with how many times the behavior occurred during the interval or how long the behavior was present, just that it occurred at some point during the interval. If the target behavior occurs multiple times during the interval, it is still scored as occurring only once. An observer using partial-interval recording to measure a student's disruptive behavior would mark an interval if disruptive behavior of any form meeting the target behavior definition occurred for any amount of time during the interval. That is, an interval would be scored as disruptive behavior even if the student were disruptive for only 1 second of a 6-second interval. Because of this, data obtained with partial-interval recording often overestimate the overall percentage of the observation period (i.e., total duration) that the behavior actually occurred.

Partial-interval data, like whole-interval data, are most often reported as a percentage of total intervals in which the target behavior was scored. Partial-interval data are used to represent the proportion of the entire observation period in which the target behavior occurred, but the results of partial-interval recording, unlike those of whole-interval recording, do not provide any information on duration per occurrence. That is because any instance of the target behavior, regardless of how brief its duration, will cause an interval to be scored.

If the observer uses partial-interval recording with brief observation intervals to measure discrete responses of short duration per occurrence, the data obtained provide a crude estimate of the minimum rate of responding. For example, data showing that a behavior measured by partial-interval recording consisting of 6-second contiguous intervals (i.e., successive intervals are not separated by time in which the behavior is not observed) occurred in 50% of the total intervals indicate a minimum response rate of five responses per minute (on the average, at least one response occurred in 5 of the 10 intervals per minute). Although partial-interval recording often overestimates the total duration, it is likely to underestimate the rate of a high-count behavior. This is because an interval in which a person made eight nonverbal sounds would be scored the

same as an interval in which the person made only one sound. When the evaluation and understanding of a target behavior require a more sensitive measure than interval recording, use rate of response.

Because an observer using partial-interval recording needs to record only that a behavior has occurred at any point during each interval (compared to having to watch the behavior throughout the entire interval with whole-interval recording), it is possible to measure multiple behaviors concurrently. Figure 4.7 shows a portion of a form for measuring four response classes by three students, using partial-interval recording with 20-second intervals. The observer watches Student 1 throughout the first 20-second interval, Student 2 for the next 20 seconds, and Student 3 for the next 20 seconds. Each student is observed for 20 seconds out of each minute of the observation period. If a student engages in any of the behaviors being measured at any time during an observation interval, the observer marks the letter(s) corresponding to those behaviors. If a student engages in none of the behaviors being measured during an interval, the observer marks N to indicate no occurrences of the target behaviors. For example, during the first interval in which Student 1 was observed, he said, "Pacific Ocean" (an academic response). During the first interval in which Student 2 was observed, she left her seat and threw a pencil (a behavior within the response class "other disruptive behavior"). Student 3 emitted none of the four target behaviors during the first interval that he was observed.

Momentary Time Sampling

An observer using **momentary time sampling** records whether the target behavior occurred *at the moment* the time interval ends. If conducting momentary time sampling with 1-minute intervals, an observer would look at the person at the 1-minute mark of the observation period, determine immediately whether the target behavior was occurring, and indicate that decision on the recording form. One minute later (i.e., 2 minutes into the observation period), the observer would look again at the person and then score the presence or absence of the target behavior. This procedure would continue until the end of the observation period.

As with interval recording methods, data from momentary time sampling are typically reported as percentages of the total intervals in which the behavior occurred and are used to estimate the proportion of the total observation period that the behavior occurred.

A major advantage of momentary time sampling is that the observer does not have to attend continuously to measurement, whereas interval-recording methods demand the undivided attention of the observer.

Because the person is observed for only a brief moment, much behavior will be missed with momentary time sampling. Momentary time sampling is used primarily to measure continuous activity behaviors such as engagement with a task or activity, because such behaviors are easily identified. Momentary time sampling is not recommended for measuring low-count, short-duration behaviors.

Numerous studies have compared measures obtained by momentary time sampling and interval recording using intervals of varying duration with measures obtained by continuous duration recording (e.g., Alvero, Struss, & Rappaport, 2007; Gunter, Venn, Patrick, Miller, & Kelly, 2003; Hanley, Cammilleri, Tiger, & Ingvarsson, 2007; Meany-Daboul, Roscoe, Bourret, & Ahearn, 2007; Powell, Martindale, Kulp, Martindale, & Bauman, 1977; Saudargas & Zanolli 1990; Test & Heward, 1984). In general, this research has found that momentary time sampling both overestimates and underestimates continuous duration measures when intervals are greater than 2 minutes. With intervals up to 1 minute, the data obtained using momentary time sampling produce data paths similar to those of continuous duration recording.

Planned Activity Check

A variation of momentary time sampling, **planned activity check (PLACHECK)**, uses head counts to measure "group behavior." A teacher using PLACHECK observes a group of students at the end of each time interval, counts the number of students engaged in the targeted activity, and records the tally with the total number of students in the group. Doke and Risley (1972) used data obtained by PLACHECK measurement to compare group participation in required and optional

	1	2	3	4

Student 3	A T S D N	A T S D N	A T S D N	A T S D N

Key:
A = Academic response
T = Talk-out
S = Out-of-seat
D = Other disruptive behavior
N = No occurrences of target behaviors

Figure 4.7 Portion of a form used for partial-interval recording of four response classes by three students.

before-school activities. Observers tallied the number of students in either the required or the optional activity area at the end of 3-minute intervals, and then the number of children actually participating in an activity in either area. They reported these data as separate percentages of children participating in required or optional activities.

Dyer, Schwartz, and Luce (1984) used a variation of PLACHECK to measure the percentage of students with disabilities living in a residential facility who were engaged in age-appropriate and functional activities. As students entered the observation area, they were observed individually for as long as it took to determine the activity in which they were engaged. The students were observed in a predetermined order not exceeding 10 seconds per student.

In a study examining the effects of response cards on the disruptive behavior of third-graders during daily math lessons, Armendariz and Umbreit (1999) recorded at 1-minute intervals whether each student in the class was being disruptive. By combining the PLACHECK data obtained across all of the no-response cards (baseline) sessions, and graphing those results as the percentage of students who were disruptive at each 1-minute mark, and doing the same with the PLACHEK data from all response cards sessions, Armendariz and Umbreit created a clear and powerful picture of the differences in "group behavior" from the beginning to the end of a typical lesson in which response cards were or were not used.

Other variations of the PLACHECK measurement can be found in the literature, though they usually are called time sampling or momentary time sampling. For example, McKenzie and colleagues have developed two PLACHECK-type observational systems, SOPLAY and SOPARC, for measuring children's physical activity in school and community play environments (McKenzie & Cohen, 2006; McKenzie, Marshall, Sallis, & Conway, 2000). "SOPLAY and SOPARC use a group momentary time-sampling format (i.e., serial observation 'snapshots') to record the physical activity level (i.e., sedentary, walking/moderate, vigorous) in specific target areas. . . . Counting the number of people in an area is itself an important endeavor because it provides an indication of how well the space/facility supports school or community physical activity goals" (McKenzie, 2016, p. 335, 336).

Recognizing Discrepancies Among and Between Time Sampling Measures and Continuous Measurement

As stated previously, all time sampling methods provide only an estimate of the actual occurrence of the behavior. Different time sampling procedures produce different results, which can influence decisions and interpretations. A series of studies by Rapp and colleagues compared the sensitivity of momentary time sampling (MTS) and partial-interval recording (PIR) to detect small, moderate, and large behavior changes evident with continuous duration measures (Carroll, Rapp, Colby-Dirksen, & Lindenberg, 2009; Devine, Rapp, Testa, Henrickson, & Schnerch, 2011; Rapp, Colby-Dirksen, Michalski, Carroll, & Lindenberg, 2008). These researchers compared measures obtained by MTS and PIR of various interval sizes (10-sec, 20-sec, 30-sec, 1-min, and 2-min intervals) within varied observation periods (10-min, 30-min, and 60-min sessions) with data provided by continuous measurement (duration or event recording). Rapp et al. (2008) found that MTS with intervals up to 30 seconds reliably detected most moderate and large changes in duration events, that MTS with 1-minute intervals detected most large changes in duration events, and that PIR with 10-second or larger intervals failed to detect a large percentage of changes in duration events. Given longer observation sessions, momentary time sampling with interval sizes up to 30 sec detected a wide range of changes in both duration and rate events.

Devine and colleagues (2011) found that momentary time sampling with interval sizes up to 30 seconds detected a wide range of changes in duration and rate events during lengthier observation periods. These authors concluded that

> [P]ractitioners with limited resources may measure behavior changes with smaller interval sizes of PIR or MTS during shorter observation sessions or with a larger interval size of MTS during lengthier sessions with comparable sensitivity. For instance, 10-s MTS during 10-min sessions and 30-s MTS during 30-min sessions yielded comparable detection of changes in duration events. Similarly, both 10-s PIR during 10-min sessions and 30-s MTS during 30-min sessions were sensitive to changes in frequency events. In both cases, the number of observations required in the 10-min session is the same as the number of observations required in the 30-min session. (pp. 120–121)

Figure 4.8 illustrates just how different the results obtained by measuring the same behavior with different time sampling methods can be. The shaded bars indicate when the behavior was occurring within an observation period divided into 10 contiguous intervals. The shaded bars reveal the three-dimensional quantities of behavior: *repeatability* (seven instances of the behavior), *temporal extent* (the duration of each response) and *temporal locus* (IRT time is depicted by the space between the shaded bars).

Because the time sampling methods used in applied behavior analysis are most often viewed and interpreted as measures of the proportion of the total observation period in which the behavior occurred, it is important to compare the results of time sampling methods with those obtained by continuous measurement of duration. Continuous measurement reveals that the behavior depicted in Figure 4.8 occurred 55% of the time during the observation period. When the same behavior during the same observation period was recorded using whole-interval recordings, the measure obtained grossly underestimated the actual occurrence of the behavior (i.e., 30% versus 55%), partial-interval recording grossly overestimated the actual occurrence (i.e., 70% versus 55%), and momentary time sampling yielded a fairly close estimate of actual occurrence of the behavior (50% versus 55%).

Although momentary time sampling resulted in a measure that most closely approximated the actual behavior, it is not always the preferred method. Different distributions of the

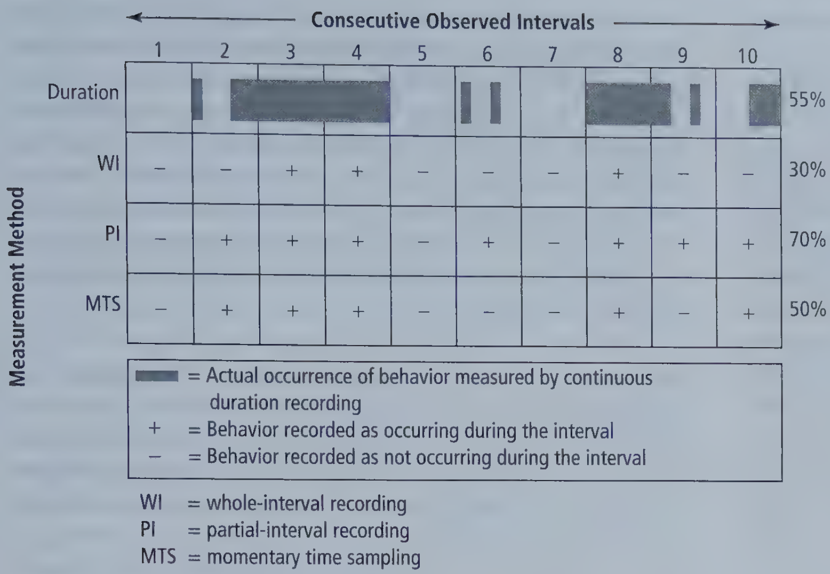

Figure 4.8 Comparing measures of the same behavior obtained by three different time sampling methods with measure obtained by continuous duration recording.

behavior (i.e., temporal locus) during the observation period, even at the same overall count and duration as the session shown in Figure 4.8, would result in widely different outcomes from each of the three time sampling methods.

Discrepancies between measures obtained by different measurement methods are usually described in terms of the relative accuracy or inaccuracy of each method. However, accuracy is not the issue here. If the shaded bars in Figure 4.8 represent the true value of the behavior, then each of the time sampling methods was conducted with complete accuracy and the resulting data are what should be obtained by applying each method. An example of the inaccurate use of one of the measurement methods would be if the observer using whole-interval recording had marked the behavior as occurring in Interval 2, when the behavior did not occur according to the rules of whole-interval recording.

But if the behavior actually occurred for 55% of the observation period, what should we call the wrong and misleading measures of 30% and 70% if not inaccurate? In this case, the misleading data are artifacts of the measurement methods used to obtain them. An **artifact** is a phenomenon that appears to exist because of the way it is examined or measured. The 30% measure obtained by whole-interval recording and the 70% measure obtained by partial-interval recording are artifacts of the way those measures were conducted. The fact that data obtained from whole-interval and partial-interval recording consistently underestimate and overestimate, respectively, actual occurrence of behavior as measured by continuous duration recording is an example of well-known artifacts.

It is clear that interval measurement and momentary time sampling result in some variability in the data analysis, which must be considered carefully when interpreting results obtained with these measurement methods. Some common causes of measurement artifacts and how to avoid them are discussed in Chapter 5.

MEASURING BEHAVIOR BY PERMANENT PRODUCTS

Behavior can be measured in real time by observing a person's actions and recording responses of interest as they occur. For example, a teacher can tally the number of times a student raises her hand during a class discussion. Some behaviors can be measured in real time by recording their effects on the environment as those effects are produced. For example, a baseball batting coach advances a handheld counter each time a batter hits a pitch to the right-field side of second base.

Some behaviors can be measured after they have occurred. A behavior that produces consistent effects on the environment can be measured after it has occurred if the effects, or products left behind by the behavior, remain unaltered until measurement is conducted. For example, if the flight of the baseballs hit by a batter during a practice session were not impeded, and the balls were left lying on the ground, a hitting instructor could collect data on the batter's performance after the batter's turn was completed by counting each ball found lying in fair territory on the right-field side of second base.

Measuring behavior after it has occurred by observing the effects the behavior produced on the environment is known as **measurement by permanent product**. A permanent product is a change in the environment produced by a behavior that lasts long enough for measurement to take place.

Although often described erroneously as a method for measuring behavior, measurement by permanent product does not refer to any particular measurement procedure or method. Instead, measurement by permanent product refers to the time of measurement (i.e., after the behavior has occurred) and the medium (i.e., the effect of the behavior, not the behavior itself) by which the measurer comes in contact with (i.e., observes) the behavior. All of the methods for measuring behavior described

in this chapter—event recording, timing, and time sampling—can be used to measure permanent products.

Permanent products can be natural or contrived outcomes of the behavior. Permanent products are natural and important outcomes of a wide range of socially significant behaviors in educational, vocational, domestic, and community environments. Examples in education include compositions written (Dorow & Boyle, 1998), computations of math problems written (Skinner, Fletcher, Wildmon, & Belfiore, 1996), spelling words written (McGuffin, Martz, & Heron, 1997), worksheets completed (Alber, Heward, & Hippler, 1999), homework assignments turned in (Alber, Nelson, & Brennan, 2002), and test questions answered (e.g., Gardner, Heward, & Grossi, 1994). Behaviors such as mopping floors and dishwashing (Grossi & Heward, 1998), incontinence (Adkins & Matthews, 1997), drawing bathroom graffiti (Mueller, Moore, Doggett, & Tingstrom, 2000), recycling (Brothers, Krantz, & McClannahan, 1994), stealing food (Maglieri, DeLeon, Rodriguez-Catter, & Sevin, 2000), and picking up litter (Powers, Osborne, & Anderson, 1973) can also be measured by the natural and important changes they make on the environment. Carbon monoxide (CO) levels in expired breath rise with increasing cigarette consumption and decline with abstention. Romanowich and Lamb's (2015) smoking abstinence study measured CO in exhaled breath as a permanent product measure. Participants took a deep breath, held it for 20 seconds, and then exhaled over 20 seconds into the mouthpiece of a Vitalograph™ CO monitor.

Many socially significant behaviors have no direct effects on the physical environment. Reading orally, sitting with good posture, and repetitive hand flapping leave no natural products in typical environments. Nevertheless, measurement of such behaviors can often be accomplished using contrived permanent products. For example, by audio recording students as they read out loud (Eckert, Ardoin, Daly, & Martens, 2002), video recording a girl sitting in class (Schwarz & Hawkins, 1970), and video recording a boy flapping his hands (Ahearn, Clark, Gardenier, Chung, & Dube, 2003), researchers obtained contrived permanent products for measuring these behaviors.

Contrived permanent products are sometimes useful in measuring behaviors that have natural permanent products that are only temporary. For example, Goetz and Baer (1973) measured variations in the form of children's block building from photographs taken of the constructions made by the children, and Twohig and Woods (2001) measured the length of fingernails from photographs of nail-biters' hands.

Advantages of Measuring Permanent Products

Frees Practitioner for Other Tasks. Not having to observe and record behavior as it occurs enables the practitioner to attend to other tasks during the observation period. For example, a teacher who audio records students' questions, comments, and talk-outs during a class discussion can concentrate on what her students are saying, provide individual help, and so on.

Enables Measurement of Some Behaviors That Occur at Inconvenient or Inaccessible Times and Places. Many socially significant behaviors occur at times and places that are inconvenient or inaccessible to the researcher or practitioner. Measuring permanent products is indicated when observing the target behavior as it occurs would be difficult because the behavior occurs infrequently, in various environments, or for extended periods. For example, a music teacher can have a guitar student make audio recordings of portions of daily practice sessions at home.

Measurement May Be More Accurate, Complete, and Continuous. Although measuring behavior as it occurs provides the most immediate access to data, it does not necessarily yield the most accurate, complete, and representative data. An observer measuring behavior from permanent products can take his time, rescore the worksheet, or listen to and watch the video recording again. Video recording enables the observer to slow down, pause, and repeat portions of the session—to literally "hold still" the behavior so it can be examined and measured repeatedly if necessary. The observer might see or hear additional nuances and aspects of the behavior, or other behaviors that he overlooked or missed altogether during live performances.

Video- or audio-recording behavior enables continuous measurement of all instances of a target behavior. Having this permanent product of all instances lends itself to later scoring by using the built-in calibrated digital timer (e.g., on a VCR or digital recorder), set to zero seconds (or the first frame) at the beginning of the session, to note the exact time of behavior onset and offset. Further, software programs facilitate data collection and analysis based on exact timings. PROCODER is a software system for facilitating the collection and analysis of video-recorded behavior. According to Miltenberger, Rapp, and Long (1999), "With a recording of the exact time of the onset and offset of the target behavior in the observation session, we are able to report the frequency (or rate) or the duration of the behavior" (p. 119).[8]

Measurement by permanent product enables data collection on more participants. An observer can view a video recording once and measure one participant's behavior, then replay the recording and measure a second participant's behavior.

Facilitates Data Collection for Interobserver Agreement and Treatment Integrity. Video- or audio recording assists with data collection tasks such as obtaining interobserver agreement data (see Chapter 5) and assessing treatment integrity (Chapter 10). Permanent products make possible the repeated measurement of behavior, eliminating the need to bring multiple observers into the research or treatment setting.

Enables Measurement of Complex Behaviors and Multiple Response Classes. Permanent products, especially video recordings of behavior, enable measurement of complex behaviors and

multiple response classes in busy social environments. Schwarz and Hawkins (1970) obtained measures of the posture, voice volume, and face touching of an elementary student from videotapes taken during two class periods. The three behaviors were targeted as the result of operationalizing the girl's "poor self-esteem." The researchers were able to view the tapes repeatedly and score them for different behaviors. In this study, the girl also watched and evaluated her behavior on the videotapes as part of the intervention.

Figure 4.9 shows an example of a recording form used by Silvestri (2004) to measure three types of statements by teachers—generic positive, specific positive, and negative—from audiotapes of classroom lessons. (See Figure 3.11 for definitions of these behaviors.) The movement, multiple voices, and general commotion that characterize any classroom would combine to make it very difficult, if not impossible, for a live observer to consistently detect and accurately record these behaviors. Each teacher participant in the study wore a small wireless microphone that transmitted a signal to a receiver connected to a cassette tape recorder.

Determining Whether Measurement by Permanent Product Is Appropriate

The advantages of measurement by permanent product are considerable, and it may seem as though permanent product measurement is always preferable to real-time measurement. Answering four questions will help practitioners and researchers determine whether measurement by permanent product is appropriate: Is real-time measurement needed? Can the behavior be measured by permanent product? Will obtaining a contrived permanent product unduly affect the behavior? How much will it cost?

Figure 4.9 Data collection form for recording count and temporal locus of three classes of teacher statements from video-recorded sessions.

From *The Effects of Self-Scoring on Teachers' Positive Statements During Classroom Instruction* by S. M. Silvestri (2004), p. 124. Unpublished doctoral dissertation, The Ohio State University. Used by permission.

Is Real-Time Measurement Needed?

A defining feature of applied behavior analysis and one of its major strengths is using data-based decisions concerning treatment procedures and experimental conditions. Data-based decision making requires more than direct and frequent measurement of behavior; it also requires ongoing and timely access to the data those measures provide. Measuring behavior as it occurs provides the most immediate access to the data. Although real-time measurement by permanent product can be conducted in some situations (e.g., counting each batted ball that lands to the right of second base as a hitter takes batting practice), measurement by permanent product will most often be conducted after the instructional or experimental session has ended.

Measures taken from video or audio recordings cannot be obtained until the recordings are viewed after a session has ended. If treatment decisions are made on a session-by-session basis, this behavior-to-measurement delay poses no problem as long as the data can be obtained from the recordings prior to the next session. However, when moment-to-moment treatment decisions must be made according to the participant's behavior during the session, real-time measurement is necessary. Consider a behavior analyst trying to reduce the rate of a person's self-injurious behavior (SIB) by providing access to a preferred stimulus contingent on increasing durations of time without SIB. Accurate implementation of the treatment protocol would require the real-time measurement of IRTs.

Can the Behavior Be Measured by Permanent Product?

Not all behaviors are suitable for measurement by permanent product. Some behaviors affect fairly permanent changes in the environment that are not reliable for the purposes of measurement. For example, SIB often produces long-lasting effects (bruises, welts, and even torn and bleeding skin) that could be measured after the occurrence of the behavior. But accurate measures of SIB could not be obtained by examining the client's body on a regular basis. The presence of discolored skin, abrasions, and other such marks would indicate that the person had been injured, but many important questions would be left unanswered. How many times did SIB occur? Were there acts of SIB that did not leave observable marks on the skin? Was each instance of tissue damage the result of SIB? These are important questions for evaluating the effects of any treatment. Yet, they could not be answered with certainty because these permanent products are not precise enough for the measurement of the SIB. Behaviors suitable for measurement with permanent product must meet two rules.

Rule 1: Each occurrence of the target behavior must produce the same permanent product. The permanent product must be a result of every instance of the behavior measured. All topographical variants of the target behavior and all responses of varying magnitude that meet the definition of target behavior must produce the same permanent product. Measuring an employee's work productivity by counting the number of correctly assembled widgets in his "completed work" bin conforms to this rule. An occurrence of the target behavior in this case is defined functionally as a correctly assembled widget. Measuring SIB by marks on the skin does not meet Rule 1 because some SIB responses will not leave discernible marks.

Rule 2: The permanent product can be produced only by the target behavior. This rule requires that the permanent product cannot result from (a) any behaviors by the participant other than the target behavior or (b) the behavior of any person other than the participant. Using the number of correctly assembled objects in the employee's "completed work" bin to measure his productivity conforms to Rule 2 *if* the observer can be assured that (a) the employee put no objects in his bin that he did not assemble and (b) none of the assembled objects in the employee's bin were put there by anyone other than the employee. Using marks on the skin as a permanent product for measuring self-injurious behavior also fails to meet Rule 2. Marks on the skin could be produced by other behaviors by the person (e.g., running too fast, which caused him to trip and hit his head; stepping in poison ivy) or by the behavior of other people (e.g., struck by another person).

Will Obtaining a Contrived Permanent Product Unduly Affect the Behavior?

Practitioners and researchers should always consider reactivity—the effects of the measurement procedure on the behavior being measured. Reactivity is most likely when observation and measurement procedures are obtrusive. Obtrusive measurement alters the environment, which may in turn affect the behavior being measured. Permanent products obtained using recording equipment, the presence of which may cause a person to behave differently, are called contrived permanent products. For example, recording conversations might encourage the participant to talk less or more. But it should be recognized that reactivity to the presence of human observers is a common phenomenon, and reactive effects are usually temporary (e.g., Haynes & Horn, 1982; Kazdin, 1982, 2001). Even so, it is appropriate to anticipate the influence that equipment may have on the target behavior.

How Much Will It Cost to Obtain and Measure the Permanent Product?

The final issues to address in determining the appropriateness of measuring a target behavior by permanent product are availability, cost, and effort. If recording equipment is required to obtain a contrived product of the behavior, is it currently available? If not, how much will it cost to buy or rent the equipment? How much time will it take to learn to use the equipment initially? How difficult and time-consuming will it be to set up, store, and use the equipment for the duration of the study or behavior change program?

MEASUREMENT TOOLS

Low-Tech

The low-tech measurement tools described here have a long history in applied behavior analysis. Researchers and practitioners will continue to use these "old school" tools described here because they are functional, easy to use, and inexpensive.

- *Pencil-and-paper data sheets.* Observers record occurrences and nonoccurrences of behavior on data sheets such as those shown in Figures 4.5, 4.6, 4.7, and 4.9.
- *Wrist counters.* Wrist counters are useful for tallying behavior. Most wrist counters record from 0 to 99 responses. These counters can be purchased from sporting goods stores or large department stores.
- *Hand-tally digital counters.* Similar to wrist counters, hand-tally digital counters are frequently used in grocery chain stores, cafeterias, military mess halls, and tollgates to tally the number of people served. These mechanical counters are available in single or multiple channels and fit comfortably in the palm of the hand. With practice, applied behavior analysts can operate the multiple-channel counters rapidly and reliably with just one hand. Digital counters can be obtained from office supply stores.
- *Abacus wrist and shoestring counters.* Landry and McGreevy (1984) described two types of abacus counters for measuring behavior. The abacus wrist counter is made from pipe cleaners and beads attached to a leather wristband to form an abacus with rows designated as ones and tens. An observer can tally from 1 to 99 occurrences of behavior by sliding the beads in abacus fashion. Responses are tallied in the same way on an abacus shoestring counter except the beads slide on shoestrings attached to a key ring, which is attached to the observer's belt, belt loop, or some other piece of clothing, such as a buttonhole.
- *Masking tape.* Practitioners tally behavioral events on strips of masking tape attached to their wrists, clothing, or desk.
- *Pennies, buttons, paper clips.* Observer moves one item from one pocket to another each time the target behavior occurs.

High-Tech

Automated measurement of subjects' responses has been standard practice in the experimental analysis of behavior (EAB) since Skinner's invention of the cumulative recorder (Lattal, 2004; Sakagami & Lattal 2016). In today's EAB laboratory, the electro-mechanical cumulative recorder has been replaced by computer-based measurement. Researchers can program sophisticated hardware and software systems to continuously measure rate, duration, latency, IRTs, and/or magnitude on multiple response classes throughout experimental sessions.

Computer-assisted measurement and data analysis tools have become increasingly sophisticated and useful for applied behavior analysts. Developers have produced data collection and analysis software for observational measurement using laptops (Bullock, Fisher, & Hagopian, 2017), mobile devices such as tablets and smartphones (Operant Systems Inc, 2017), personal digital assistants (PDAs) (Fogel, Miltenberger, Graves, & Koehler, 2010), and wearables that automatically record movement such as steps taken and distance traveled (Hayes & Van Camp, 2015; Valbuena, Miltenberger, & Solley, 2015).

Practitioners using apps designed for data collection during treatment sessions tap icons on a touchscreen representing response classes, prompt levels, and consequences (e.g., Richard, Taylor, DeQuinzio, & Katz, 2010; Sleeper et al., 2017). At session's end, practitioners can add notes and tap an icon to produce graphs immediately available for inspection.

Developments in microchip technology have advanced the measurement and data analysis capabilities of these systems, and have made the software increasingly easier to learn and apply. Observers using some of these computerized tools can record multiple frequency- and duration-based behaviors, including discrete trials, the number of responses per unit of time, duration, latency, interresponse time (IRT), and fixed and variable intervals for time sampling measurement. These systems can present data calculated as rate, duration, latency, IRT, percentage of intervals, percentage of trials, and conditional probabilities (e.g., BDataPro [Bullock, Fisher, and Hagopian, 2017]; MOOSES [Tapp, Wehby, & Ellis, 1995]; BEST—Behavioral Evaluation Strategy and Taxonomy—Sidenar, Shabani, & Carr, 2004).[9]

Computer-based (automated) observation and measurement systems have distinct advantages over non-automated measurement when working with aggregates of rates of response, time-series analyses, conditional probabilities, sequential dependencies, interrelationships, and combinations of events. Automated measurement facilitates the clustering and analyzing of complex data sets. Because these systems allow for the simultaneous recording of multiple behaviors across multiple dimensions, outputs can be examined and analyzed from perspectives that would be difficult and time-consuming with paper-and-pencil methods.

In addition to recording and calculating data, some systems produce graphs (e.g., Sleeper et al., 2017) and analyses of interobserver agreement (IOA) (e.g., smaller/larger, overall, occurrence, nonoccurrence) and measurement from audio and video documents. The automated computer-driven systems, as compared to the commonly used paper-and-pencil data-recording and analysis methods, have the potential to improve IRAs, the reliability of observational measurements, and the efficiency of data calculation (Kahng & Iwata, 1998). Automated measurement has the capacity to eliminate many human observer errors (e.g., observer drift, expectancy bias).

We believe continued advances in digital measurement tools will further enrich research and practice in applied behavior analysis. Some cautions, however, are associated with automated measurement of behavior. The equipment must be monitored because machines can break, and programmers can make mistakes. Kahng, Ingvarsson, Quigg, Seckinger, and Teichman (2011) caution applied behavior analysts' use of automated measurement. "Computer programs of this kind should be used only if they provide improvements in data collection that are of sufficient importance considering the behavior of interest and the ultimate goals of data collection." (p. 117).

SELECTING A MEASUREMENT METHOD

Although it may go without saying that the measurement method must fit the target behavior dimension one wants to measure (e.g., event recording for rate, timing for duration and latency), selecting the most appropriate measurement method for a given situation is hardly as simple as that. Researchers and practitioners must also consider the behavior change goals and expected direction of behavior change, the relative ease of detecting occurrences of the behavior, the environments where and times when the behavior will be measured, and the availability and skills of personnel who will observe and record the

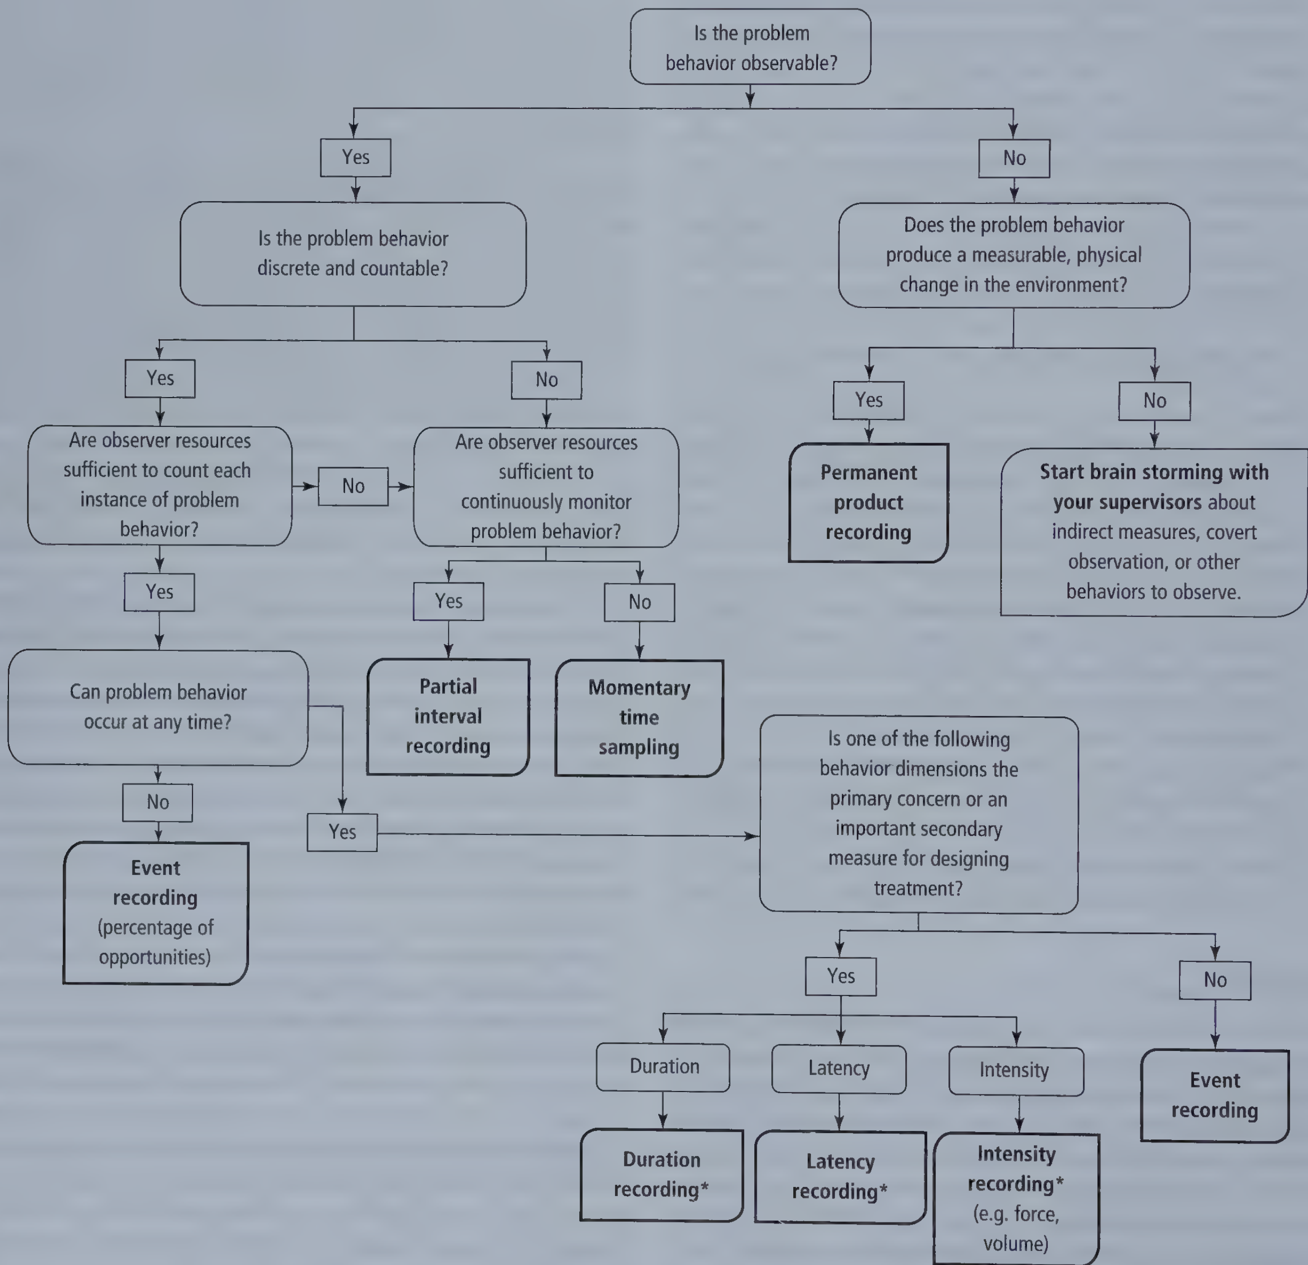

Figure 4.10 Decision-making model for selecting measurement procedures for problem behavior. *Note*: Asterisks denote measurement procedures that also generate count data.

From "A Proposed Model for Selecting Measurement Procedures for the Assessment and Treatment of Problem Behavior" by L. A. LeBlanc, P. B. Raetz, T. P. Sellers, and J. E. Carr, 2016, *Behavior Analysis in Practice*, 9(1), p. 79. Copyright 2016 by the Association for Behavior Analysis International. Used by permission.

behavior (Fiske & Delmolino, 2012; Gast 2014; LeBlanc, Raetz, Sellers, & Carr, 2016). We believe the decision-making model selecting measurement methods proposed by LeBlanc and colleagues (2016) provides useful guidance to practitioners (see Figure 4.10).

Practitioners should balance the resources required to observe and measure the target behavior with the planned uses of the data. The old adage "Just because you can, doesn't mean you should" can be a useful guide when designing behavioral measurement systems. Recording every response emitted by a client and every therapist-delivered prompt and consequence is not always necessary (Lerman, Dittlinger, Fentress, & Lanagan, 2011; Najdowski et al., 2009). Collect the type and number of behavioral measures needed to make timely, data-based decisions about treatment effects. Measurement that does not provide a decision maker with close, continuous contact with relevant outcome data may be superfluous (cf. Bushell & Baer, 1994).

Additional considerations and issues with respect to designing behavioral measurement systems are discussed in Chapter 5.

SUMMARY

Definition and Functions of Measurement in Applied Behavior Analysis

1. Measurement is the process of applying quantitative labels to observed properties of events using a standard set of rules.
2. Measurement is how scientists operationalize empiricism.
3. Without measurement, all three levels of scientific knowledge—description, prediction, and control—would be relegated to guesswork and subjective opinions.
4. Applied behavior analysts measure behavior to obtain answers to questions about the existence and nature of functional relations between socially significant behavior and environmental variables.
5. Practitioners measure behavior before and after treatment to evaluate the overall effects of interventions (summative evaluation) and frequent measures of behavior during treatment (formative assessment) to guide decisions concerning the continuation, modification, or termination of treatment.
6. Without frequent measures of the behavior targeted for intervention, practitioners may (a) continue an ineffective treatment when no real behavior change occurred or (b) discontinue an effective treatment because subjective judgment detects no improvement.
7. Measurement also helps practitioners optimize their effectiveness; verify the legitimacy of practices touted as "evidence based"; identify treatments based on pseudoscience, fad, fashion, or ideology; be accountable to clients, consumers, employers, and society; and achieve ethical standards.

Measurable Dimensions of Behavior

8. Because behavior occurs within and across time, it has three dimensional quantities: repeatability (i.e., count), temporal extent (i.e., duration), and temporal locus (i.e., when behavior occurs). These properties, alone and in combination, provide the basic and derivative measures used by applied behavior analysts.
9. Count is a simple tally of the number of occurrences of a behavior.
10. Rate is a ratio of count per observation period; it is expressed as count per standard unit of time.
11. Celeration is a measure of the change (acceleration or deceleration) in rate of responding per unit of time.
12. Duration is the amount of time from the onset to the end point of a behavior.
13. Response latency is a measure of the elapsed time between the onset of a stimulus and the initiation of a subsequent response.
14. Interresponse time (IRT) is the amount of time that elapses between two consecutive instances of a response class.
15. Percentage, a ratio formed by combining the same dimensional quantities, expresses the proportional quantity of an event in terms of the number of times the event occurred per 100 opportunities that the event could have occurred.
16. Trials-to-criterion is a measure of the number of response opportunities needed to achieve a predetermined level of performance.
17. Although form (i.e., topography) and intensity of responding (i.e., magnitude) are not fundamental dimensional quantities of behavior, they are important quantitative parameters for defining and verifying the occurrence of many response classes.
18. Topography refers to the physical form or shape of a behavior.
19. Magnitude refers to the force or intensity with which a response is emitted.

Methods for Measuring Behavior

20. Event recording encompasses a wide variety of procedures for detecting and recording the number of times a behavior of interest is observed.

21. Time sampling refers to a variety of methods for observing and recording behavior during intervals or at specific moments in time.

22. Observers using whole-interval recording divide the observation period into a series of equal time intervals. At the end of each interval, they record whether the target behavior occurred throughout the entire interval.

23. Observers using partial-interval recording divide the observation period into a series of equal time intervals. At the end of each interval, they record whether behavior occurred at any point during the interval.

24. Observers using momentary time sampling divide the observation period into a series of time intervals. At the end of each interval, they record whether the target behavior is occurring at that specific moment.

25. Planned activity check (PLACHECK) is a variation of momentary time sampling in which the observer records whether each individual in a group is engaged in the target behavior.

Measuring Behavior by Permanent Products

26. Measuring behavior after it has occurred by measuring its effects on the environment is known as measurement by permanent product.

27. Measurement of many behaviors can be accomplished with contrived permanent products.

28. Measurement by permanent product offers numerous advantages: The practitioner is free to do other tasks; it enables the measurement of behaviors that occur at inconvenient or inaccessible times and places; measurement may be more accurate, complete, and continuous; it facilitates the collection of interobserver agreement and treatment integrity data; and it enables the measurement of complex behaviors and multiple response classes.

29. If moment-to-moment treatment decisions must be made during the session, measurement by permanent product may not be warranted.

30. Behaviors suitable for measurement with permanent products must meet two rules. Rule 1: Each occurrence of the target behavior must produce the same permanent product. Rule 2: The permanent product can be produced only by the target behavior.

Measurement Tools

31. Low tech tools are functional, easy to use, inexpensive, and effective for research, education, and treatment.

32. High-tech, digital and computer hardware and software systems for behavioral measurement and data analysis have become increasingly sophisticated and easier to use.

33. Developers have produced data collection and analysis software for observational measurement using laptops, handheld computers, personal digital assistants (PDAs), and desktop computers. These measurement tools provide the researcher and practitioner with advantages of practical value, efficiency, and ease of use.

Selecting a Measurement Method

34. When selecting a measurement method, consider the behavior change goals and expected direction of behavior change, the relative ease of detecting occurrences of the behavior, the environments where and times when the behavior will be measured, and the availability and skills of personnel who will observe and record the behavior.

KEY TERMS

artifact
celeration
count
discrete trial
duration
event recording
free operant
frequency
interresponse time (IRT)
latency
magnitude
measurement
measurement by permanent product
momentary time sampling
partial-interval recording
percentage
planned activity check (PLACHECK)
rate
repeatability
temporal extent
temporal locus
time sampling
topography
trials-to-criterion
whole-interval recording

MULTIPLE-CHOICE QUESTIONS

1. In order to be understood by everyone, measurement units must be:
   a. Analytic
   b. Subjective
   c. Labeled
   d. Unambiguous
   Hint: (See "Definition and Functions of Measurement in Applied Behavior Analysis")

2. Practitioners need measurement in order to do all of the following except
   a. Operationalize empiricism
   b. Identify current behavior levels
   c. Evaluate treatment
   d. Make accurate decisions
   Hint: (See "Definition and Functions of Measurement in Applied Behavior Analysis")

3. The dimensional quantity of duration is described as:
   a. Temporal locus
   b. Repeatability
   c. Temporal extent
   d. Count
   Hint: (See "Measurable Dimensions of Behavior")

4. _________ is obtained by combining observation time with a tally of the number of occurrences of behavior.
   a. Response latency
   b. Rate
   c. Celeration
   d. Whole interval
   Hint: (See "Measurable Dimensions of Behavior")

5. All of the following are procedures for measuring behavior except
   a. Event recording
   b. Timing
   c. Time sampling
   d. Observation
   Hint: (See "Measurement Tools")

6. Devices such as wrist counters, masking tape, buttons, and calculators are all useful when using ________ recording procedures.
   a. Event
   b. Timing
   c. Rate
   d. Duration
   Hint: (See "Measurement Tools")

7. The procedure that measures behavior after it has occurred by measuring its effect on the environment is called:
   a. Measurement artifact
   b. Planned activity check
   c. Permanent product
   d. Time sampling
   Hint: (See "Measuring Behavior by Permanent Products")

8. Which of the following is a reason not to use permanent product measurement?
   a. Moment-to-moment decisions must be made
   b. The behavior has a direct effect on the environment
   c. The product can only be produced by the target behavior
   d. Each behavior occurrence results in the same product
   Hint: (See "Measuring Behavior by Permanent Products")

9. One advantage of using computer-based observation and measurement systems is
   a. Many practitioners are familiar with it
   b. Data can be clustered and analyzed easily
   c. It is less expensive
   d. It is less intrusive than traditional methods
   Hint: (See "Measurement Tools")

10. Computer-assisted measurement of behavior allows the observer to do all of the following except:
    a. Collect permanent products
    b. Record multiple behaviors simultaneously
    c. Aggregate data easily
    d. Analyze data from different perspectives
    Hint: (See "Measurement Tools")

11. You are preparing to observe Jennifer, a second-grade student who has difficulty following teacher direction and frequently wanders around the classroom. The target behavior for Jennifer is being out of her seat. What is the most appropriate method for measuring this target behavior?
    a. Event recording
    b. Interresponse time
    c. Duration
    d. Planned activity check
    Hint: (See "Measurement Tools")

12. Marco is learning to assemble computer components as part of his new job at a factory. Speed and accuracy are critical skills for him to learn in assembling his component. What is the most appropriate method for measuring his behavior?
    a. Whole interval recording
    b. Duration
    c. Permanent product
    d. Response latency
    Hint: (See "Measurement Tools")

ESSAY-TYPE QUESTIONS

1. Describe one of the functions of measurement for practitioners of applied behavior analysis.

   Hint: (See "Definition and Functions of Measurement in Applied Behavior Analysis")

2. Define the three fundamental dimensional qualities of behavior.

   Hint: (See "Measurable Dimensions of Behavior")

3. Describe a one-time sampling procedure for measuring behavior and the appropriate conditions for using that procedure.

   Hint: (See "Measurement Tools")

4. Describe three advantages of measuring behavior by permanent product.

   Hint: (See "Measuring Behavior by Permanent Products")

5. Give two reasons for the increasing popularity of computer-assisted measurement systems.

   Hint: (See "Measurement Tools")

6. John, a fourth-grade teacher, wants to collect data on task completion for seven of his students. John has 34 students and does not have access to an aide or teaching assistant. Identify the most appropriate recording procedure for John to use and explain why it is the best choice.

   Hint: (See "Measurement Tools")

NOTES

1. Measurement is necessary but not sufficient for scientific understanding. (See Chapter 7.)
2. Noting that **frequency** has been used in the behavior analysis literature to refer to both count and rate, a practice that may cause confusion and misunderstanding, Merbitz, Merbitz, and Pennypacker (2016) made a case for limiting the use of frequency to mean rate. Carr, Nosik, and Luke (2018) surveyed the usage of *frequency* in contemporary behavior-analytic journals and textbooks and found that "the predominant usage of *frequency* was as *count*, not *rate*" (p. 436). Carr et al. encouraged behavior analysts to use *frequency* as a synonym for *count*.
3. *Latency* is most often used to describe the time between the onset of an antecedent stimulus change and the initiation of a response. However, the term can be used to refer to any measure of the temporal locus of a response with respect to any type of antecedent event. See Johnston and Pennypacker (2009).
4. Because percentages are ratios based on the same dimensional quantity, the dimensional quantity is canceled out and no longer exists in the percentage. For example, an accuracy percentage created by dividing the number of correct responses by the number of response opportunities removes the actual count. However, ratios created from different dimensional quantities retain the dimensional quantities of each component. For example, rate retains a count per unit of time. See Johnston and Pennypacker (2009) for further explication.
5. When a person reports a percentage in excess of 100% (e.g., "Our mutual fund grew by 120% during the recent bear market"), he is probably using the misstated percentage in *comparison to* the previous base unit, not as a proportion of it. In this example, the mutual fund's 20% increase makes its value 1.2 times greater than its value when the bear market began.
6. Researchers sometimes manipulate and control response topography and magnitude to assess their possible effects as independent variables. Piazza, Roane, Kenney, Boney, and Abt (2002) analyzed the effects of different response topographies on the occurrence of pica (e.g., ingesting nonnutritive matter that may threaten one's life) by three females. Pica items were located in various places, which required the subjects to respond in different ways (e.g., reach, bend over, get on the floor, open a container) to obtain them. Pica decreased when more elaborate response topographies were required to obtain pica items. Van Houten (1993) reported that when a boy with a long history of intense and high occurrences of face slapping wore 1.5-pound wrist weights, face slapping immediately dropped to zero. Studies such as these suggest that problem behaviors may be reduced when engaging in those behaviors requires more effortful responses in terms of topography or magnitude (Friman & Poling, 1995).
7. A variety of terms appear in the applied behavior analysis literature to describe measurement procedures that involve observing and recording behavior within or at the end of specified intervals. Some authors use *time sampling* to refer only to momentary time sampling. We consider whole-interval and partial-interval recording as time sampling methods because the data they produce provide a representative "sample" of the target behavior during the observation period.
8. Edwards and Christophersen (1993) described a time-lapse videotape recorder (TLVCR) that automatically records on one 2-hour tape time samples of behavior over observation periods ranging from 2 to 400 hours. A TLVCR programmed to record over a 12-hour period would record for 0.10 of each second. Such a system can be useful for recoding very low rate behaviors and for behaviors that occur over long periods (e.g., a child's sleep behavior).
9. Descriptions of a variety of computer-assisted behavioral measurement systems can be found in Bullock, Fisher, and Hagopian (2001); Emerson, Reever, and Felce (2000); Gravlee, Zenk, Woods, Rowe, and Schultz (2006); Kahng & Iwata (1998, 2000); Noldus, Trienes, Hendriksen, and Jansen (2000); Sidenar, Shabani, and Carr (2004); Tapp & Walden (2000); and Tapp and Wehby (2000).

CHAPTER 5

Improving and Assessing the Quality of Behavioral Measurement

LEARNING OBJECTIVES

- State and describe the elements of useful scientific measurement.
- Identify threats to measurement validity.
- Describe various threats to the accuracy and reliability of measurement.
- Identify and explain ways to assess the accuracy and reliability of behavioral measurement.
- Identify and explain how to assess interobserver agreement (IOA) for a variety of data sets.

Three friends—John, Tim, and Bill—took a bicycle ride together. At the end of the ride John looked at his handlebar-mounted bike computer and said, "We rode 68 miles. Excellent!" "My computer shows 67.5 miles. Good ride, fellas!" Tim replied. As he dismounted and rubbed his rump, the third biker, Bill, said, "Gee whiz, I'm sore! We must've ridden 100 miles!" A few days later, the three friends completed the same route. After the second ride, John's computer showed 68 miles, Tim's computer read 70 miles, and Bill, because he wasn't quite as sore as he was after the first ride, said they had ridden 90 miles. Following a third ride on the same country roads, John, Tim, and Bill reported distances of 68, 65, and 80 miles, respectively.

The data obtained by measuring behavior are the primary material with which behavioral researchers and practitioners guide and evaluate their work. Applied behavior analysts measure socially significant behaviors to help determine which behaviors need to be changed, to detect and compare the effects of various interventions on behaviors targeted for change, and to evaluate the acquisition, maintenance, and generalization of behavior changes.

Because so much of what the behavior analyst does either as a researcher or as a practitioner depends on measurement, concerns about the legitimacy of the data it produces must be paramount. Do the data meaningfully reflect the original reason(s) for measuring the behavior? Do the data represent the true extent of the behavior as it actually occurred? Do the data provide a consistent picture of the behavior? In other words, can the data be trusted?

Chapter 4 identified the measurable dimensions of behavior and described the measurement methods most often used in applied behavior analysis. This chapter focuses on improving and assessing the quality of behavioral measurement. We begin by defining the essential indicators of trustworthy measurement: validity, accuracy, and reliability. Next, common threats to measurement are identified and suggestions for combating these threats are presented. The chapter's final sections detail procedures for assessing the accuracy, reliability, and believability of behavioral measurement.

INDICATORS OF TRUSTWORTHY MEASUREMENT

How trustworthy were the measures reported by the three bicyclists in the opening anecdote? Which of the three friends' data would contribute to a scientific account of the miles they had ridden? To contribute to a scientific account of events, measurement must be valid, accurate, and reliable. Were the three friends' measurements characterized by validity, accuracy, and reliability?

Validity

Measurement has **validity** when it yields data directly relevant to the phenomenon measured and to the reason(s) for measuring it. Determining the validity of measurement revolves around this basic question: Was a relevant dimension of the behavior that is the focus of the investigation measured directly and legitimately?

Did the measurements of miles ridden by the three bicyclists have validity? Because the bikers wanted to know how far they had ridden each time, number of miles ridden was a relevant, or valid, dimension of their riding behavior. Had the bikers' primary interest been how long or how fast they had ridden, the number of miles ridden would not have been a valid measure. John and Tim's use of their bike computers to measure directly the miles they rode was a valid measure. Because Bill used an indirect measure (the relative tenderness of his backside)

to determine the number of miles he had ridden, the validity of Bill's mileage data is suspect. A direct measure of the actual behavior of interest will always possess more validity than an indirect measure, because a direct measure does not require an inference about its relation to the behavior of interest, whereas an indirect measure always requires such an inference. Although soreness may be related to the distance ridden, because it is also influenced by such factors as the time on the bike saddle, the roughness of the road, riding speed, and how much (or little) a person has ridden recently, soreness as a measure of mileage has little validity.

Valid measurement in applied behavior analysis requires three equally important elements: (a) measuring directly a socially significant target behavior (see Chapter 3), (b) measuring a dimension (e.g., rate, duration) of the target behavior relevant to the question or concern about the behavior (see Chapter 4), and (c) ensuring that the data are representative of the behavior's occurrence under conditions and during times that are most relevant to the question or concern about the behavior. When any of these elements are suspect or lacking—no matter how accurate and reliable was the measurement that produced the data—the validity of the resultant data is compromised, perhaps to the point of being meaninglessness.

Accuracy

When used in the context of measurement, **accuracy** refers to the extent to which the **observed value** (i.e., the quantitative labels produced by measuring an event) match the true value of the event. In other words, measurement is accurate to the degree that it corresponds to the true value of the thing measured. Obtaining a **true value** requires special observation and recording procedures that "must be at least somewhat different from those used to produce the data being evaluated, and the differences must have the effect of minimizing the possibility of error to an uncommon degree" (Johnston & Pennypacker, 2009, pp. 136–137).

How accurate were the three bikers' measures of miles ridden? Because each biker reported a different measure of the same event, all of their data could not be accurate. Skeptical of the training miles the three cyclists were claiming, a friend of theirs, Lee, drove the same country roads with GPS-calibrated odomenter in his car. At the end of the route, the odometer read 58 miles. Using the measure obtained by the odometer as the true value of the route's distance, Lee determined that none of the three cyclists' measures was accurate. Each rider had overestimated the true mileage.

By comparing the mileage reported by John, Tim, and Bill with the true value of the route's distance, Lee discovered not only that the riders' data were inaccurate but also that the data reported by all three riders were contaminated by a particular type of measurement error called measurement bias. **Measurement bias** refers to nonrandom measurement error—that an error in measurement that is likely to be in one direction. Random measurement error is just as likely to overestimate the true value of an event as it is to underestimate it. Because John, Tim, and Bill consistently overestimated the actual miles they had ridden, their data contained measurement bias.

Reliability

Reliability refers to the consistency of measurement, specifically, the extent to which repeated measurement of the same event yields the same value. In other words, reliable measurement is consistent measurement. Like validity and accuracy, reliability is a relative concept; it is a matter of degree. The closer the values obtained by repeated measurement of the same event are to one another, the greater the reliability. Conversely, the more observed values from repeated measurement of the same event differ from one another, the less the reliability.

How reliable were the bicyclists' measurements? Because John obtained the same value, 68 miles, each time he measured the same route, his measurement had complete reliability. Tim's three measures of the same ride—67.5, 70, and 65 miles—differed from one another by as much as 5 miles. Therefore, Tim's measurement was less reliable than John's. Bill's measurement system was the least reliable of all, yielding values for the same route ranging from 80 to 100 miles.

Relative Importance of Validity, Accuracy, and Reliability

Behavioral measurement should provide legitimate data for evaluating behavior change and guiding research and treatment decisions. Data of the highest quality (i.e., data that are most useful and trustworthy for advancing scientific knowledge or for guiding practice) are produced by valid, accurate, and reliable measurement (see Figure 5.1). Validity, accuracy, and reliability are relative concepts; each can range from high to low.

Measurement must be both valid and accurate for the data to be trustworthy. If measurement is not valid, accuracy is moot. Accurately measuring a behavior that is not the focus of the investigation, accurately measuring an irrelevant dimension of the target behavior, or accurately measuring the behavior under circumstances or at times not representative of the conditions and times relevant to the analysis will yield invalid data. Conversely, the data obtained from measuring a meaningful dimension of the right behavior under the relevant circumstances and times are of little use if the observed values provide an inaccurate picture of the behavior. Inaccurate measurement renders invalid the data obtained by otherwise valid measurement.

Reliability should never be confused with accuracy. Although John's bicycle computer provided totally reliable measures, it was also totally inaccurate. Concern about the reliability of data in the absence of a prior interest in their accuracy suggests that reliability is being mistaken for accuracy. The question for a researcher or someone who is reading a published study is not "Are the data reliable?" but "Are the data accurate?" (Johnston & Pennypacker, 1993a, p. 146)

If accuracy trumps reliability—and it does—why should researchers and practitioners be concerned with the reliability of measurement? Although high reliability does not mean high accuracy, poor reliability reveals problems with accuracy. Because Tim and Bill's measurements were not reliable, we know that at least some of the data they reported could not be

Figure 5.1 Valid, accurate, and reliable measurement yields the most trustworthy and useful data for science and science-based practice.

Measurement that is . . .

Valid	Accurate	Reliable	. . . yields data that are . . .
Yes	Yes	Yes	. . . most useful for advancing scientific knowledge and guiding data-based practice.
No	Yes	Yes	. . . meaningless for the purposes for which measurement was conducted.
Yes	No	Yes	. . . always wrong.[a]
Yes	Yes	No[b]	. . . sometimes wrong.[c]

a. If adjusted for consistent measurement error of standard size and direction, inaccurate data may still be usable.

b. If the accuracy of every datum in a data set can be confirmed, reliability is a moot point. In practice, however, that is seldom possible; therefore, knowing the consistency with which observers applied a valid and accurate measurement system contributes to the level of confidence in the overall trustworthiness of the data set.

c. User is unable to separate good data from bad.

accurate, knowledge that could and should lead to checking the accuracy of their measurement tools and procedures.

Highly reliable measurement means that whatever degree of accuracy (or inaccuracy) exists in the measurement system will be revealed consistently in the data. If it can be determined that John's computer reliably obtains observed values higher than the true values by a constant amount or proportion, the data could be adjusted to accommodate for that constant degree of inaccuracy.

The next two sections of the chapter describe methods for combating common threats to the validity, accuracy, and reliability of behavioral measurement.

THREATS TO VALID MEASUREMENT

The validity of behavioral data is threatened when measurement is indirect, when the wrong dimension of the target behavior is measured, or when measurement is conducted in such a way that the data it produces are an artifact of the actual events.

Indirect Measurement

Indirect measurement occurs when the researcher or practitioner measures a proxy, or stand-in, for the actual behavior of interest. Indirect measurement provides secondhand or "filtered" information that requires the researcher or practitioner to make inferences about the relationship between the event that was measured and the actual behavior of interest (Komaki, 1998). For example, a student's responses to a questionnaire designed to measure his socialization with peers is an indirect measure. Using a student's score on a standardized math achievement test as an indicator of mastery is another example of indirect measurement. Both of these illustrations require an inference about the behavior being measured and the actual behavior of interest. By contrast, a student's score on a properly constructed test consisting of math problems from recently covered curriculum content is a direct measure requiring no inferences about what it means with respect to her performance in the curriculum (e.g., Hosp & Hosp, 2003; Stecker, Fuchs, & Fuchs, 2005). Conversely, **direct measurement** occurs when the behavior measured is exactly the same as the behavior that is the focus of the investigation or behavior change program.

Indirect measurement rarely occurs in applied behavior analysis because meeting the applied dimension of ABA includes the targeting and meaningful (i.e., valid) measurement of socially significant behavior. Sometimes, however, the researcher or practitioner has no direct and reliable access to the behavior of interest and so must use some form of indirect measurement. Because researchers studying adherence to medical regimens cannot directly observe and measure patients' behavior in their homes, they rely on self-reports for their data (e.g., La Greca & Schuman, 1995).[1]

Indirect measurement is sometimes used to make inferences about private events or affective states. For example, Green and Reid (1996) used direct measures of smiling to represent "happiness" by persons with profound multiple disabilities. However, research on private events does not necessarily involve indirect measurement. A research participant who has been trained to observe his own private events is measuring the behavior of interest directly (e.g., Kostewicz, Kubina, & Cooper, 2000; Kubina, Haertel, & Cooper, 1994).

Whenever indirect measurement is used, it is the researcher's responsibility to provide evidence that the event measured directly reflects, in some reliable and meaningful way, something about the behavior for which the researcher wishes to draw conclusions (Johnston & Pennypacker, 2009). In other words, it is incumbent upon the researcher to provide a convincing case for the validity of her data. Although it is sometimes attempted, the case for validity cannot be achieved by simply attaching the name of the thing one claims to be measuring to the thing actually measured. With respect to that point, Marr (2003) recounted this anecdote about Abraham Lincoln:

> "Sir, how many legs does this donkey have?"
> "Four, Mr. Lincoln."
> "And how many tails does it have?"
> "One, Mr. Lincoln."
> "Now, sir, what if we were to call a tail a leg; how many legs would the donkey have?"
> "Five, Mr. Lincoln."
> "No sir, for you cannot make a tail into a leg by calling it one." (pp. 66–67)

Measuring the Wrong Dimension of the Target Behavior

The validity of behavioral measurement is threatened much more often by measuring the wrong dimension of the behavior of interest than it is by indirect measurement. Valid measurement yields data that are relevant to the questions about the behavior one seeks to answer through measurement. Validity is compromised when measurement produces values for a dimension of the behavior ill suited for, or irrelevant to, the reason for measuring the behavior.

Johnston and Pennypacker (1980) provided an excellent example of the importance of measuring a dimension that fits the reasons for measurement. "Sticking a ruler in a pot of water as the temperature is raised will yield highly reliable measures of the depth of the water but will tell us very little about the changing temperature" (p. 192). While the units of measurement on a ruler are well suited for measuring length, or in this case, depth, they are not at all valid for measuring temperature. If the purpose of measuring the water is to determine whether it has reached the ideal temperature for making a pot of tea, a thermometer is the correct measurement tool.

If you are interested in measuring a student's academic endurance with oral reading, counting the number of correct and incorrect words read per minute without measuring and reporting the total time that the student read will not provide valid data on endurance. Number of words read per minute alone does not fit the reason for measuring reading (i.e., academic endurance). To measure endurance, the practitioner would need to report the duration of the reading period (e.g., 30 minutes). Similarly, measuring the percentage of trials on which a student makes a correct response would not provide valid data for answering questions about the student's developing fluency with a skill, whereas measuring the number of correct responses per minute and the changing rates of responding (celeration) would.

Measurement Artifacts

Directly measuring a relevant dimension of a socially significant target behavior does not guarantee valid measurement. Validity is reduced when the data—no matter how accurate or reliable they are—do not give a meaningful (i.e., valid) representation of the behavior. When data give an unwarranted or misleading picture of the behavior because of the way measurement was conducted, the data are called an *artifact*. As introduced in Chapter 4, a *measurement artifact* is something that appears to exist because of the way it is measured. Discontinuous measurement, poorly scheduled measurement periods, and using insensitive or limiting measurement scales are common causes of measurement artifacts.

Discontinuous Measurement

Because behavior is a dynamic and continuous phenomenon that occurs and changes over time, continuous measurement is the gold standard in behavior analysis research and practice. **Continuous measurement** is measurement that detects all instances of the target behavior during the observation period. The development of automated data collection technologies has produced an increasing trend of continuous measurement in behavioral research (Kostewicz, King, Datchuk, & Brennan, 2016).

Discontinuous measurement is any form of measurement in which some instances of the response class(es) of interest may not be detected. A data set produced by discontinuous measurement—no matter how accurate and reliable—may be an artifact of the measurement system rather than accurate portrayal of behavioral events.

In the absence of automatic measurement technology, continuous measurement may be prohibited by factors such as the nature of the target behavior being measured; the number of participants or clients whose behavior must be measured; the number, duration, and scheduling of observation periods; and the availability of trained personnel to observe and collect the data. In such instances, applied behavior analysts typically use one of the three primary methods of discontinuous measurement described in Chapter 4 (partial-interval recording, whole-interval recording, or momentary time sampling).

A study by Thomson, Holmber, and Baer (1974) demonstrated the extent of artificial variability in a data set that may be caused by discontinuous measurement. A single, highly experienced observer used three different procedures for scheduling time sampling observations to measure the behavior of four subjects (two teachers and two children) in a preschool setting during 64-minute sessions. Thomson and colleagues called the three time sampling procedures *contiguous*, *alternating*, and *sequential*. With each time sampling procedure, one fourth of the observer's time (i.e., 16 minutes) was assigned to each of the four subjects.

When the contiguous observation schedule was used, the observer recorded the behavior of Subject 1 throughout the first 16 minutes of the session, recorded the behavior of Subject 2 during the second 16 minutes, and so on until all four students had been observed. In the alternating mode, Subjects 1 and 2 were observed in alternating intervals during the first half of the session, and Subjects 3 and 4 were observed in the same fashion during the last half of the session. Specifically, Subject 1 was observed during the first 4 minutes, Subject 2 during the next 4 minutes, Subject 1 during the next 4 minutes, and so on until 32 minutes had expired. The same procedure was then used for Subjects 3 and 4 during the last 32 minutes of the session. The sequential approach systematically rotated the four subjects through 4-minute observations. Subject 1 was observed during the first 4 minutes, Subject 2 during the second 4 minutes, Subject 3 during the third 4 minutes, and Subject 4 during the fourth 4 minutes. This sequence was repeated 4 times to give the total of 64 minutes of observation.

To arrive at the percentage of artifactual variance in the data associated with each time sampling schedule, Thomson and colleagues (1974) compared the observer's data with "actual rates" for each subject produced by continuous measurement of each subject for the same 64-minute sessions. Results of the study showed clearly that the contiguous and alternating schedules produced the most unrepresentative (and, therefore, less valid) measures of the target behaviors (often more than 50% variance from continuous measurement), whereas sequential sampling procedure produced results that more closely resembled the data obtained through continuous recording (from 4% to 11% variance from continuous measurement) (cf. Tiger et al., 2013).

In spite of its inherent limitations, discontinuous measurement is used in many studies in applied behavior analysis in which individual observers measure the behavior of multiple subjects within the same session. Minimizing the threat to validity posed by discontinuous measurement requires careful consideration of when observation and measurement periods should be scheduled. Infrequent measurement, no matter how accurate and reliable it is, often yields results that are an artifact. Although a single measure reveals the presence or absence of the target behavior at a given point in time, it may not be representative of the typical value for the behavior.[2] As a general rule, observations should be scheduled on a daily or frequent basis, even if for only brief periods.

Ideally, all occurrences of the behavior of interest should be recorded. However, when available resources preclude continuous measurement throughout an observation period, the use of sampling procedures is necessary. A sampling procedure may be sufficient for decision making and analysis if the samples represent a valid approximation of the true parameters of the behavior of interest. When measurement cannot be continuous throughout an observation period, it is generally preferable to sample the occurrence of the target behavior for numerous brief observation intervals that are evenly distributed throughout the session than it is to use longer, less frequent intervals (Thomson et al., 1974; Thompson, Symons, & Felce, 2000). For example, measuring a subject's behavior in thirty 10-second intervals equally distributed within a 30-minute session will likely yield more representative data than will observing the person for a single 5-minute period during the half hour.

Measuring behavior with observation intervals that are too short or too long may result in data that grossly over- or underestimates the true occurrence of behavior. For example, measuring off-task behavior by partial-interval recording with 10-minute intervals may produce data that make even the most diligent of students appear to be highly off task.

Poorly Scheduled Measurement Periods

The observation schedule should be standardized to provide an equal opportunity for the occurrence or nonoccurrence of the behavior across sessions and consistent environmental conditions from one observation session to the next. When neither of these requirements is met, the resultant data may not represent actual events and therefore be invalid. If observation periods are scheduled at times when and/or places where the frequency of behavior is atypical, the data may not represent periods of high or low responding. For example, measuring students' being on task during only the first 5 minutes of each day's 20-minute cooperative learning group activity may yield data that make on-task behavior appear higher than it actually is over the entire activity.

When data will be used to assess the effects of an intervention or treatment, the most conservative observation times should be selected. That is, target behaviors should be measured during those times when their rates of occurrence is most likely to be different from the desired or predicted outcomes of the treatment. Measurement of behaviors targeted for reduction should occur during times when those behaviors are most likely to occur at their highest response rates. Conversely, behaviors targeted for increase should be measured when high-rate responding is least likely. If an intervention is not planned—as might be the case in a descriptive study—it is important to select the observation times most likely to yield data that are generally representative of the behavior.

Insensitive and/or Limited Measurement Scales

Artifactual data may result from using measurement scales that cannot detect the full range of relevant values or that are insensitive to meaningful changes in behavior. Data obtained with a measurement scale that does not detect the full range of relevant performances may incorrectly imply that behavior cannot occur at levels below or above obtained measures because the scale has imposed an artificial floor or ceiling on performance. For example, measuring a student's oral reading fluency by giving him a 100-word passage to read in 1 minute may yield data that suggest that his maximum performance is 100 wpm.

Measurement scales that are over- or under-sensitive to relevant changes in behavior may produce misleading data showing that meaningful behavior change has (or has not) occurred. For example, using a percentage measure scaled in 10% increments to evaluate the effects of an intervention to improve quality control in a manufacturing plant may not reveal important changes in performance if improvement in the percentage of correctly fabricated widgets from a baseline level of 92% to a range of 97% to 98% is the difference between unacceptable and acceptable (i.e., profitable) performance.

THREATS TO ACCURATE AND RELIABLE MEASUREMENT

Human error is the biggest threat to the accuracy and reliability of data in applied behavior analysis. Unlike the experimental analysis of behavior, in which measurement is typically automated, most investigations in applied behavior analysis use human observers to measure behavior.[3] Factors that contribute to human measurement error include poorly designed measurement systems, inadequate observer training, and expectations about what the data should reveal.

Poorly Designed Measurement System

Unnecessarily cumbersome and difficult-to-use measurement systems create needless loss of accuracy and reliability. Collecting behavioral data in applied settings requires attention, keen judgment, and perseverance. The more taxing and difficult a measurement system is to use, the less likely an observer will be to consistently detect and record all instances of the target behavior. Simplifying the measurement system as much as possible minimizes measurement errors.

The complexity of measurement includes such variables as the number of individuals observed, the number of behaviors recorded, the duration of observation periods, and/or the duration of the observation intervals, all of which may affect the quality of measurement. For instance, observing several individuals is more complex than observing one person; recording several behaviors is more complex than recording a single behavior; and using contiguous 5-second observation intervals with no time between intervals to record the results of the observation is more difficult than a system in which time is reserved for recording data.

Specific recommendations for reducing complexity depend on the particular nature of the study. However, when using time sampling measurements, applied behavior analysts can consider modifications such as decreasing the number of simultaneously observed individuals or behaviors, decreasing the duration of the observation sessions (e.g., from 30 minutes to 15 minutes), and increasing the duration of time intervals (e.g., from 5 to 10 seconds). Requiring more practice during observer training, establishing a higher criterion for mastery of the observational code, and providing more frequent feedback to observers may also reduce the possible negative effects of complex measurement.

Inadequate Observer Training

Careful attention must be paid to the selection and training of observers. Explicit and systematic observer training is essential for the collection of trustworthy data. Observation and coding systems require observers to discriminate the occurrence and nonoccurrence of specific classes of behaviors or events against an often complex and dynamic background of other behaviors or events and to record their observations onto a data sheet. Observers must learn the definitions for each behavior or event to be measured; a coded notation system or icon for each event to be measured; a common set of recording procedures (e.g., marking a data collection form, keystrokes, touching icons); and how to correct recording errors (e.g., writing a plus sign instead of a minus sign, hitting the F6 key instead of the F5 key, touching the 'on-task' icon instead of the 'off-task' icon).

Selecting Observers Carefully

Admittedly, applied researchers often scramble to find data collectors, but not all volunteers should be accepted into training. Potential observers should be interviewed to determine past experiences with observation and measurement activities, current schedule and upcoming commitments, work ethic and motivation, and overall social skills. The interview might include a pretest to determine current observation and skill levels. This can be accomplished by having potential observers watch short video clips of behaviors similar to what they may be asked to observe and noting their performance against a criterion.

Training Observers to an Objective Standard of Competency

Observer trainees should meet a specified criterion for recording before conducting observations in applied settings. During training, observers should practice recording numerous examples and nonexamples of the target behavior(s) and receive a critique and performance feedback. Observers should have numerous practice sessions before actual data collection. Training should continue until a predetermined criterion is achieved (e.g., 95% accuracy for two or three consecutive sessions). For example, in training observers to measure the completion of preventive maintenance tasks of heavy equipment by military personnel, Komaki (1998) required three consecutive sessions of at least 90% agreement with a true value.

Various methods can be used to train observers. These include sample vignettes, narrative descriptions, video modeling sequences (see Chapter 21), role playing, and practice sessions in the environment in which actual data will be collected. Practice sessions in natural settings are especially beneficial because they allow both observers and participants to adapt to each other's presence and may reduce the reactive effects of the presence of observers on participants' behavior. For example, observer trainees for a study that measured appropriate and inappropriate recruiting responses by middle school students with learning disabilities during collaborative learning group (CLG) activities and three types of peer reactions to those responses (instructional feedback, praise, and negative statements) were required to first demonstrate accurate recording (using experimenters' descriptions of events as true values) and then practice observing and measuring those events in a classroom similar to the experimental setting:

> The first author created two observation training scripts, each script consisting of 10 vignettes of various CLG interactions the observers were likely to encounter. The vignettes included appropriate and inappropriate recruiting responses and various types of peer reactions to recruiting. The first author discussed the first script with the observers, demonstrating how each vignette should be marked on the recording form. Each observer then independently completed a recording form based on the second script. When the observers achieved at least 95% interobserver agreement (IOA) with the first author on the frequency and type of student recruiting and peer assistance, they began practicing data collection in the language arts classroom during CLG activities. Baseline data collection began when the observers attained 95% IOA with the first author in the classroom. (Wolford, Alber, & Heward, 2001, p. 164)

The following steps are an example of a systematic approach for training observers.

Step 1 Trainees read the target behavior definitions and become familiar with data collection forms, procedures for recording their observations, and the proper use of any measurement or recording devices (e.g., tape recorders, stopwatches, laptops, PDAs, bar code scanners).

Step 2 Trainees practice recording simplified narrative descriptions of behavioral vignettes until they obtain 100% accuracy over a predetermined number of instances.

Step 3 Trainees practice recording longer, more complex narrative descriptions of behavioral vignettes until they obtain 100% accuracy for a predetermined number of episodes.

Step 4 Trainees practice observing and recording data from videorecorded or role-played vignettes depicting the target behavior(s) at the same speed and complexity as will occur in the natural environment. Training vignettes should be scripted and sequenced to provide trainees practice in making increasingly difficult discriminations between the occurrence and nonoccurrence of the target behavior(s). Having trainees rescore the same series of vignettes a second time and comparing the reliability of their measures provides an assessment of the consistency with which the trainees are applying the measurement system. Trainees remain at this step until their data reach pre-established accuracy and reliability criteria. (If the study involved collecting data from natural permanent products such as compositions or academic worksheets, Steps 2 through 4 should provide trainees with practice scoring increasingly extensive and more difficult-to-score examples.)

Step 5 The final training step of observer training is practice in collecting data in the natural environment. An experienced observer accompanies the trainee and simultaneously and independently measures the target behaviors. Each practice session ends with the trainee and experienced observer comparing their data sheets and discussing any questionable or heretofore unforeseen instances. Training continues until a pre-established criterion of agreement between the experienced observer and the trainee is achieved (e.g., at least 90% for three consecutive sessions).

Providing Ongoing Training to Minimize Observer Drift

Over the course of a study, observers sometimes alter, often unknowingly, the way they apply a measurement system. Called **observer drift**, these unintended changes in the way data are collected may produce measurement error. Observer drift usually entails a shift in the observer's interpretation of the definition of the target behavior from that used in training. Observer drift occurs when observers expand or compress the original definition of the target behavior. For example, observer drift might be responsible for the same behaviors by a child that were recorded by an observer as instances of noncompliance during the first week of a study being scored as instances of compliance during the study's final week. Observers are usually unaware of the drift in their measurement.

Occasional observer retraining or booster sessions throughout the investigation can minimize observer drift. Continued training provides the opportunity for observers to receive frequent feedback on the accuracy and reliability of measurement. Ongoing training can occur at regular, prescheduled intervals (e.g., every Friday morning) or randomly.

Unintended Influences on Observers

Ideally, data reported by observers have been influenced only by the actual occurrences and nonoccurrences of the target behavior(s) observers have been trained to measure. In reality, however, a variety of unintended and undesired influences on observers can threaten the accuracy and reliability of the data they report. Common causes of this type of measurement error include an observer's presuppositions about the expected outcomes of the data and awareness that others are measuring the same behavior.

Observer Expectations

Observer expectations that the target behavior should occur at a certain level under particular conditions, or change when a change in the environment has been made, pose a major threat to accurate measurement. For example, if an observer believes or predicts that a teacher's implementation of a token economy should decrease inappropriate student behavior, she may record fewer inappropriate behaviors during the token reinforcement condition than she would have recorded otherwise without holding that expectation. Data influenced by an observer's expectations or efforts to obtain results that will please the researcher are characterized by measurement bias.

The surest way to minimize measurement bias caused by observer expectations is to use naive observers. A totally **naive observer** is a trained observer who is unaware of the study's purpose and/or the experimental conditions in effect during a given phase or observation period. Researchers should inform observer trainees that they will receive limited information about the study's purpose and why that is. However, maintaining observers' naiveté is often difficult and sometimes impossible.

When observers are aware of the purpose or hypothesized results of an investigation, measurement bias can be minimized by using target behavior definitions and recording procedures that will give a conservative picture of the behavior (e.g., whole-interval recording of on-task behavior with 10-second rather than 5-second intervals), frank and repeated discussion with observers about the importance of collecting accurate data, and frequent feedback to observers on the extent to which their data agree with true values or data obtained by naive observers. Observers should not receive feedback about the extent to which their data confirm or run counter to hypothesized results or treatment goals.

Observer Reactivity

Measurement error resulting from an observer's awareness that others are evaluating the data he reports is called **observer reactivity**. Like reactivity that may occur when

participants are aware that their behavior is being observed, the behavior of observers (i.e., the data they record and report) can be influenced by the knowledge that others are evaluating the data. For example, knowing that the researcher or another observer is watching the same behavior at the same time, or will monitor the measurement through video or audio recording later, may produce observer reactivity. If the observer anticipates that another observer will record the behavior in a certain way, his data may be influenced by what he anticipates the other observer may record.

Monitoring observers as unobtrusively as possible on an unpredictable schedule helps reduce observer reactivity. Separating multiple observers by distance or partition reduces the likelihood that their measures will be influenced by one another's during an observation. One-way mirrors in some research and clinical settings eliminate visual contact between the primary and secondary observers. If audio or video recordings are made of sessions, the secondary observer can measure the behavior at a later time and the primary observer never has to come into contact with the secondary observer. In settings where one-way mirrors are not possible, and where audio or video recording may be intrusive, the secondary observer might begin measuring the behavior at a time unknown to the primary observer. For example, if the primary observer begins measuring behavior with the first interval, the secondary observer could start measuring behavior after 10 minutes have elapsed. The intervals used for comparisons would begin at the 10-minute mark, ignoring those intervals that the primary observer recorded beforehand.

ASSESSING THE ACCURACY AND RELIABILITY OF BEHAVIORAL MEASUREMENT

After designing a measurement system that will produce a valid representation of the target behavior and training observers to use it in a manner likely to yield accurate and reliable data, the researcher's next measurement-related tasks are evaluating the extent to which the data are, in fact, accurate and reliable. Essentially, all procedures for assessing the accuracy and reliability of behavioral data entail some form of "measuring the measurement system."

Assessing the Accuracy of Measurement

Measurement is accurate when the observed values (i.e., the numbers obtained by measuring an event) match the true values of the event. The fundamental reason for determining the accuracy of data is obvious: No one wants to base research conclusions or make treatment decisions on faulty data. More specifically, conducting accuracy assessments serves four interrelated purposes. First, it is important to determine early in an analysis whether the data are good enough to serve as the basis for making experimental or treatment decisions. The first person the researcher or practitioner must try to convince that the data are accurate is herself. Second, accuracy assessments enable the discovery and correction of specific instances of measurement error. The two other approaches to assessing the quality of data, to be discussed later in this chapter—reliability assessments and interobserver agreement—can alert the behavior analyst to the likelihood of measurement errors, but neither approach identifies errors. Only the direct assessment of measurement accuracy allows practitioners or applied researchers to detect and correct faulty data.

A third reason for conducting accuracy assessments is to reveal consistent patterns of measurement error, which can lead to calibration of the measurement system. **Calibration** entails comparing the data produced by a measurement system to a known standard or true value and, if necessary, adjusting the measurement system so the data it produces match the known standard. For example, knowing that John's bicycle computer reliably obtained a measure of 68 miles for a route with a true value of 58 miles led not only to the cyclists correcting the data in hand (in this case, confessing to one another and to their friend Lee that they had not ridden as many miles as previously claimed) but to their calibrating John's bicycle computer (in this case, by adjusting the wheel circumference setting) so that future measures would be accurate.

Mudford, Zeleny, Fisher, Klum, and Owen (2011) calibrated human observers by comparing their data to criterion (known) values for the same events. Five experienced and five novice observers participated in the study. Observers viewed scripted video records of two adults playing the roles of therapist and client and recorded three behaviors (client pinches therapist, model prompts by the therapist, and verbal+gestural prompts by the therapist) with laptop computers. Each observer recorded data from 10 different 10-minute samples viewed in random order. Each sample included a varied number of pinches (from 0 to 80) and 15 randomly distributed therapist prompts.

Because the video samples were scripted, the number of occurrences for each of the three target behaviors was a known (true) value. What the researchers called the "criterion records" for when each response occurred during the video samples to 1-second precision were obtained by three of the study's co-authors independently, noting times of occurrence while playing, pausing, rewinding, and replaying the video recordings. "The only discrepancies between independent records were on the exact second in which responses occurred. Discrepancies were resolved by authors reviewing the sample together until agreement on time of occurrence was achieved" (p. 575).

After using three different IOA methods and linear regression to compare each observer's data with "criterion records," Mudford et al. (2011) concluded that, "Experienced observers demonstrated almost uniformly high levels of agreement with criterion records, accuracy, and precision. . . . Novice observers, as a group, did not fall far behind the experienced observers in accuracy and precision" (p. 582). Although these results apply only to the measurement system and observers assessed, the study demonstrates a calibration method that may improve the accuracy of data collected by applied behavior analysts.

Calibrating any measurement tool, whether it is a mechanical device or human observer, entails comparing the data obtained by the tool against a true value. The measure obtained by the GPS-odometer served as the true value for calibrating John's bike computer. Calibration of a timing device such as a stopwatch or countdown timer could be made against a known

standard: the "ytterbium clock."[4] If no differences are detected when comparing the timing device against the ytterbium clock, or if the differences are tolerable for the intended purposes of measurement, then calibration is satisfied. If significant differences are found, the timing device would need to be reset to the standard. We recommend frequent accuracy assessments in the beginning stages of an analysis. Then, if the assessments have produced high accuracy, less frequent assessments can be conducted to check the calibration of the recorders.

A fourth reason for conducting accuracy assessments is to assure consumers that the data are accurate. Including the results of accuracy assessments in research reports helps readers judge the trustworthiness of the data being offered for interpretation.

Establishing True Values

True values for some behaviors are evident and universally accepted. For example, obtaining the true values of correct responses in academic areas such as math and spelling is straightforward. The correct response to the arithmetic problem 2 + 2 = ? has a true value of 4, and the *Oxford English Dictionary* is a source of true values for assessing the accuracy of measuring the spelling of English words.[5]

Although not universal, true values for many socially significant behaviors of interest to applied researchers and practitioners can be established conditionally on local context. For example, the correct response to the question "Name the three starches recommended as thickeners for pan gravy" on a quiz given to students in a culinary school has no universal true value. Nevertheless, a true value relevant to the students taking the quiz can be found in the instructor's course materials.

> There is no single way to obtain true values. There are only the requirements that: (a) the procedure must be different from that used to collect the data that are being evaluated; and (b) the procedure must incorporate extraordinary steps that avoid or remove possible sources of error. (Johnston & Pennypacker, 2009, p. 146)

True values for each of the preceding examples were obtained through sources independent of the measures to be evaluated. Establishing true values for many behaviors studied by applied behavior analysts is difficult because the process for determining a true value must be different from the measurement procedures used to obtain the data one wishes to compare to the true value.

This is difficult, true, but not impossible. For example, in Mudford and colleagues' (2011) calibration study described earlier, true values were obtained by a procedure that (a) was different from the procedure used by the observers to record their data (the researchers paused and replayed the video recordings while measuring the behaviors), and (b) incorporated extraordinary steps (the researcher resolved discrepant measures by viewing the video together until reaching agreement within 1-second tolerance).

It can be easy to mistake as true values, measures that only *appear* to be so. For example, suppose that four well-trained and experienced observers view a video recording of teacher and student interactions. Their task is to identify the true value of all instances of teacher praise contingent on academic accomplishments. Each observer views the recording independently and counts all occurrences of contingent teacher praise. After recording their respective observations, the four observers share their measurements, discuss disagreements, and suggest reasons for the disagreements. The observers independently record contingent praise a second time. Once again they share and discuss their results. After repeating the recording and sharing process several times, all observers agree that they have recorded every instance of teacher praise. However, the observers did not produce a *true value* of teacher praise for two reasons: (1) The observers could not calibrate their measurement of teacher praise to an independent standard of teacher praise, and (2) the process used to identify all instances of teacher praise may be biased (e.g., one of the observers may have convinced the others that her measures represented the true value). When true values cannot be established, researchers must rely on reliability assessments and measures of interobserver agreement to evaluate the quality of their data.

Accuracy Assessment Procedures

Determining the accuracy of measurement is a straightforward process of calculating the correspondence of each measure, or datum, assessed to its true value. For example, a researcher or practitioner assessing the accuracy of the score for a student's performance on a 30-word spelling test reported by a grader would compare the grader's scoring of each word on the test with the true value for that word found in a dictionary. Each word on the test that matched the correct letter sequence (i.e., orthography) provided by the dictionary and was marked correct by the grader would be an accurate measure by the grader, as would each word marked incorrect by the grader that did not match the dictionary's spelling. If the original grader's scoring of 29 of the test's 30 words corresponded to the true values for those words, the grader's measure would be 96.7% accurate.

Although an individual researcher or practitioner can assess the accuracy of the data she has collected, multiple independent observers are often used. Brown, Dunne, and Cooper (1996) described the procedures they used to assess the accuracy of measurement in a study of oral reading comprehension as follows:

> An independent observer reviewed one student's audio-tape of the delayed one-minute oral retell each day to assess our accuracy of measurement, providing an assessment of the extent that our counts of delayed retells approximated the true value of the audio-taped correct and incorrect retells. The independent observer randomly selected each day's audiotape by drawing a student's name from a hat, then listened to the tape and scored correct and incorrect retells using the same definitions as the teacher. Observer scores were compared to teacher scores. If there was a discrepancy between these scores, the observer and the teacher reviewed the tape (i.e., the true value) together to identify the source of the discrepancy and corrected the counting error on the data sheet and the Standard Celeration Chart. The observer also used a stopwatch to time the duration of the audio-tape

> to ensure accuracy of the timings. We planned to have the teacher re-time the presentation or retell and recalculate the frequency per minute for each timing discrepancy of more than 5 seconds. All timings, however, met the 5-second accuracy definition. (p. 392)

Reporting Accuracy Assessments

In addition to describing procedures used to assess the accuracy of the data, researchers should report the number and percentage of measures that were checked for accuracy, the degree of accuracy found, the extent of measurement error detected, and whether those measurement errors were corrected in the data. Brown and colleagues (1996) used the following narrative to report the results of their accuracy assessment:

> The independent observer and the teacher achieved 100% agreement on 23 of the 37 sessions checked. The teacher and the observer reviewed the tape together to identify the source of measurement errors for the 14 sessions containing measurement discrepancies and corrected the measurement errors. Accurate data from the 37 sessions rechecked were then displayed on the Standard Celeration Charts. The magnitude of the measurement errors was very small, often a difference of 1 to 3 discrepancies. (p. 392)

A full description and reporting of the results of accuracy assessment helps readers of the study evaluate the accuracy of all the data included in the report. For example, suppose a researcher reported that she conducted accuracy checks on a randomly selected 20% of the data, found those measures to be 97% accurate with the 3% error being nonbiased, and corrected the assessed data as needed. A reader of the study would know that 20% of the data are 100% accurate and be fairly confident that the remaining 80% of the data (i.e., all of the measures that were not checked for accuracy) is 97% accurate.

Assessing the Reliability of Measurement

Measurement is reliable when it yields the same values across repeated measures of the same event. Reliability is established when the same observer measures the same data set repeatedly from archived response products such as audiovisual products and other forms of permanent products. The more frequently a consistent pattern of observation is produced, the more reliable the measurement. Conversely, if similar observed values are not achieved with repeated observations, the data are considered unreliable. This leads to a concern about accuracy, which is the primary indicator of quality measurement.

But, as we have pointed out repeatedly, reliable data are not necessarily accurate data. As the three bicyclists discovered, totally reliable (i.e., consistent) measurement may be totally wrong. Relying on the reliability of measurement as the basis for determining the accuracy of measurement would be, as the philosopher Wittgenstein (1953) noted, "As if someone were to buy several copies of the morning paper to assure himself that what it said was true" (p. 94).

In many research studies and most practical applications, however, checking the accuracy of every measure is not possible or feasible. In other cases, true values for measures of the target behavior may be difficult to establish. When confirming the accuracy of each datum is not possible or practical, or when true values are not available, knowing that a measurement system has been applied with a high degree of consistency contributes to confidence in the overall trustworthiness of the data. Although high reliability cannot confirm high accuracy, discovering a low level of reliability signals that the data are then suspect enough to be disregarded until problems in the measurement system can be determined and repaired.

Assessing the reliability of behavioral measurement requires either a natural or contrived permanent product so the observer can re-measure the same events. For example, reliability of measurement of variables such as the number of adjectives or action verbs in students' essays could be accomplished by having an observer rescore essays. The reliability of the measurement reporting the number and type of response prompts and feedback statements parents presented to their children at the family dinner table could be evaluated by having an observer replay and rescore videos of the family's mealtime and compare the data obtained from the two measurements.

Observers should not re-measure the same permanent product soon after measuring it the first time. Doing so might result in the measures from the second scoring being influenced by what the observer remembered from the initial scoring. To avoid such unwanted influence, a researcher can insert several previously scored essays or videos randomly into the sequence of "new data" being recorded by observers.

USING INTEROBSERVER AGREEMENT TO ASSESS BEHAVIORAL MEASUREMENT

Interobserver agreement is the most commonly used indicator of measurement quality in applied behavior analysis (Kostewicz et al., 2016). **Interobserver agreement (IOA)** refers to the degree to which two or more independent observers report the same observed values after measuring the same events.

Benefits and Uses of IOA

Obtaining and reporting interobserver agreement serves four distinct purposes. First, IOA can function as a basis for determining the competence of new observers. As noted earlier, a high degree of agreement between a newly trained observer and an experienced observer provides an objective index of the extent to which the new observer is measuring the behavior in the same way as experienced observers.

Second, systematic assessment of IOA over the course of a study can detect observer drift. When observers who obtained the same, or nearly the same, observed values when measuring the same behavioral events at the beginning of a study (i.e., IOA was high) obtain different measures of the same events later in the study (i.e., IOA is now low), one of the observers may be using a definition of the target behavior that has drifted. Deteriorating IOA assessments cannot indicate with assurance which of the observer's data are being influenced by drift (or any other reason for disagreement), but the information reveals the need for further evaluation of the data and/or for retraining and calibration of the observers.

Third, knowing that two or more observers consistently obtained similar data increases confidence that the definition of the target behavior was clear and unambiguous and the measurement code and system not too difficult. Fourth, for studies that employ multiple observers as data collectors, consistently high levels of IOA increase confidence that variability in the data is not a function of which observer(s) happened to be on duty for any given session, and therefore that changes in the data more likely reflect actual changes in the behavior.

The first two reasons for assessing IOA are proactive: They help researchers determine and describe the degree to which observers have met training criteria and detect possible drift in observers' use of the measurement system. The second two purposes or benefits of IOA are as summative descriptors of the consistency of measurement across observers. By reporting the results of IOA assessments, researchers enable consumers to judge the relative **believability** of the data as trustworthy and deserving of interpretation.

Requisites for Obtaining Valid IOA Measures

A valid assessment of IOA depends on three equally important criteria. Although these criteria are perhaps obvious, it is nonetheless important to make them explicit. Two observers (usually two, but there may be more) must (a) use the same observation code and measurement system, (b) observe and measure the same participant(s) and events, and (c) observe and record the behavior independent of any influence from one other.

Observers Must Use the Same Measurement System

Interobserver agreement assessments conducted for any of the four previously stated reasons require observers to use the same definitions of the target behavior, observation procedures and codes, and measurement devices. Beyond using the same measurement system, all observers participating in IOA measures used to assess the believability of data (as opposed to evaluating the observer trainees' performance) should have received identical training with the measurement system and achieved the same level of competence in using it.

Observers Must Measure the Same Events

The observers must observe the same subject(s) at precisely the same observation intervals and periods. IOA for data obtained by real-time measurement requires that both observers be in the setting simultaneously. Real-time observers must be positioned such that each has a similar view of the subject(s) and environment. Two observers sitting on opposite sides of a classroom, for example, might obtain different measures because the different vantage points enable only one observer to see or hear some occurrences of the target behavior.

Observers must begin and end the observation period at precisely the same time. Even a difference of a few seconds between observers may produce significant measurement disagreements. To remedy this situation, the timing devices could be started simultaneously and outside the observation setting, but before data collection begins, with the understanding that the data collection would actually start at a prearranged time (e.g., exactly at the beginning of the fifth minute). Alternatively, but less desirably, one observer could signal the other at the exact moment the observation is to begin.

A common and effective procedure is for both observers to listen by earphones to prerecorded audio cues signaling the beginning and end of each observation interval (see Chapter 4). An inexpensive splitter device that enables two earphones to be plugged into the same playback device allows observers to receive simultaneous cues unobtrusively and without depending on one another.

When assessing IOA for data obtained from permanent products, the two observers do not need to measure the behavior simultaneously. For example, the observers could each watch and record data from the same video or audio recording at different times. Procedures must be in place, however, to ensure that both observers watched or listened to the same recording and that they started and stopped their independent observations at precisely the same point(s) on the tapes. Ensuring that two observers measure the same events when the target behavior produces natural permanent products, such as completed academic assignments or widgets manufactured, would include procedures such as clearly marking the session number, date, condition, and subject's name on the product and guarding the response products to ensure they are not disturbed until the second observer has obtained his measure.

Observers Must Be Independent

The third essential ingredient for valid IOA assessment is ensuring that neither observer is influenced by the other's measurements. Procedures must be in place to guarantee each observer's independence. For example, observers conducting real-time measurement of behavior must not be seated or positioned so closely to one another that either observer can detect or be influenced by the other observer's recordings (Johnston & Pennypacker, 2009).

Giving the second observer academic worksheets or written assignments that have already been marked by another observer would violate the observers' independence. To maintain independence, the second observer must score photocopies of unadulterated and unmarked worksheets or assignments as completed by the subjects.

Methods for Calculating IOA

Numerous methods for calculating IOA are available, each of which provides a somewhat different view of the extent and nature of agreement and disagreement between observers (e.g., Hartmann, 1977; Hawkins & Dotson, 1975; Page & Iwata, 1986; Mudford, Taylor, & Martin, 2009; Repp, Dietz, Boles, Dietz, & Repp, 1976). The following explanation of different IOA formats is organized by the three major methods for measuring behavioral data described in Chapter 4: event recording, timing, and interval recording or time sampling. Although other statistics are sometimes used, the percentage of agreement between observers is by far the most common convention for reporting IOA in applied behavior analysis.[6] Therefore, we have provided the formula for calculating a percentage of agreement for each type of IOA.

The formula for calculating **mean duration-per-occurrence IOA** is similar to the one used to determine mean count-per-interval IOA:

$$\frac{\text{Dur IOA R1} + \text{Dur IOA R2} + \text{Dur IOA R}n}{n \text{ responses with Dur IOA}} \times 100 = \text{mean duration-per-interval IOA }\%$$

Using this formula to calculate the mean duration-per-occurrence IOA for the two observers' timing data of the five responses just presented would entail the following steps:

1. Calculate duration-per-occurrence IOA for each response: R1, 29 ÷ 0.35 = 0.83; R2, 15 ÷ 21 = 0.71; R3, 7 ÷ 9 = 0.78; R4, 14 ÷ 14 = 1.0; and R5, 14 ÷ 17 = 0.82
2. Add the individual IOA percentages for each occurrence: 0.83 + 0.71 + 0.78 + 1.00 + 0.82 = 4.14
3. Divide the sum of the individual IOAs per occurrence by the total number of responses for which two observers measured duration: 4.14 ÷ 5 = 0.828
4. Multiply by 100 and round to the nearest whole number: 0.828 × 100 = 83%

This basic formula is also used to compute the *mean latency-per-response IOA* or *mean IRT-per-response IOA* for latency and IRT data. An observer's timings of latencies or IRTs in a session should never be added and the total time compared to a similar total time obtained by another observer as the basis for calculating IOA for latency and IRT measures.

In addition to reporting mean agreement per occurrence, IOA assessment for timing data can be enhanced with information about the range of differences between observers' timings and the percentage of responses for which the two observers each obtained measures within a certain range of error. For example, a researcher might report: "Mean duration-per-occurrence IOA for Participant 1's compliance was 87% (range across responses, 63% to 100%), and 96% of all timings obtained by the second observer were within +/−2 seconds of the primary observer's measures."

IOA for Data Obtained by Interval Recording/Time Sampling

Three techniques commonly used by applied behavior analysts to calculate IOA for interval data are interval-by-interval IOA, scored-interval IOA, and unscored-interval IOA.

Interval-by-Interval IOA. When using an interval-by-interval IOA (sometimes referred to as the *point-by-point, total interval*, or *block-by-block method*), the primary observer's record for each interval is matched to the secondary observer's record for the same interval. The formula for calculating **interval-by-interval IOA** is as follows:

$$\frac{\text{Number of intervals agreed}}{\text{Number of intervals agreed} + \text{number of intervals disagreed}} \times 100 = \text{interval-by-interval IOA }\%$$

The hypothetical data in Figure 5.3 show the interval-by-interval method for calculating IOA based on the record of two observers who recorded the occurrence (X) and nonoccurrence (0) of behavior in each of 10 observation intervals. The observers' data sheets show that they agreed on the occurrence or the nonoccurrence of the behavior for seven intervals (Intervals 2, 3, 4, 5, 7, 9, and 10). Interval-by-interval IOA for this data set is 70% (i.e., 7 ÷ [7 + 3] × 100 = 70%).

Interval-by-interval IOA is likely to overestimate the actual agreement between observers measuring behaviors that occur at very low or very high rates. This is because interval-by-interval IOA is subject to random or accidental agreement between observers. For example, with a behavior whose actual frequency of occurrence is only about 1 or 2 intervals per 10 observation intervals, even a poorly trained and unreliable observer who misses some of the few occurrences of the behavior and mistakenly records the behavior as occurring in some intervals when the behavior did not occur is likely to mark most intervals as nonoccurrences. As a result of this chance agreement, interval-by-interval IOA is likely to be quite high. Two IOA methods that minimize the effects of chance agreements for interval data on behaviors that occur at very low or very high rates are scored-interval IOA and unscored-interval IOA (Hawkins & Dotson, 1975).

Figure 5.3 When calculating interval-by-interval IOA, the number of intervals in which both observers agreed on the occurrence or the nonoccurrence of the behavior (shaded intervals: 2, 3, 4, 5, 7, 9, 10) is divided by the total number of observation intervals (10). Interval-by-interval IOA for the data shown here is 70% (7/10).

Interval-by-Interval IOA

Interval no. →	1	2	3	4	5	6	7	8	9	10
Observer 1	X	X	X	0	X	X	0	X	X	0
Observer 2	0	X	X	0	X	0	0	0	X	0

X = behavior was recorded as occurring during interval
0 = behavior was recorded as not occurring during interval

Scored-Interval IOA. Only those intervals in which either or both observers recorded the *occurrence of the target behavior* are used in calculating **scored-interval IOA**. An agreement is counted when both observers recorded that the behavior occurred in the same interval, and each interval in which one observer recorded the occurrence of the behavior and the other recorded its nonoccurrence is counted as a disagreement. For example, for the data shown in Figure 5.4, only Intervals 1, 3, and 9 would be used in calculating scored-interval IOA. Intervals 2, 4, 5, 6, 7, 8, and 10 would be ignored because both observers recorded that the behavior did not occur in those intervals. Because the two observers agreed that the behavior occurred in only one (Interval 3) of the three scored intervals, the scored-interval IOA measure is 33% (1 interval of agreement divided by the sum of 1 interval of agreement plus 2 intervals of disagreement × 100 = 33%).

For behaviors that occur at low rates, scored-interval IOA is a more conservative measure of agreement than interval-by-interval IOA. This is because scored-interval IOA ignores the intervals in which agreement by chance is highly likely. For example, using the interval-by-interval method for calculating IOA for the data in Figure 5.4 would yield an agreement of 80%. To avoid overinflated and possibly misleading IOA measures, we recommend using scored-interval interobserver agreement for behaviors that occur at frequencies of approximately 30% or fewer intervals.

Unscored-Interval IOA. Only intervals in which either or both observers recorded the *nonoccurrence of the target behavior* are considered when calculating **unscored-interval IOA**. An agreement is counted when both observers recorded the nonoccurrence of the behavior in the same interval, and each interval in which one observer recorded the nonoccurrence of the behavior and the other recorded its occurrence is counted as a disagreement. For example, only Intervals 1, 4, 7, and 10 would be used in calculating the unscored-interval IOA for the data in Figure 5.5 because at least one observer recorded the nonoccurrence of the behavior in each of those intervals. The two observers agreed that the behavior did not occur in Intervals 4 and 7. Therefore, the unscored-interval IOA in this example is 50% (2 intervals of agreement divided by the sum of 2 intervals of agreement plus 2 intervals of disagreement × 100 = 50%).

For behaviors that occur at relatively high rates, unscored-interval IOA provides a more stringent assessment of interobserver agreement than does interval-by-interval IOA. To avoid overinflated and possibly misleading IOA measures, we recommend using unscored-interval interobserver agreement for behaviors that occur at frequencies of approximately 70% or more of intervals.

The equations for calculating each of the aforementioned types of IOA are summarized in Figure 5.6.

Considerations in Selecting, Obtaining, and Reporting Interobserver Agreement

The guidelines and recommendations that follow are organized under a series of questions concerning the use of interobserver agreement to evaluate the quality of behavioral measurement.

Figure 5.4 Scored-interval IOA is calculated using only those intervals in which either observer recorded the occurrence of the behavior (shaded intervals: 1, 3, 9). Scored-interval IOA for the data shown here is 33% (1/3: interval 3).

Scored-Interval IOA

Interval no. →	1	2	3	4	5	6	7	8	9	10
Observer 1	X	0	X	0	0	0	0	0	0	0
Observer 2	0	0	X	0	0	0	0	0	X	0

X = behavior was recorded as occurring during interval
0 = behavior was recorded as not occurring during interval

Figure 5.5 Unscored-interval IOA is calculated using only those intervals in which either observer recorded the nonoccurrence of the behavior (shaded intervals: 1, 4, 7, 10). Unscored-interval IOA for the data shown here is 50% (2/4: Interval 4 and 7).

Unscored-Interval IOA

Interval no. →	1	2	3	4	5	6	7	8	9	10
Observer 1	X	X	X	0	X	X	0	X	X	0
Observer 2	0	X	X	0	X	X	0	X	X	X

X = behavior was recorded as occurring during interval
0 = behavior was recorded as not occurring during interval

Figure 5.6 Equations for calculating various types of interobserver agreement (IOA).

Type of IOA	Equation
Total count	$\frac{\text{smaller count}}{\text{larger count}} \times 100$
Mean count-per-interval	$\frac{\text{Int 1 IOA} + \text{Int 2 IOA} + \text{Int } n \text{ IOA}}{n \text{ intervals}} \times 100$
Exact count-per-interval	$\frac{\text{number of intervals of 100\% IOA}}{n \text{ intervals}} \times 100$
Trial-by-trial	$\frac{\text{number of trials (items) agreed}}{\text{total number of trials (items)}} \times 100$
Total duration	$\frac{\text{shorter duration}}{\text{longer duration}} \times 100$
Mean duration-per-occurrence	$\frac{\text{Dur IOA R1} + \text{Dur IOA R2} + \text{Dur IOA R}n}{n \text{ responses with Dur IOA}} \times 100$
Interval-by-zinterval	$\frac{\text{number of intervals agreed}}{\text{no. intervals agreed} + \text{no. intervals disagreed}} \times 100$
Scored-interval	$\frac{\text{no. of intervals in which either observer recorded the occurrence of the behavior}}{\text{total number of all scored intervals}} \times 100$
Unscored-interval	$\frac{\text{no. of intervals in which either observer recorded the nonoccurrence of the behavior}}{\text{total number of all unscored intervals}} \times 100$

How Often and When Should IOA Be Obtained?

Interobserver agreement should be assessed during each condition and phase of a study and be distributed across days of the week, times of day, settings, and observers. Scheduling IOA assessments in this manner ensures that the results will provide a representative (i.e., valid) picture of all data obtained in a study. It is generally recommended that IOA be obtained for a minimum of 20% of a study's sessions, and preferably between 25% and 33% of sessions (Gast & Ledford, 2014; Kennedy, 2005; Poling, Methot, & LeSage, 1995).

In general, studies using data obtained with real-time measurement will have IOA assessed for a higher percentage of sessions than studies with data obtained from permanent products.

The frequency with which data should be assessed using interobserver agreement will vary depending on the complexity of the measurement code, the number and experience of observers, the number of conditions and phases, and the results of the IOA assessments themselves. More frequent IOA assessments are expected in studies that involve complex or new measurement systems, inexperienced observers, and numerous conditions and phases. If appropriately conservative methods for obtaining and calculating IOA reveal high levels of agreement early in a study, the number and proportion of sessions in which IOA is assessed may decrease as the study progresses. For instance, IOA assessment might be conducted in each session at the beginning of an analysis, and then reduced to a schedule of once per four or five sessions.

For What Variables Should IOA Be Obtained and Reported?

In general, researchers should obtain and report IOA at the same levels at which they report and discuss the results of their study. For example, a researcher analyzing the relative effects of two treatment conditions on two behaviors of four participants in two settings should report IOA outcomes on both behaviors for each participant separated by treatment condition and setting. This would enable consumers of the research to judge the relative believability of the data within each component of the experiment.

Which Method of Calculating IOA Should Be Used?

No method for calculating IOA is universally superior. Because each method shows systematic bias in various situations (Mudford, Martin, Hui, & Taylor, 2009), behavior analysts should select IOA method(s) best suited to the measurement system and resulting data set. As a general rule, more stringent

and conservative methods of calculating IOA should be used over methods that are likely to overestimate actual agreement as a result of chance. With event recording data, we recommend reporting overall IOA on a trial-by-trial or item-by-item basis, perhaps supplemented with separate IOA calculations for correct responses and incorrect responses. For data obtained by interval or time sampling measurement, we recommend supplementing interval-by-interval IOA with scored-interval IOA or unscored-interval IOA, depending on the relative frequency of the behavior. In situations in which the primary observer scores the target behavior as occurring in approximately 30% or fewer intervals, scored-interval IOA provides a conservative supplement to interval-by-interval IOA. Conversely, when the primary observer scores the target behavior as occurring in approximately 70% or more of the intervals, unscored-interval IOA should supplement interval-by-interval IOA. If the rate at which the target behavior occurs changes from very low to very high, or from very high to very low, across conditions or phases of a study, reporting both unscored-interval and scored-interval IOA may be warranted.

If in doubt about which form of IOA to report, calculating and presenting several variations will help readers make their own judgments regarding the believability of the data. However, if the acceptance of the data for interpretation or decision making rests on which formula for calculating IOA is chosen, serious concerns about the data's trustworthiness exist and must be addressed.

What Are Acceptable Levels of IOA?

Carefully collected and conservatively computed IOA assessments increasingly enhance the believability of a data set as agreement approaches 100%. The usual convention in applied behavior analysis is to expect independent observers to achieve a mean of no less than 80% agreement when using observational recording. However, as Kennedy (2005) pointed out, "There is no scientific justification for why 80% is necessary, only a long history of researchers using this percentage as a benchmark of acceptability and being successful in their research activities" (p. 120).

According to Kleinmann et al. (2009), "convention stipulates that mean [interobserver] agreement should equal or exceed 85%" (p. 474). However, various factors at work in a given situation may make an 85% criterion too low or too high (Kazdin, 2011). For example, 95% IOA on the number of words contained in student compositions should raise serious questions about the trustworthiness of the data. IOA at or very near 100% is needed to enhance the believability of count data obtained from permanent products. However, some analysts might accept data with a mean IOA below 80% for the simultaneous measurement of multiple behaviors by several subjects in a complex environment, especially if it is based on a sufficient number of individual IOA assessments with a small range (e.g., 75% to 83%).

The degree of behavior change revealed by the data should also be considered when determining an acceptable level of interobserver agreement. When behavior change from one condition to another is small, the variability in the data might represent inconsistent observation more than actual change in the behavior. Therefore, the smaller the change in behavior across conditions, the higher the criterion should be for an acceptable IOA percentage.

How Should IOA Be Reported?

IOA scores can be reported in narrative, table, and graphic form. Whichever format is chosen, it is important to note how, when, and how often interobserver agreement was assessed.

Narrative Description. The most common approach for reporting IOA is a simple narrative description of the mean and range of agreement percentages. For example, Craft, Alber, and Heward (1998) described the methods and results of IOA assessments in a study in which four dependent variables were measured as follows:

> *Student recruiting and teacher praise.* A second observer was present for 12 (30%) of the study's 40 sessions. The two observers independently and simultaneously observed the 4 students, recording the number of recruiting responses they emitted and teacher praise they received. Descriptive narrative notes recorded by the observers enabled each recruiting episode to be identified for agreement purposes. Interobserver agreement was calculated on an episode-by-episode basis by dividing the total number of agreements by the total number of agreements plus disagreements and multiplying by 100%. Agreement for frequency of student recruiting ranged across students from 88.2% to 100%; agreement for frequency of recruited teacher praise was 100% for all 4 students; agreement for frequency of nonrecruited teacher praise ranged from 93.3% to 100%.
>
> *Academic work completion and accuracy.* A second observer independently recorded each student's work completion and accuracy for 10 (25%) sessions. Interobserver agreement for both completion and accuracy on the spelling worksheets was 100% for all 4 students. (p. 403)

Table. An example of reporting interobserver agreement outcomes in table format is shown in Table 5.1. Krantz and McClannahan (2003) reported the range and mean IOA computed for three types of social interactions by three children across each experimental condition.

Graphic Display. Interobserver agreement can be represented visually by plotting the measures obtained by the secondary observer on a graph of the primary observer's data, as shown in Figure 5.7. Looking at both observers' data on the same graph reveals the extent of agreement between the observers and the existence of observer drift or bias. The absence of observer drift is suggested in the hypothetical study shown in Figure 5.6 because the secondary observer's measures changed in concert with the primary observer's measures. Although the two observers obtained the same measure on only 2 of the 10 sessions in which IOA was assessed

TABLE 5.1 Example of Reporting Interobserver Agreement Results for Each Dependent Variable by Participant and Experimental Condition

Range and Mean Percentage Interobserver Agreement on Scripted Interaction, Elaborations, and Unscripted Interaction by Child and Condition

	Condition									
	Baseline		**Teaching**		**New recipient**		**Script fading**		**New activities**	
Type of interaction	**Range**	**M**	**Range**	**M**	**Range**	**M**	**Range**	**M**	**Range**	**M**
Scripted										
David			88–100	94		100		100		
Jeremiah			89–100	98		100		—[a]		
Ben			80–100	98		90		—[a]		
Elaborations										
David			75–100	95	87–88	88	90–100	95		
Jeremiah			83–100	95	92–100	96		—[a]		
Ben			75–100	95		95		—[a]		
Unscripted										
David		100		100	87–88	88	97–100	98	98–100	99
Jeremiah		100		100	88–100	94	93–100	96		98
Ben		100		100		100	92–93	92	98–100	99

[a]No data are available for scripted responses and elaborations in the script-fading condition, because interobserver agreement was obtained after scripts were removed (i.e., because scripts were absent, there could be only unscripted responses).

From "Social Interaction Skills for Children with Autism: A Script-Fading Procedure for Beginning Readers," by P. J. Krantz and L. E. McClannahan, 1998, *Journal of Applied Behavior Analysis, 31*, p. 196. Copyright 1998 by the Society for the Experimental Analysis of Behavior, Inc. Reprinted by permission.

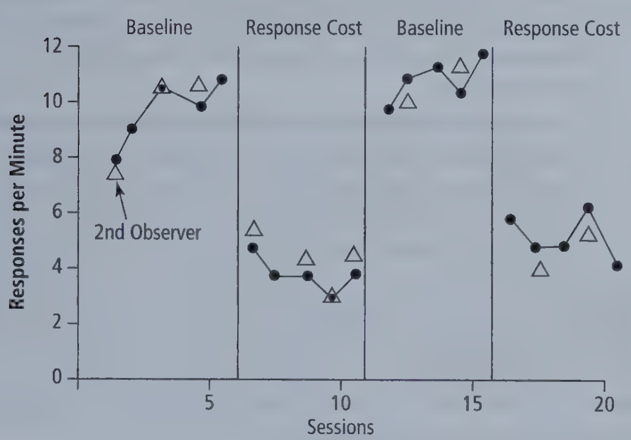

Figure 5.7 Plotting the second observer's data on a graph with the primary observer's data provides a visual representation of the extent and nature of interobserver agreement and may enable assessment of observer drift, bias, and conclusions regarding the presence of a functional relation.

(Sessions 3 and 8), the fact that neither observer consistently reported measures that were higher or lower than the other suggests the absence of observer bias. An absence of bias is usually indicated by a random pattern of overestimation and underestimation.

In addition to revealing observer drift and bias, a third way that graphically displaying IOA assessments can enhance the believability of measurement is illustrated by the data in Figure 5.6. When the data reported by the primary observer show clear change in the behavior between conditions or phases and all of the measures reported by the secondary observer within each phase fall within the range of observed values obtained by the primary observer, confidence increases that the data represent actual changes in the behavior measured rather than changes in the primary observer's behavior due to drift or extra-experimental contingencies. Likewise, graphic displays that reveal disagreement among observers can reduce viewers' confidence that a functional relationship is evident (Ledford, Artman, Wolery, & Wehby, 2012; Ledford & Wolery, 2013).

Although published research reports in applied behavior analysis seldom include graphic displays of IOA,[8] measures in creating and using such displays during a study constitute a simple and direct way for researchers to detect patterns in the consistency (or inconsistency) with which observers are measuring behavior that might not be as evident in comparing a series of percentages.

Which Approach Should Be Used for Assessing the Quality of Measurement: Accuracy, Reliability, or Interobserver Agreement?

Assessments of the accuracy of measurement, the reliability of measurement, and the extent to which different observers obtain the same measures each provide different indications

of data quality. Ultimately, the reason for conducting any type of assessment of measurement quality is to obtain quantitative evidence that can be used for the dual purposes of improving measurement during the course of an investigation and judging and convincing others of the trustworthiness of the data.

After ensuring the validity of what they are measuring and how they are measuring it, applied behavior analysts should choose to assess the accuracy of measurement whenever possible, rather than reliability or interobserver agreement. If it can be determined that all measurements in a data set meet an acceptable accuracy criterion, questions regarding the reliability of measurement and interobserver agreement are moot. For data confirmed to be accurate, conducting additional assessments of reliability or IOA is unnecessary.

When assessing the accuracy of measurement is not possible because true values are unavailable, an assessment of reliability provides the next best quality indicator. If natural or contrived permanent products can be archived, applied behavior analysts can assess the reliability of measurement, allowing consumers to know that observers have measured behavior consistently from session to session, condition to condition, and phase to phase.

When true values and permanent product archives are unavailable, interobserver agreement provides a level of believability for the data. Although IOA is not a direct indicator of the validity, accuracy, or reliability of measurement, it has proven to be a valuable and useful research tool in applied behavior analysis. Reporting interobserver agreement has been an expected and required component of published research in applied behavior analysis for several decades. In spite of its limitations, "the homely measures of observer agreement so widely used in the field are exactly relevant" (Baer, 1977, p. 119) to efforts to develop a robust technology of behavior change.

> Percentage of agreement, in the interval-recording paradigm, does have a direct and useful meaning: how often do two observers watching one subject, and equipped with the same definitions of behavior, see it occurring or not occurring at the same standard times? The two answers, "They agree about its occurrence X% of the relevant intervals, and about its nonoccurrence Y% of the relevant intervals," are superbly useful. (Baer, 1977, p. 118)

There are no reasons to prevent researchers from using multiple assessment procedures to evaluate the same data set. When time and resources permit, a combination of data assessments may be desirable. Applied behavior analysts can use any possible combination assessment (e.g., accuracy plus IOA, reliability plus IOA). In addition, some aspects of the data set could be assessed for accuracy or reliability, while other aspects are assessed with IOA. The previous example of accuracy assessment reported by Brown and colleagues (1996) included assessments for accuracy and IOA. Independent observers recorded correct and incorrect student-delayed retells. When IOA was less than 100%, data for that student and session were assessed for accuracy. IOA was used as an assessment to enhance believability, and also as a procedure for selecting data to be assessed for accuracy.

SUMMARY

Indicators of Trustworthy Measurement

1. To be most useful for science, measurement must be valid, accurate, and reliable.
2. Valid measurement in ABA encompasses three equally important elements: (a) measuring directly a socially significant target behavior, (b) measuring a dimension of the target behavior relevant to the question or concern about the behavior, and (c) ensuring that the data are representative of the behavior under conditions and during times most relevant to the reason(s) for measuring it.
3. Measurement is accurate when observed values, the data produced by measuring an event, match the true state, or true values, of the event.
4. Measurement is reliable when it yields the same values across repeated measurement of the same event.

Threats to Valid Measurement Validity

5. Indirect measurement—measuring a behavior different from the behavior of interest—threatens validity because it requires the researcher or practitioner to make inferences about the relationship between the measures obtained and the actual behavior of interest.
6. A researcher who uses indirect measurement must provide evidence that the behavior measured directly reflects, in some reliable and meaningful way, something about the behavior for which the researcher wishes to draw conclusions.
7. Measuring a dimension of the behavior that is ill suited for, or irrelevant to, the reason for measuring the behavior compromises validity.
8. Measurement artifacts are data that give an unwarranted or misleading picture of the behavior because of the way measurement was conducted. Discontinuous measurement, poorly scheduled observations, and insensitive or limiting measurement scales are common causes of measurement artifacts.

Threats to Accurate and Reliable Measurement

9. Most investigations in applied behavior analysis use human observers to measure behavior, and human error is the biggest threat to the accuracy and reliability of data.
10. Factors that contribute to measurement error include poorly designed measurement systems, inadequate observer training, and expectations about what the data should look like.

11. Observers should receive systematic training and practice with the measurement system and meet predetermined accuracy and reliability criteria before collecting data.
12. Observer drift—unintended changes in the way an observer uses a measurement system over the course of an investigation—can be minimized by booster training sessions and feedback on the accuracy and reliability of measurement.
13. An observer's expectations or knowledge about predicted or desired results can impair the accuracy and reliability of data.
14. Observers should not receive feedback about the extent to which their data confirm or run counter to hypothesized results or treatment goals.
15. Measurement bias caused by observer expectations can be avoided by using naive observers.
16. Observer reactivity is measurement error caused by an observer's awareness that others are evaluating the data he reports.

Assessing the Accuracy and Reliability of Behavioral Measurement

17. Researchers and practitioners who assess the accuracy of their data can (a) determine early in an analysis whether the data are usable for making experimental or treatment decisions, (b) discover and correct measurement errors, (c) detect consistent patterns of measurement error that can lead to the overall improvement or calibration of the measurement system, and (d) communicate to others the relative trustworthiness of the data.
18. Assessing the accuracy of measurement is a straightforward process of calculating the correspondence of each measure, or datum, assessed to its true value.
19. True values for many behaviors of interest to applied behavior analysts are evident and universally accepted or can be established conditionally by local context. True values for some behaviors (e.g., cooperative play) are difficult because the process for determining a true value must be different from the measurement procedures used to obtain the data one wishes to compare to the true value.
20. Assessing the extent to which observers are reliably applying a valid and accurate measurement system provides a useful indicator of the overall trustworthiness of the data.
21. Assessing the reliability of measurement requires a natural or contrived permanent product so the observer can remeasure the same behavioral events.
22. Although high reliability does not confirm high accuracy, discovering a low level of reliability signals that the data are suspect enough to be disregarded until problems in the measurement system can be determined and repaired.

Using Interobserver Agreement to Assess Behavioral Measurement

23. The most commonly used indicator of measurement quality in ABA is interobserver agreement (IOA), the degree to which two or more independent observers report the same observed values after measuring the same events.
24. Researchers and practitioners use measures of IOA to (a) determine the competence of new observers, (b) detect observer drift, (c) judge whether the definition of the target behavior is clear and the system not too difficult to use, and (d) convince others of the relative believability of the data.
25. Measuring IOA requires that two or more observers (a) use the same observation code and measurement system, (b) observe and measure the same participant(s) and events, and (c) observe and record the behavior independent of influence by other observers.
26. There are numerous techniques for calculating IOA, each of which provides a somewhat different view of the extent and nature of agreement and disagreement between observers.
27. Percentage of agreement between observers is the most common convention for reporting IOA in ABA.
28. IOA for data obtained by event recording can be calculated by comparing (a) the total count recorded by each observer per measurement period, (b) the counts tallied by each observer during each of a series of smaller intervals of time within the measurement period, or (c) each observer's count of 1 or 0 on a trial-by-trial basis.
29. Total count IOA is the simplest and crudest indicator of IOA for event recording data, and exact count-per-interval IOA is the most stringent for most data sets obtained by event recording.
30. IOA for data obtained by timing duration, response latency, or interresponse time (IRT) is calculated in essentially the same ways as for event recording data.
31. Total duration IOA is computed by dividing the shorter of the two durations reported by the observers by the longer duration. Mean duration-per-occurrence IOA is a more conservative and usually more meaningful assessment of IOA for total duration data and should always be calculated for duration-per-occurrence data.
32. Three techniques commonly used to calculate IOA for interval data are interval-by-interval IOA, scored-interval IOA, and unscored-interval IOA.
33. Because it is subject to random or accidental agreement between observers, interval-by-interval IOA is likely to overestimate the degree of agreement between observers measuring behaviors that occur at very low or very high rates.

34. Scored-interval IOA is recommended for behaviors that occur at relatively low frequencies; unscored-interval IOA is recommended for behaviors that occur at relatively high frequencies.

35. IOA assessments should occur during each condition and phase of a study and be distributed across days of the week, times of day, settings, and observers.

36. Researchers should obtain and report IOA at the same levels at which they report and discuss the results of their study.

37. More stringent and conservative IOA methods should be used over methods that may overestimate agreement as a result of chance.

38. The convention for acceptable IOA has been a minimum of 80%, but there can be no set criterion. The nature of the behavior being measured and the degree of behavior change revealed by the data must be considered when determining an acceptable level of IOA.

39. IOA scores can be reported in narrative, table, and graphic form.

40. Researchers can use multiple indices to assess the quality of their data (e.g., accuracy plus IOA, reliability plus IOA).

KEY TERMS

accuracy
believability
calibration
continuous measurement
direct measurement
discontinuous measurement
exact count-per-interval IOA
indirect measurement
interobserver agreement (IOA)
interval-by-interval IOA
mean count-per-interval IOA
mean duration-per-occurrence IOA
measurement bias
naïve observer
observed value
observer drift
observer reactivity
reliability
scored-interval IOA
total count IOA
total duration IOA
trial-by-trial IOA
true value
unscored-interval IOA
validity

MULTIPLE-CHOICE QUESTIONS

1. A(n) _______ measure of the actual behavior of interest will always possess more validity than a(n) _______ measure.
   - **a.** Indirect, direct
   - **b.** Direct, indirect
   - **c.** Discontinuous, continuous
   - **d.** Reliable, accurate

   Hint: (See "Indicators of Trustworthy Measurement")

2. ________ measurement is consistent measurement.
   - **a.** Reliable
   - **b.** Valid
   - **c.** Accurate
   - **d.** Discontinuous

   Hint: (See "Indicators of Trustworthy Measurement")

3. When data give an unwarranted or misleading picture of the behavior because of the way measurement was conducted, the data are called a(n):
   - **a.** Bias
   - **b.** Artifact
   - **c.** Drift
   - **d.** Variable

   Hint: (See "Threats to Valid Measurement")

4. In general, artifacts can be limited by scheduling ________ observations.
   - **a.** Indirect
   - **b.** Infrequent
   - **c.** Frequent
   - **d.** Mini

   Hint: (See "Threats to Valid Measurement")

5. Cumbersome and difficult to use measurement ________ can lead to inaccurate and unreliable measurements.
   - **a.** Agreement
   - **b.** Instruments
   - **c.** Observers
   - **d.** Rulers

   Hint: (See "Threats to Accurate and Reliable Measurement")

6. Which of the following is not a suggested training method for potential observers?
   a. Select observers carefully
   b. Train observers to an objective standard of competency
   c. Use a systematic approach to training
   d. Explicit feedback about data collection as it relates to the hypothesis

   Hint: (See "Threats to Accurate and Reliable Measurement")

7. Reliable data are not necessarily _______ data.
   a. Complete
   b. Direct
   c. Accurate
   d. Real

   Hint: (See "Assessing the Accuracy and Reliability of Behavioral Measurement")

8. Which of the following is not a requisite for obtaining valid IOA measures?
   a. Use the same observation code and measurement system
   b. Observe and measure the same participant(s) and events
   c. Observe and record the behavior independent of any influence from one another
   d. Score all IOA while sitting side-by-side with another observer

   Hint: (See "Assessing the Accuracy and Reliability of Behavioral Measurement")

9. Which of the following is a limitation of total count IOA?
   a. Provides no assurance that the two observers recorded the same instances of behavior
   b. Useful for event recording
   c. Is expressed as percentage of agreement
   d. Is calculated by dividing the smaller of the counts by the larger count and multiplying by 100

   Hint: (See "Methods for Calculating IOA")

10. Which of the following is the most stringent method for calculating IOA for behaviors that occur at relatively high rates and obtained by interval recording?
    a. Total Count IOA
    b. Unscored-interval IOA
    c. Scored-interval IOA
    d. Mean Count-per-Interval IOA

    Hint: (See "Methods for Calculating IOA")

ESSAY-TYPE QUESTIONS

1. Discuss the difference between accuracy and reliability as they relate to behavioral data and suggest methods to evaluate both.

   Hint: (See "Threats to Valid Measurement")

2. Describe threats to measurement validity in applied behavior analysis. Suggest ways to control the threats you describe.

   Hint: (See "Threats to Valid Measurement")

3. Describe ways in which applied behavior analysis researchers can control human error before, during, and after data collection.

   Hint: (See "Threats to Accurate and Reliable Measurement")

4. Discuss a training strategy you might use for data collectors/observers.

   Hint: (See "Threats to Accurate and Reliable Measurement")

5. Discuss the role of collecting interobserver agreement measures in applied behavior analysis research. List various methods for assessing agreement for event recording and interval recordings of behavioral data.

   Hint: (See "Using Interobserver Agreement to Assess Behavioral Measurement")

NOTES

1. Strategies for increasing the accuracy of self-reports can be found in Critchfield, Tucker, and Vuchinich (1998) and Finney, Putnam, and Boyd (1998).
2. Single measures, such as pretests and posttests, can provide valuable information on a person's knowledge and skills before and after instruction or treatment. The use of *probes*, occasional but systematic measures, to assess maintenance and generalization of behavior change is discussed in Chapter 30.
3. We recommend using automatic data-recording devices whenever possible. For example, to measure the amount of exercise by boys on stationary bicycles, DeLuca and Holborn (1992) used magnetic counters that automatically recorded the number of wheel revolutions.
4. The official time in the United States can be accessed through the National Institute of Standards and Technology: https://www.time.gov/. The ytterbium clock, though experimental at this time, exceeds the accuracy of the cesium clock with respect to emerging standards of uncertainty, stability, and reproducibility!
5. The preferred spelling of a word may change (e.g., *judgement* becomes *judgment*), but in such cases a new true value is established.

6. IOA can be calculated by product-moment correlations, which range from +1.0 to −1.0. However, expressing IOA by correlation coefficients has two major weaknesses: (a) High coefficients can be achieved if one observer consistently records more occurrences of the behavior than the other, and (b) correlation coefficients provide no assurance that the observers agreed on the occurrence of any given instance of behavior (Poling, Methot, & LeSage, 1995). Hartmann (1977) described the use of *kappa (k)* as a measure of IOA. The *k* statistic was developed by Cohen (1960) as a procedure for determining the proportion of agreements between observers that would be expected as a result of chance. However, the *k* statistic is seldom reported in the behavior analysis literature.
7. Multiple terms are used in the applied behavior analysis literature for the same methods of calculating IOA, and the same terms are sometimes used with different meanings. We believe the IOA terms used here represent the discipline's most used conventions. To point out and preserve some meaningful distinctions among variations of IOA measures, we have introduced several terms.
8. A hand search by Artman, Wolery, and Yoder (2012) of all publications in the *Journal of Applied Behavior Analysis* from 1977 through May 2009 found just four studies that presented both observers' data on the same graph (Luce, Delquardi, & Hall, 1980; Tertinger, Greene, & Lutzker, 1984; Van Houten & Nau, 1980; Van Houten & Rolider, 1984). Artman et al. discovered no articles containing graphic displays of IOA published in *JABA* in the 25 years following the two instances in 1984.

PART 3

Evaluating and Analyzing Behavior Change

Part 2 described considerations and procedures for selecting and defining target behaviors; outlined detailed methods for measuring behavior; and examined techniques for improving, assessing, and reporting the veracity of behavioral measurement. The product of these measurements—*data*—is the medium with which behavior analysts work. But what does the behavior analyst do with data? The five chapters in Part 3 focus on the presentation and interpretation of behavioral data and the design, conduct, and evaluation of experiments that analyze the effects of interventions.

Chapter 6 presents the purpose and benefits of graphic displays of behavioral data, identifies the types of graphs used in applied behavior analysis, explains how to construct line graphs, and describes how behavior analysts interpret graphically displayed data.

Although measurement and graphic displays can reveal whether, when, and to what extent behavior has changed, they alone cannot reveal what brought about the behavior change. Chapters 7 through 10 are devoted to what constitutes *analysis* in applied behavior analysis. Chapter 7 outlines the concepts and assumptions underlining the analysis of behavior; describes the requisite components of an experiment in behavior analysis; and explains how researchers and practitioners apply steady state strategy and the three elements of basic logic—prediction, verification, and replication—to seek and verify functional relations between behavior and its controlling variables. Chapters 8 and 9 describe the logic and operation of reversal, multielement, multiple baseline, and changing criterion designs—the most commonly used experimental designs in applied behavior analysis. Chapter 10 covers a wide range of topics requisite to a more complete understanding of behavioral research. Beginning with the assumption that the research methods of any science should reflect the characteristics of its subject matter, we examine the importance of analyzing the behavior of the individual client or research participant, discuss the value of flexibility in experimental design, identify common confounds to the internal validity of experiments, present methods for assessing the social validity of behavior changes and the treatments that accomplish them, and explain how replication is used to determine the external validity of research. Chapter 10 concludes with a series of issues and questions to consider in evaluating the "goodness" of a published applied behavior analysis study.

PART 3

Evaluating and Analyzing Behavior Change

Chapter 10 concludes with a series of issues and questions to consider in evaluating the "goodness" of a published applied behavior analysis study.

CHAPTER 6

Constructing and Interpreting Graphic Displays of Behavioral Data

LEARNING OBJECTIVES

- State the purpose and list the benefits of graphic displays of behavioral data.
- List and describe the types of graphs used in applied behavior analysis.
- Given a set of behavioral data, select the appropriate data display to communicate quantitative relations.
- Given an unlabeled line graph, provide the correct labels.
- Describe and state the purpose of semilogarithmic charts.
- Describe and discuss the proper use of a cumulative record.
- Describe and discuss the proper use of a scatterplot.
- Given a set of behavioral data, construct and label a line graph.
- Given a set of behavioral data, select the most appropriate graphic display.
- Given a graphic display of behavioral data, identify the presence or absence of variability, level, and trends.

Applied behavior analysts quantify behavior change with direct and repeated measurement. The product of these measurements, called **data**, is the medium with which applied behavior analysts work. In everyday usage, the word *data* refers to a wide variety of often imprecise and subjective information offered as facts. In scientific usage *data* means "the results of measurement, usually in quantified form" (Johnston & Pennypacker, 1993a, p. 365).[1]

Because behavior change is dynamic and ongoing, behavior analysts—practitioners and researchers—strive for direct and continuous contact with the target behavior. The data obtained throughout a behavior change program or research study provide the empirical basis for every important decision: continue with the current intervention or experimental condition, implement a different intervention or condition, or reinstitute a previous condition. But making valid and reliable decisions from raw data (a series of numbers) is difficult, if not impossible, and inefficient. Inspecting a long sequence of numbers will reveal only large and abrupt changes in performance, or no change at all, and important features of behavior change can easily be overlooked.

Consider the three data sets that follow, each one a series of numbers representing consecutive measures of different target behaviors. The first data set shows the number of responses emitted under two conditions (A and B):

Condition A	Condition B
120, 125, 115, 130,	114, 110, 115, 121,
126, 130, 123, 120,	110, 116, 107, 120,
120, 127	115, 112

The second data set comprises consecutive measures of the percentage of correct responses:

80, 82, 78, 85, 80, 90, 85, 85, 90, 92

The third data set consists of responses per minute measured on successive school days:

35, 42, 33, 30, 25, 38, 41, 35, 35, 32, 40, 35, 49, 33, 30

What do these numbers tell you? What conclusions can you draw from each data set? How long did it take you to reach your conclusions? How sure of them are you? What if the data sets contained many more measures to interpret? How likely is it that others interested in the behavior change program or research study would reach the same conclusions? How could these data be directly and effectively communicated to others? This chapter will show you how graphs can help answer these questions.

Graphs—relatively simple formats for visually displaying relationships among and between a series of measurements and relevant variables—help people "make sense" of quantitative information. Graphs are the major device with which applied behavior analysts organize, store, interpret, and communicate the results of their work. Figure 6.1 includes a graph for each of the three data sets presented previously. The top graph reveals a level of responding during Condition B lower than measured during Condition A. The middle graph shows an upward trend over time in correct responding. Evident in the bottom graph is a variable pattern of responding, characterized by higher response rates during the first part of each week and a decreasing trend toward the end of each week. The graphs in Figure 6.1 illustrate three fundamental properties of behavior change over time—level, trend, and variability—each of

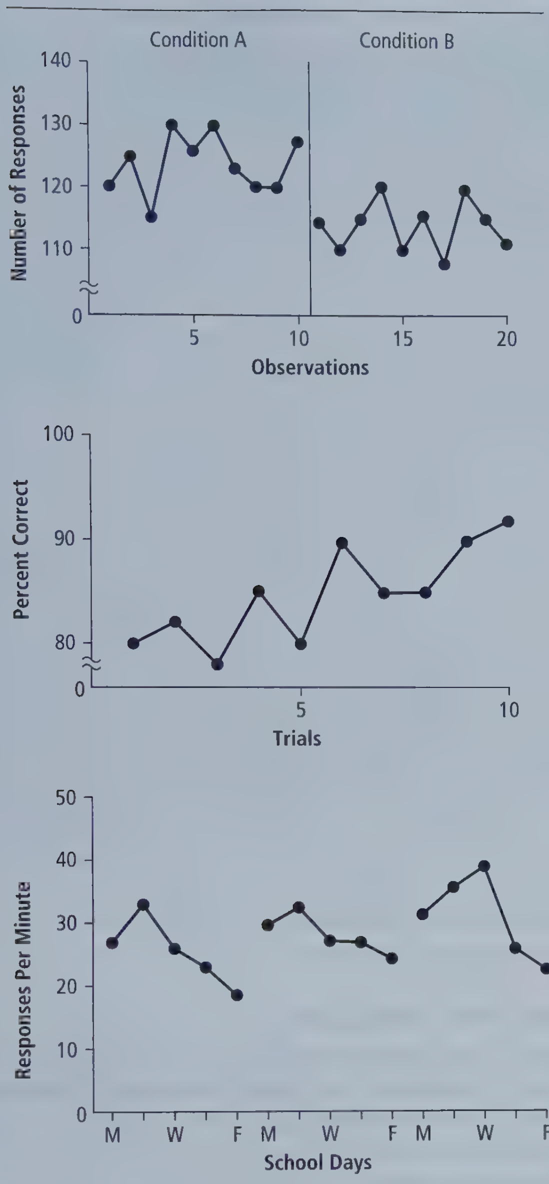

Figure 6.1 Graphic displays of three sets of hypothetical data illustrating changes in the level of responding across conditions (top), trend (middle), and cyclical variability (bottom).

which will be discussed in detail later in the chapter. Graphic displays of behavioral data are an effective means of illustrating and communicating these aspects of behavior change.

PURPOSE AND BENEFITS OF GRAPHIC DISPLAYS OF BEHAVIORAL DATA

> *In essence, the function of the graph is to communicate, in a readily assimilable and attractive manner, descriptions and summaries of data that enable rapid and accurate analysis of the facts.*
>
> —Parsonson and Baer (1978, p. 134)

The graphic display and visual analysis of behavioral data provide seven benefits to behavior analysts and their clients. First, plotting each measure of behavior on a graph soon after the observational period gives the practitioner or researcher immediate access to an ongoing visual record of the participant's behavior. Continual assessment of behavior change enables treatment and experimental decisions to be responsive to the participant's performance. Graphs provide the "close, continual contact with relevant outcome data" that can lead to "measurably superior instruction" (Bushell & Baer, 1994, p. 9).

Second, direct and continual contact with the data in a readily analyzable format enables the researchers to explore interesting variations in behavior as they occur. Some of the most important research findings about behavior have been made because scientists followed the leads suggested by their data instead of following predetermined experimental plans (Sidman, 1960, 1994; Skinner, 1956).

Third, graphs, like statistical analyses of behavior change, are judgmental aids: devices that help practitioners, researchers, and consumers interpret the results of a study or treatment (Michael, 1974). In contrast to the statistical tests of inference used in group comparison research, however, visual analysis of graphed data takes less time, is relatively easy to learn, imposes no predetermined or arbitrary level for determining the significance of behavior change, and does not require the data to meet preset mathematical properties or statistical assumptions to be analyzed.[2]

Fourth, visual analysis is a conservative method for determining the significance of behavior change. A behavior change deemed statistically significant by a test of mathematical probabilities may not look very impressive when the data are plotted on a graph that reveals great variability and repeated overlaps in the data within and across experimental or treatment conditions. This screening out of weak variables in favor of robust interventions has enabled applied behavior analysts to develop a useful technology of behavior change (Baer, 1977b).[3]

Fifth, graphs enable and encourage independent judgments and interpretations of the meaning and significance of behavior change. Instead of relying on conclusions based on statistical manipulations of the data or an author's interpretations, readers of published reports of applied behavior analysis can (and should) form independent conclusions based on their visual analysis of the data.[4]

Sixth, in addition to their primary purpose of displaying relationships between behavior change (or lack thereof) and variables manipulated by the researcher or practitioner, graphs can provide feedback to the people whose behavior the graphs depict. Numerous studies have reported improved performance of a wide variety of target behaviors by participants when receiving graphical feedback, alone or as part of a package intervention, (e.g., Gil & Carter, 2016; Grossi & Heward, 1998; Perrin, Fredrick, & Klick, 2016; Quinn, Miltenberger, Abreu, & Narozanick, 2017; Squires et al., 2008). Graphing one's own performance has also been demonstrated to be an effective intervention for a variety of academic and behavior change objectives (e.g., Kasper-Ferguson & Moxley, 2002; Stolz, Itoi, Konrad, & Alber-Morgan, 2008).

Seventh, graphs facilitate the communication, dissemination, and comprehension of behavior change among a wide variety of recipients (e.g., professionals, parents, government agents responsible for policymaking). A well-constructed

BOX 6.1

Page Space Devoted to Graphs by Behavior Analysis Journals

Open any issue of the *Journal of Applied Behavior Analysis (JABA)* to an article reporting an experimental study and chances are good you will see a graph. If not, turn a page or two in either direction, and a graph will almost certainly appear.

Does that matter? Yes, it does, for several reasons. First, *JABA's* frequent use of graphs emphasizes the central role of visual analysis of data in applied behavior analysis and underscores the obligation that practitioners, researchers, and journal article reviewers and editors know how to create and interpret graphic displays. Second, graphs take up a greater proportion of page space of journals in scientific disciplines (i.e., natural sciences) considered more mature, harder, and with greater consensus of knowledge than they do in less mature, softer scientific disciplines (i.e., social sciences) (Arsenault, Smith, & Beauchamp, 2006; Best, Smith, & Stubbs, 2001; Cleveland, 1984; Smith, Best, Stubbs, Johnston, & Bastiani-Archibald, 2000).

How do behavior analysis journals compare to other sciences in that regard? In an effort to shed light on that question, Kubina, Kostewicz, and Datchuk (2008) computed the fractional graph area (FGA)—the proportion of page space devoted to graphs—in research articles from one randomly selected issue from each of three volume years (1995, 2000, and 2005) from 11 behavioral journals. Diagrams and flow charts that did not graphically present quantitative data were not included.

Kubina and colleagues (2008) reported a mean FGA of .057 for all behavior analysis journals, which included journals such as *Behavior Therapy, Child and Family Therapy, Cognitive and Behavioral Practices*, and the *Journal of Behavior Therapy and Experimental Psychiatry* (see Figure A). The four behavior analysis journals with the highest FGA ranged from .08 for *The Analysis of Verbal Behavior* to .17 for the *Journal of the Experimental Analysis of Behavior (JEAB)*, equal to the FGAs of journals in the natural sciences, which range from .06 in geology to .18 in chemistry (as measured by Cleveland [1984]).

Notable among Kubina and colleagues' findings is that behavior analysis flagship journals' (*JABA* and *JEAB*) composite FGA of .147 ranked third among the natural sciences, trailing only chemistry and physics. While the authors cautioned that their results were obtained from just three issues from each journal, they noted that Best, Smith, and Stubbs's (2001) independent assessment of page space devoted to graphs yielded an identical measure of .17 for *JEAB*.

graph condenses aggregated individual numerical data so that relevant elements are visually salient and can be understood commonly.

Behavior analysts' heavy reliance on graphic data displays puts them in good company with scientists in other natural sciences (see Box 6.1).

GRAPHS USED BY APPLIED BEHAVIOR ANALYSTS

The graphic displays most often used by applied behavior analysts are line graphs, bar graphs, cumulative records, ratio charts, and scatterplots.

Line Graphs

The simple **line graph**, or frequency polygon, is far and away the most common graphic format in applied behavior analysis. Based on the Cartesian coordinate system created by René Descartes in the 17th century, the line graph is a two-dimensional area formed by the intersection of two perpendicular reference lines, called *axes*. Any point within the area enclosed by the two axes represents a specific relationship between values of the two dimensions (or variables) described by the intersecting lines. In applied behavior analysis, each point on a line graph shows the level of some quantifiable dimension of the target behavior (i.e., the **dependent variable**) in relation to a specified point in time and/or environmental condition (i.e., the **independent variable**) in effect when the measure was taken. Comparing points on a graph reveals the presence and extent of changes in level, trend, and/or variability within and across conditions.

Parts of a Basic Line Graph

Although graphs vary considerably in their final appearance, all properly constructed line graphs share certain elements. The basic parts of a simple line graph are shown in Figure 6.2 and described in the following sections.

1. Horizontal Axis. The *horizontal axis*, also called the *x*-axis, or *abscissa*, is a straight horizontal line that most often represents the passage of time and the presence, absence, and/or value of the independent variable. A defining characteristic of applied behavior analysis is the repeated measurement of behavior across time. Time is also the unavoidable dimension in which all manipulations of the independent variable occur. On most line graphs the passage of time is marked in equal intervals on the horizontal axis. The horizontal axis in Figure 6.2 represents consecutive observational sessions from 9:00 to 10:00 AM on weekdays.

The horizontal axis on some graphs represents different values of the independent variable instead of time. For example, Lalli, Mace, Livezey, and Kates (1998) scaled the horizontal axis of one graph in their study from less than 0.5 meter to 9.0 meters to show how the occurrence of self-injurious behavior by a girl with severe intellectual disabilities decreased as the distance between the therapist and the girl increased.

2. Vertical Axis. The *vertical axis*, also called the *y*-axis, or *ordinate*, is a vertical line drawn upward from the left-hand end of the horizontal axis. The vertical axis most often represents

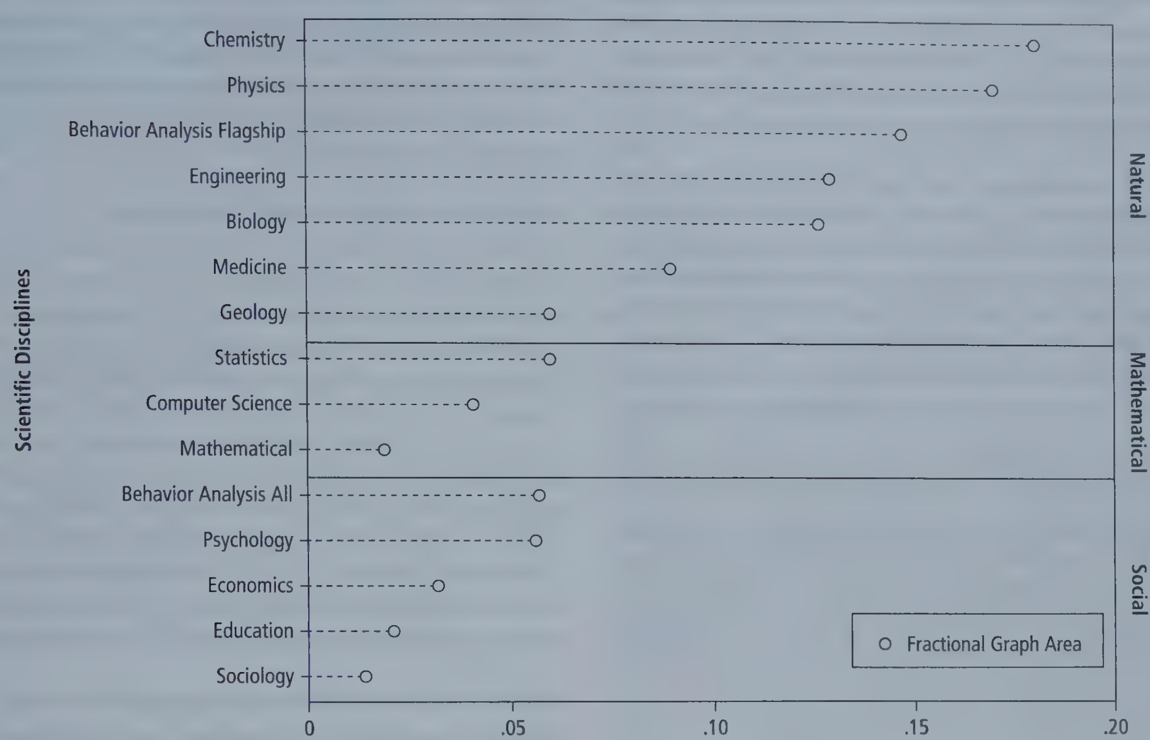

Figure A Proportion of page space devoted to graphic data displays by journals in various scientific disciplines. (Behavior analysis flagship journals are *JABA* and *JEAB*.)

From "An Initial Survey of Fractional Graph and Table Area in Behavioral Journals," by R. M. Kubina, D. E. Kostewicz, and S. M. D. Datchuk, 2008, *The Behavior Analyst, 31*, p. 65. Copyright 2008 by the Association for Behavior Analysis International. Used by permission.

a range of values of the dependent variable, which in applied behavior analysis is always some quantifiable dimension of behavior. The intersection of the horizontal and vertical axes is called the *origin* and most often, though not necessarily, represents the zero value of the dependent variable. Each successive point upward on the vertical axis represents a greater value of the dependent variable. The most common practice is to mark the vertical axis with an **equal-interval scale**, in which equal distances on the axis represent equal absolute amounts of behavior change. The vertical axis in Figure 6.2 represents the number of 50-meter laps walked in 1 hour.

3. Axis Labels. *Axis labels* are brief descriptions of the dimension represented by and scaled along each axis; most often a response measure on the vertical axis and experimental conditions across time on the horizontal axis.

4. Condition Change Lines. *Condition change lines* are vertical lines drawn upward from the horizontal axis to show points in time at which changes in the independent variable occurred. The condition change lines in Figure 6.2 coincide with the introduction or withdrawal of an intervention the researchers called Token Reinforcement.

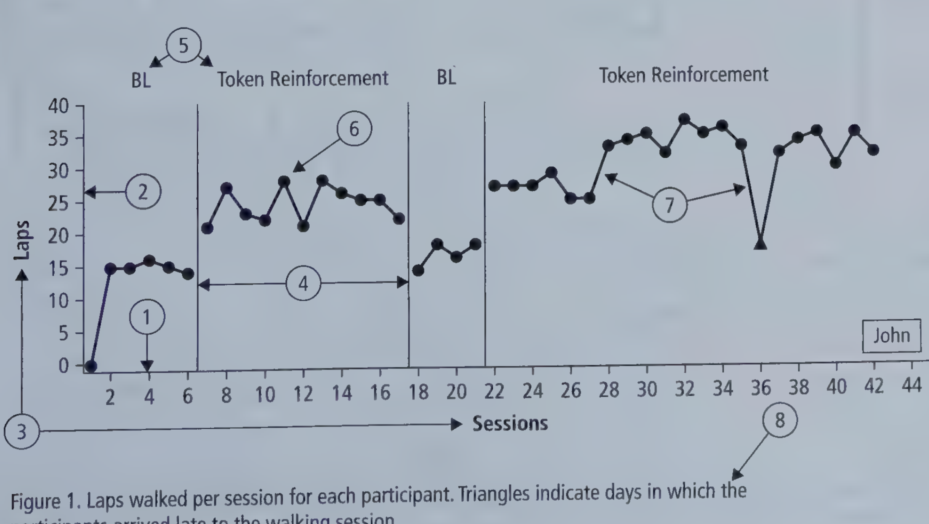

Figure 6.2 Major parts of a simple line graph: (1) horizontal axis, (2) vertical axis, (3) axis labels, (4) condition change lines, (5) condition labels, (6) data points, (7) data path, and (8) figure caption. (Original figure includes graphs for four additional participants.)

Based on "Using Token Reinforcement to Increase Walking for Adults with Intellectual Disabilities" by H. Krentz, R. Miltenberger, and D. Valbuena, 2016, *Journal of Applied Behavior Analysis, 49*, p. 749. Copyright 2016 by the Society for the Experimental Analysis of Behavior.

5. Condition Labels. *Condition labels* are single words or brief descriptive phrases printed along the top of the graph and parallel to the horizontal axis. These labels identify the experimental conditions (i.e., the presence, absence, or some value of the independent variable) in effect during each phase of the study.[5]

6. Data Points. Each *data point* on a graph represents two facts: (a) a quantifiable measure of the target behavior recorded during a given observation period and (b) the time and/or experimental conditions under which that particular measurement was conducted. Using two data points from Figure 6.2 as examples, we can see that John walked 14 laps during Session 6, the last session of the first baseline phase, and 21 laps in Session 7, the first session of the first phase of the token reinforcement condition.

7. Data Path. Connecting successive data points within a given condition with a straight line creates a **data path**. The data path represents the level and trend of behavior between successive data points and is a primary focus of attention in the interpretation and analysis of graphed data. Because behavior is rarely observed and recorded continuously in applied behavior analysis, the data path represents an estimate of the actual course taken by the behavior during the time between the two consecutive measures. The more measures and resultant data points per unit of time (given an accurate observation and recording system), the more confidence one can place in the story told by the data path.

8. Figure Caption. The *figure caption* is a concise statement that, in combination with the axis and condition labels, provides the reader with sufficient information to identify the independent and dependent variables. The figure caption should explain any symbols (see Figure 6.2) or observed but unplanned events that may have affected the dependent variable and point out and clarify any potentially confusing features of the graph (see Figure 6.6 and Figure 6.7).

Variations of the Simple Line Graph: Multiple Data Paths

The line graph is a remarkably versatile vehicle for displaying behavior change. Whereas Figure 6.2 is an example of the line graph in its simplest form (one data path showing a series of successive measures of behavior across time and experimental conditions), by the addition of multiple data paths, the line graph can display more complex behavior–environment relations. Graphs with multiple data paths are used frequently in applied behavior analysis to show (a) two or more dimensions of the same behavior, (b) two or more different behaviors, (c) the same behavior under different and alternating experimental conditions, (d) changes in target behavior relative to the changing values of an independent variable, and (e) the behavior of two or more participants.

Two or More Dimensions of the Same Behavior. Showing multiple dimensions of the dependent variable on the same graph enables visual analysis of the absolute and relative effects of the independent variable on those dimensions. Figure 6.3 shows the results of a study of the effects of training three members of a women's college basketball team proper foul shooting form

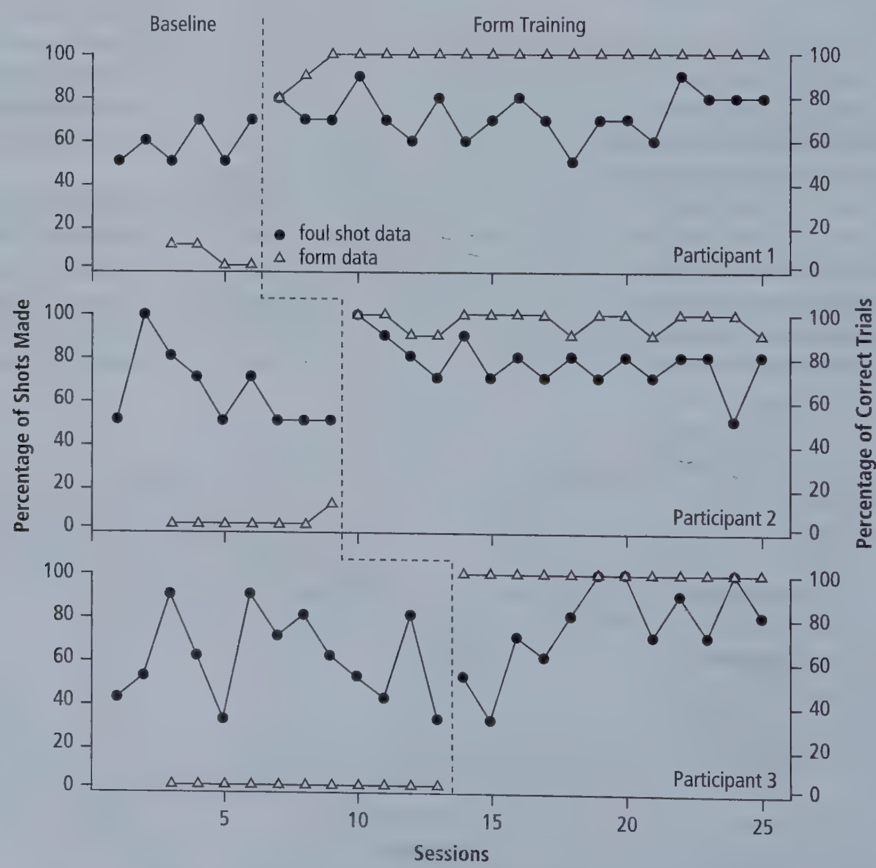

Figure 1. Percentage of shots made (filled circles) and percentage of shots taken with correct form (open triangles) across sessions for each participant.

Figure 6.3 Graph with multiple data paths showing the effects of the independent variable (Form Training) on two dimensions (accuracy and topography) of the dependent variable.

From "The Effects of Form Training on Foul-Shooting Performance in Members of a Women's College Basketball Team," by C. N. Kladopoulos and J. J. McComas, 2001, *Journal of Applied Behavior Analysis, 34*, p. 331. Copyright 2001 by the Society for the Experimental Analysis of Behavior, Inc. Used by permission.

(Kladopoulos & McComas, 2001). The data path created by connecting the open triangle data points shows changes in the percentage of foul shots executed with the proper form, whereas the data path connecting the solid data points reveals the percentage of foul shots made. Had the experimenters recorded and graphed only the players' foul shooting form, they would not have known whether any improvements in the target behavior on which training was focused (correct foul shooting form) coincided with improvements in the behavior by which the social significance of the study would ultimately be judged—foul shooting accuracy. By measuring and plotting both form and outcome on the same graph, the experimenters were able to analyze the effects of their treatment procedures on two critical dimensions of the dependent variable.

Two or More Different Behaviors. Multiple data paths are also used to facilitate simultaneous comparison of the effects of experimental manipulations on two or more different behaviors. Determining the variation of two behaviors as a function of changes in the independent variable is accomplished more easily if both behaviors can be displayed on the same graph. Figure 6.4 shows the percentage of intervals in which a boy with autism exhibited stereotypy (e.g., repetitive body movements, rocking) across three conditions, and the number of times that he raised his hand for attention (in the attention condition), signed for a break (in the demand condition), and signed for access to preferred tangible stimuli (in the no-attention condition) in a study investigating a strategy called *functional communication training* (Kennedy, Meyer, Knowles, & Shukla, 2000).[6] By recording and graphing both stereotypic responding and appropriate behavior, the investigators were able to determine whether increases in alternative communication responses (raising his hand and signing) were accompanied by reductions in stereotypy. Note that Figure 6.4 includes a second vertical axis showing the dimensional units and scaling for signing frequency. Because of the differences in scale, readers of dual-vertical axis graphs must view them with care, particularly when assessing the magnitude of behavior change.

Measures of the Same Behavior Under Different Conditions. Multiple data paths can also be used to represent measures of the same behavior taken under different experimental conditions that alternate throughout an experimental phase.

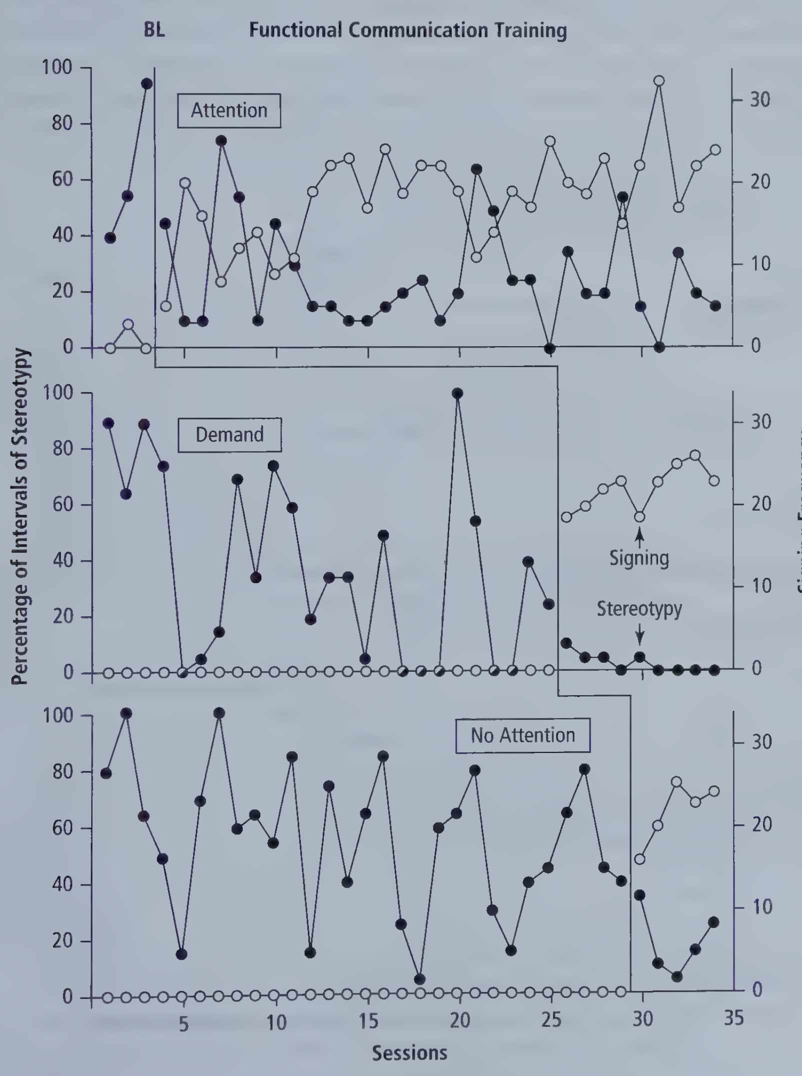

Figure 2. Occurrence of stereotypy for James across attention, demand, and no-attention conditions. Data are arrayed as the percentage of intervals of stereotypy on the left *y* axis and number of signs per sessions on the right *y* axis.

Figure 6.4 Graph with multiple data paths showing two different behaviors by one participant during baseline and training across three different conditions. Note the different dimensions and scaling of the dual vertical axes.

Shukla, 2000, *Journal of Applied Behavior Analysis, 33*, p. 565. Copyright 2000 by the Society for the Experimental Analysis of Behavior, Inc. Used by permission.

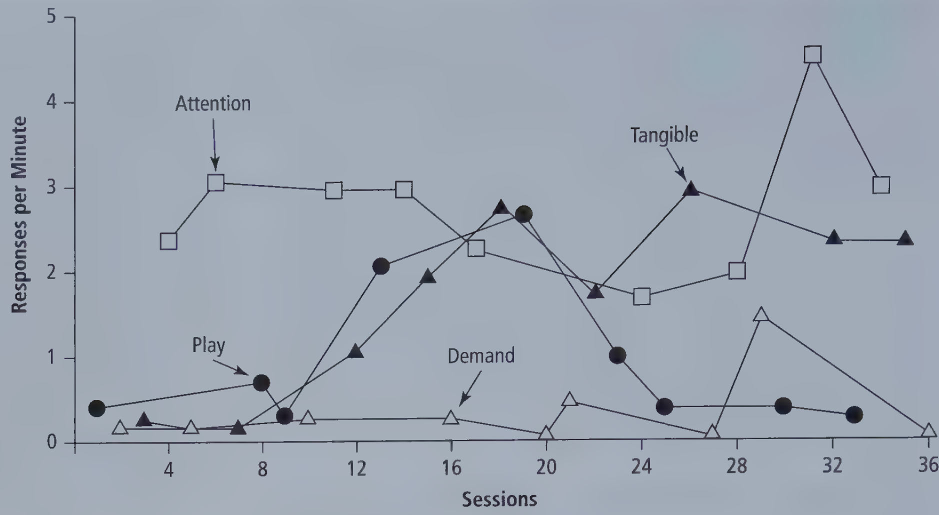

Figure 1. Rate of self-injurious behavior during the initial functional analysis.

Figure 6.5 Graph with multiple data paths showing the same behavior measured under four different conditions.

Based on "The Influence of Therapist Attention on Self-Injury during a Tangible Condition" by J. W. Moore, M. M. Mueller, M. Dubard, D. S. Roberts, and H. E. Sterling-Turner, 2002, *Journal of Applied Behavior Analysis, 35,* p. 285. Copyright 2002 by the Society for the Experimental Analysis of Behavior, Inc. Used by permission.

Figure 6.5 shows self-injurious responses per minute by a 6-year-old girl with developmental disabilities under four different conditions (Moore, Mueller, Dubard, Roberts, & Sterling-Turner, 2002). Graphing an individual's behavior under multiple conditions on the same set of axes allows direct visual comparisons of differences in absolute levels of responding at any given time as well as relative changes in performance over time.

Changing Values of an Independent Variable. Multiple data path graphs can also show changes in the target behavior (shown on one data path) relative to changing values of the independent variable (represented by a second data path). In each of the two graphs in Figure 6.6 one data path shows the duration of problem behavior (plotted against the left-hand *y*-axis scaled in seconds) relative to changes in noise level depicted by a second data path (plotted

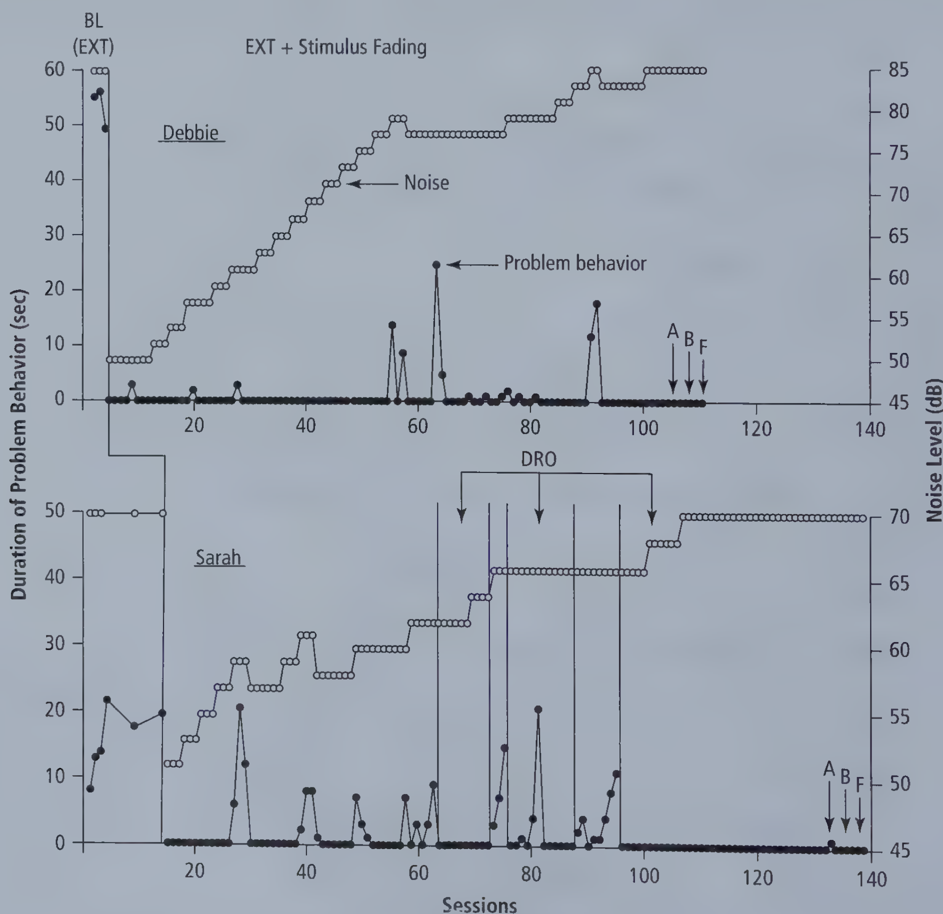

Figure 4. Results of Debbie's and Sarah's treatment evaluation. Sessions marked A and B near the end of treatment indicate two generalization probes in the natural environment; F indicates a follow-up probe.

Figure 6.6 Graph using two data paths to show the duration of problem behavior (dependent variable) by two adults with severe or profound intellectual disabilities as noise level was increased gradually (independent variable).

From "Functional Analysis and Treatment of Problem Behavior Evoked by Noise", B. E. McCord, B. A. Iwata, T. L. Galensky, S. A. Ellingson, and R. J. Thomson, 2001, Reproduced with permission of John Wiley & Sons Inc.

against the right-hand *y*-axis scaled in decibels) (McCord, Iwata, Galensky, Ellingson, & Thomson, 2001).

The Same Behavior of Two or More Participants. Multiple data paths are sometimes used to show the behavior of two or more participants on the same graph.

Depending on the levels and variability of the data encompassed by each data path, a maximum of four different data paths can be displayed effectively on one set of axes. However, there is no rule; Didden, Prinsen, and Sigafoos (2000) displayed five data paths in a single display. If too many data paths are displayed on the same graph, the benefits of making additional comparisons may be outweighed by the distraction of too much visual "noise." A combination of data paths and bars can help viewers distinguish measures of different behaviors or events. In a study evaluating a toilet training intervention, Greer, Neibert, and Dozier (2016) used one data path to represent the number self-initiations, another data path for the percentage of appropriate eliminations, and bars for the number of accidents (see Figure 6.7).

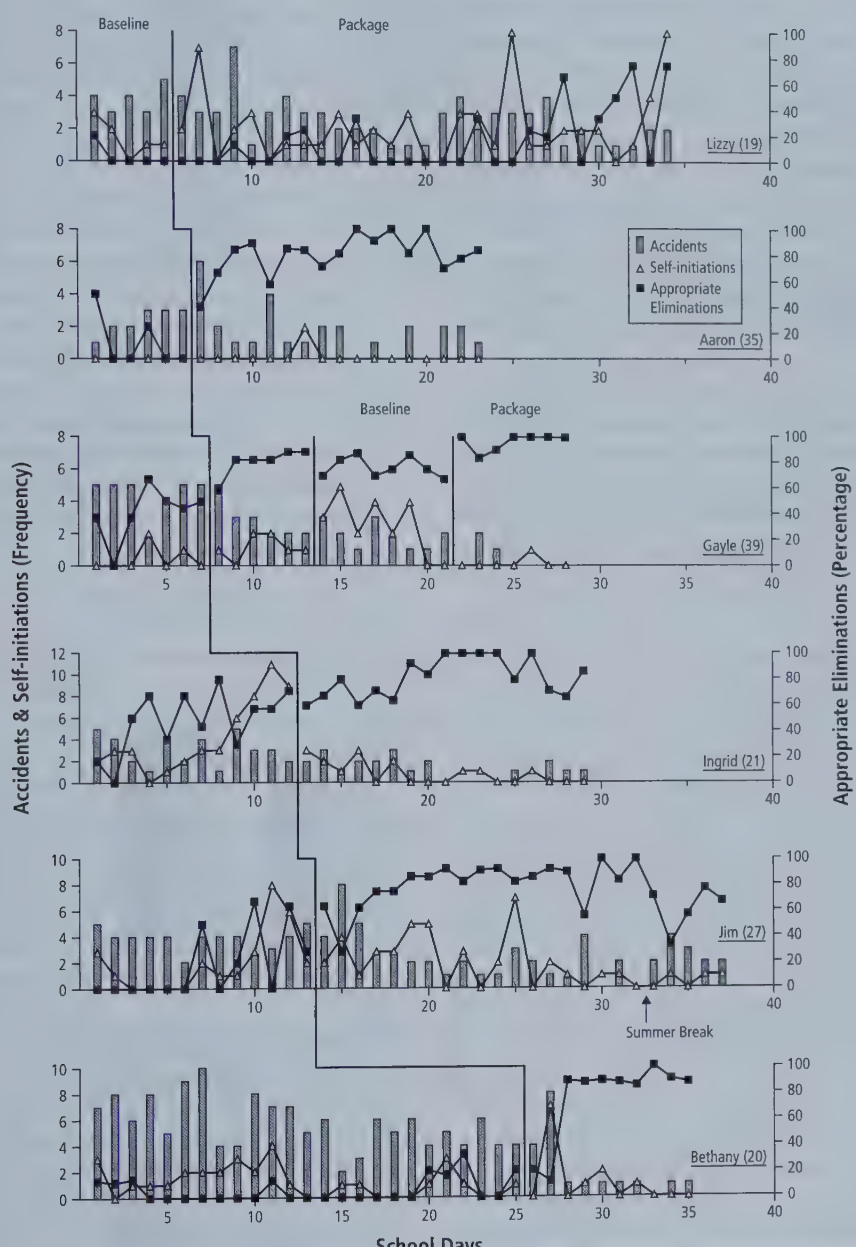

Figure 1. Results of the component analysis for children exposed to the toilet-training package after baseline. Each chid's age (in months) is noted parenthetically.

Figure 6.7 Graph using a combination of data path and bars to display changes in three response classes.

Bar Graphs

The **bar graph**, or histogram, is a simple and adaptable format for graphically summarizing data. Bar graphs sacrifice the presentation of the variability and trends in data (which are apparent in a line graph) in exchange for the efficiency of summarizing and comparing large amounts of data in a simple, easy-to-interpret format.

Bar graphs are used frequently to summarize the performance of a participant or group of participants during different conditions. For example, Figure 6.8 shows the mean percentage of spelling worksheet items completed and completed correctly by four students during baseline and the combined generalization programming and maintenance conditions that followed training each child to recruit teacher attention while working (Craft, Alber, & Heward, 1998).

Bar graphs that present a measure of central tendency, such as the mean or median score for each condition, may mask important variability in the data. The range of measures represented by a mean or median can be shown with range bars (e.g., Putnam & Tiger, 2016). Figure 6.9 is an example of a bar graph showing both the range of measures and individual performances.

Bar graphs are also used to display discrete sets of data that are not related to one another by a common underlying dimension by which the horizontal axis could be scaled. For example, in a study analyzing the effects of establishing operations on preference assessments, Gottschalk, Libby, and Graff (2000) used bar graphs to show the percentage of trials in which four children reached toward and picked up different items (see Figure 6.10).

The *y*-axis on some bar graphs is scaled to negative values/below zero to show amount of behavior change above or below a baseline average or point in time (e.g., Greer, Neibert, & Dozier, 2016; Jessel, Hanley & Ghaemmaghami, 2016; Meindl, Ivy, Miller, Neef, & Williamson, 2013).

Cumulative Records

In the 1930s, Skinner invented the **cumulative recorder**, a device that automatically draws a graph of a subject's rate of behavior. In a book cataloging 6 years of experimental research on schedules of reinforcement, Ferster and Skinner (1957) described a cumulative record in the following manner:

> A graph showing the number of responses on the ordinate against time on the abscissa has proved to be the most convenient representation of the behavior observed in this research. Fortunately, such a "cumulative" record may be made directly at the time of the experiment. The record is raw data, but it also permits a direct inspection of rate and changes in rate not possible when the behavior is observed directly. . . . Each time the bird responds, the pen moves one step across the paper. At the same time, the paper feeds continuously. If the bird does not respond at all, a horizontal line is drawn in the direction of the paper feed. The faster the bird pecks, the steeper the line. (p. 23)

For decades, cumulative records (graphs produced by a cumulative recorder) served as the primary form of data display in basic behavior analysis research laboratories around the world (Kangas & Cassidy, 2010). Although behavioral researchers seldom use cumulative recorders today, the cumulative graphs remain an important form of data display in both experimental and applied behavior analysis.[7]

A **cumulative record** is constructed by adding the number of responses recorded during each observation period (thus the term *cumulative*) to the total number of responses recorded during all previous observation periods. The *y*-axis value of any data point on a cumulative graph represents the total number of responses recorded since the beginning of data collection. Exceptions occur when the data path resets to the 0 value of the *y*-axis and begins its ascent again. Resets occur when the total number of responses has exceeded the upper limit of the *y*-axis scale, a new condition is implemented (Wilson & Gratz, 2016), or a performance criterion has been met (Williams, Perez-Gonzales, & Queiroz, 2005).

Figure 6.12 shows the cumulative number of spelling words mastered by a man with intellectual disabilities during baseline and two training conditions (Neef, Iwata, & Page, 1980). The individual mastered 1 word during the 12 sessions of baseline (social praise for correct spelling responses and rewriting incorrectly spelled words three times), 22 words under the interspersal condition (baseline procedures plus the presentation of a previously learned word after each unknown word), and 11 words under the high-density reinforcement condition (baseline procedures plus social praise given after each trial for task-related behaviors such as paying attention and writing neatly).

In addition to the total number of responses recorded at any given point in time, cumulative records show the overall and local response rates. Rate is the number of responses emitted per unit of time, usually reported as responses per minute in applied behavior analysis. An **overall response rate** is the average rate of response over a given time period, such as during a specific session, phase, or condition of an experiment. Overall rates are calculated by dividing the total number of responses recorded during the period by the number of observation periods indicated on the horizontal axis. In Figure 6.12 the overall response rates are 0.46 and 0.23 words mastered per session for the interspersal and high-density reinforcement conditions, respectively.[8]

On a cumulative record, the steeper the slope, the higher the response rate. To produce a visual representation of an overall rate on a cumulative graph, the first and last data points of a given series of observations should be connected with a straight line. A straight line connecting Points a and c in Figure 6.12 would represent the learner's overall rate of mastering spelling words during the interspersal condition. A straight line connecting Points a and e represents the overall rate during the high-density reinforcement condition. Relative rates of response can be determined by visually comparing one slope to another: the steeper the slope, the higher the rate of response. A visual comparison of Slopes a–c and a–e shows that the interspersal condition produced the higher overall response rate.

Response rates often fluctuate within a given period. The term **local response rate** refers to the rate of response during periods smaller than that for which an overall rate has been given. Over the last four sessions of the study shown in

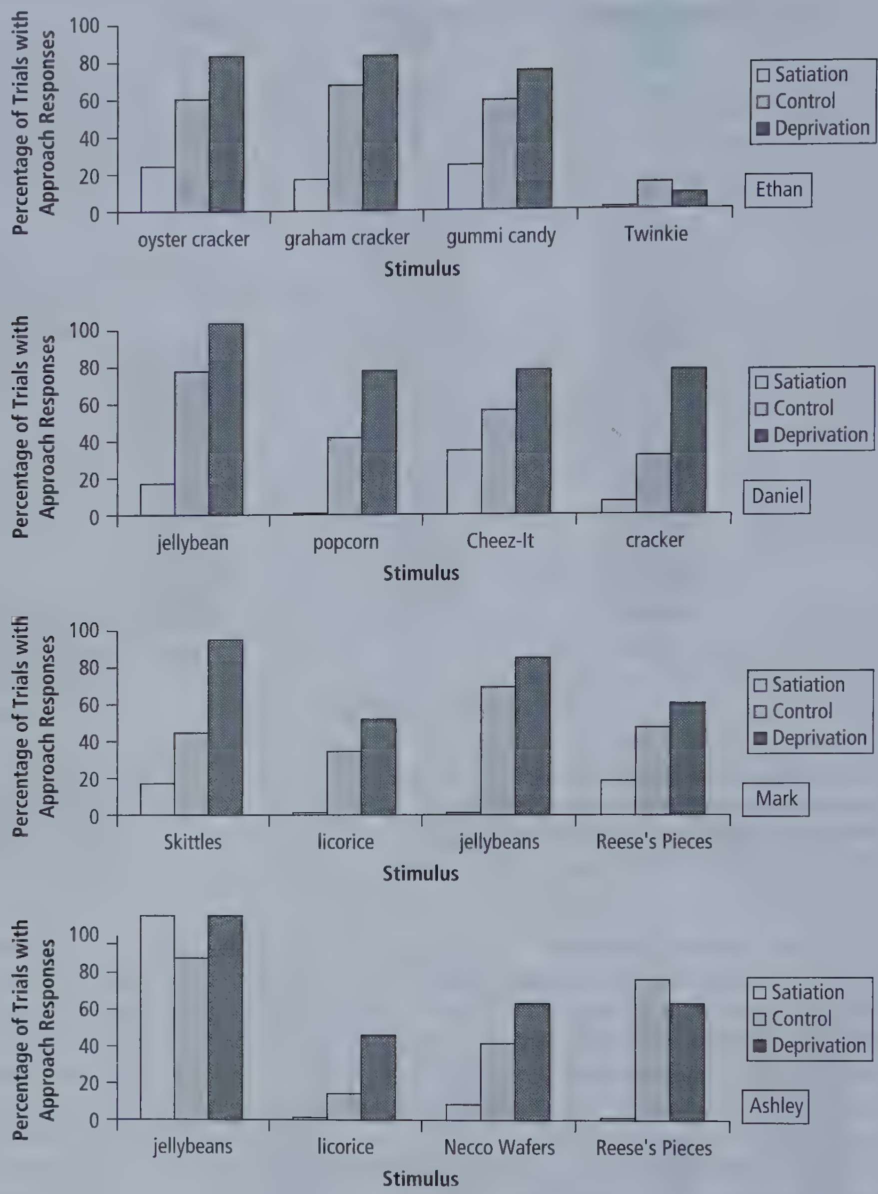

Figure 1. Percentage of approach responses across conditions for Ethan, Daniel, Mark, and Ashley.

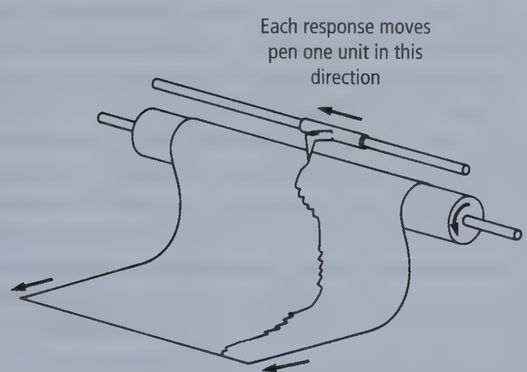

Figure 6.11 Diagram of a cumulative recorder.

Based on *Schedules of Reinforcement*, pp. 24–25, by C. B. Ferster and B. F. Skinner, 1957, Upper Saddle River, NJ: Prentice Hall. Copyright 1957 by Prentice Hall.

Figure 6.12, the learner exhibited a local rate of responding during interspersal training (Slope b–c) that was considerably higher than his overall rate for that condition. At the same time his performance during the final four sessions of the high-density reinforcement condition (Slope d–e) shows a lower local response rate than his overall rate for that condition.

A legend giving the slopes of some representative rates can aid considerably in the determination and comparison of relative response rates both within and across cumulative curves plotted on the same set of axes (e.g., see Kennedy & Souza, 1995, Figure 2). However, very high rates of responding are difficult to compare visually with one another on cumulative records.

> Although the rate of responding is directly proportional to the slope of the curve, at slopes above 80 degrees small differences in angle represent very large differences in

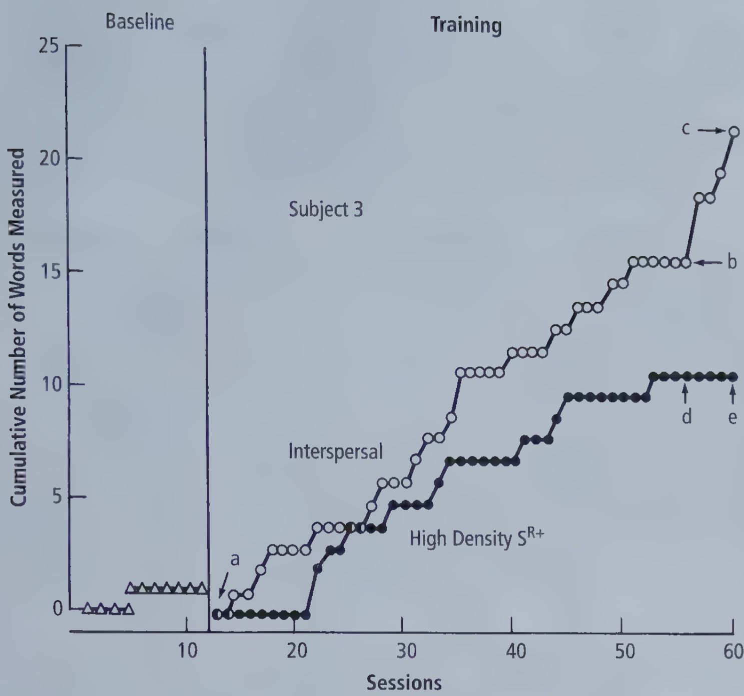

Figure 6.12 Cumulative graph of number of spelling words learned by a man with intellectual disabilities during baseline, interspersal training, and high-density reinforcement training. Points a–e have been added to illustrate the differences between overall and local response rates.

Based on "The Effects of Interspersal Training Versus High Density Reinforcement on Spelling Acquisition and Retention" by N. A. Neef, B. A. Iwata, and T. J. Page, 1980, *Journal of Applied Behavior Analysis, 13*, p. 156. Copyright 1980 by the Society for the Experimental Analysis of Behavior, Inc. Adapted by permission.

rate; and although these can be measured accurately, they cannot be evaluated easily by [visual] inspection. (Ferster & Skinner, 1957, pp. 24–25)

Even though cumulative records derived from continuous recording are the most directly descriptive displays of behavioral data available, two other features of behavior, in addition to the comparison of very high rates, can be difficult to determine on some cumulative graphs. One, although the total number of responses since data collection began can be easily seen on a cumulative graph, the number of responses recorded for any given session can be hard to ascertain, given the number of data points and the scaling of the vertical axis. Two, gradual changes in slope from one rate to another can be hard to detect on cumulative graphs.

A cumulative graph may be preferable to a noncumulative line graph in four situations. First, cumulative records are desirable when the total number of responses emitted over time is important or when progress toward a specific goal can be measured in cumulative units of behavior. The number of new words learned, dollars saved, or miles trained for an upcoming marathon are examples. One look at the most recent data point on the graph reveals the total amount of behavior up to that point in time.

Second, a cumulative graph may be more effective than a noncumulative graph when used as a source of feedback for clients. This is because both total progress and relative rate of performance are easily detected by visual inspection. Further, a cumulative graph does not reveal decelerating trends; it either ascends or plateaus. For individuals for whom a decelerating trend may signal failure, spark embarrassment, incite retaliation by members of a peer group, or otherwise affect them negatively, a cumulative graph, with its ascending trend (or plateaus), may mitigate concerns.

Third, a cumulative record should be used when the target behavior can occur or not occur just once per observation session. In these instances, the effects of an intervention may be easier to detect on a cumulative graph. Figure 6.13 shows the same data plotted on a noncumulative graph and a cumulative graph. The cumulative graph clearly shows a relation between behavior and intervention, whereas the noncumulative graph gives the impression of greater variability in the data than really exists.

Fourth, cumulative records can "reveal the intricate relations between behavior and environmental variables" (Johnston & Pennypacker, 2009, p. 317). Figure 6.14 is an excellent example of how a cumulative graph enables a detailed analysis of behavior change (Hanley, Iwata, & Thompson, 2001). By plotting the data from single sessions cumulatively by 10-second intervals, the researchers revealed patterns of responding not shown by a graph of session-by-session data. Comparing the data paths for the three sessions for which the results were graphed cumulatively (Mult #106, Mixed #107, and Mixed #112) revealed two undesirable patterns of responding (in this case, pushing a switch that operated a voice output device that said "talk to me, please" as an alternative to self-injurious behavior and aggression) that are likely to occur during mixed schedules, and the benefits of including schedule-correlated stimuli (Mult #106).

Ratio Charts

All of the line graphs discussed so far have been equal-interval graphs on which the distance between any two consecutive points on each axis is always the same. On the horizontal axis, the distance between data on Day 1 and Day 2 has the same distance as Day 11 to Day 12; on the vertical axis, the distance between 10 and 20 responses per minute visually matches the distance between 35 and 45 responses per minute. On an equal-interval graph, equal vertical distances on the vertical axis represent equal amounts of behavior change, whether the performance increases or decreases.

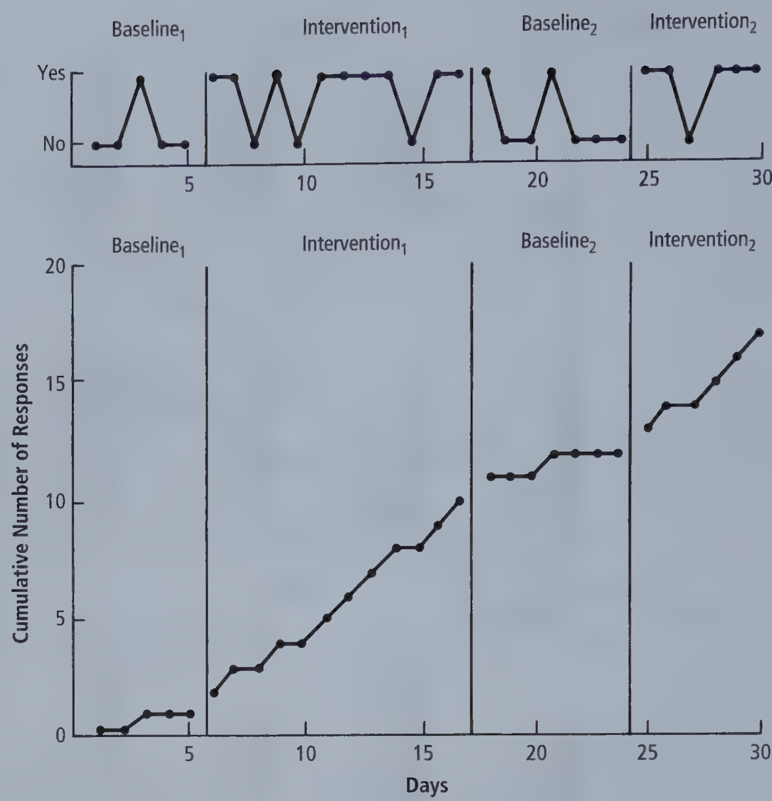

Figure 6.13 Same set of hypothetical data plotted on noncumulative and cumulative graphs. Cumulative graphs more clearly reveal patterns of and changes in responding for behaviors that can occur only once during each period of measurement.

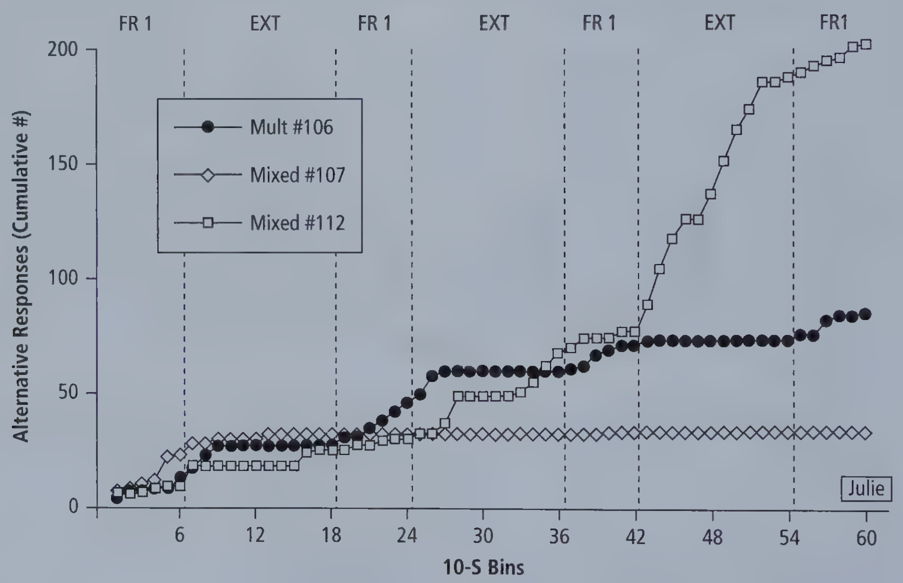

Figure 4. Cumulative number of alternative responses across schedule components for three sessions from Julie's assessment of schedule-correlated stimuli. Open symbols represent two mixed-schedule sessions; filled symbols represent a single multiple-schedule session.

Figure 6.14 Cumulative record used to make a detailed analysis and comparison of behavior across components of multiple- and mixed-reinforcement schedules within specific sessions of a study.

Based on "Reinforcement Schedule Thinning Following Treatment with Functional Communication Training" by G. P. Hanley, B. A. Iwata, and R. H. Thompson, 2001, *Journal of Applied Behavior Analysis, 34*, p. 33. Copyright 2001 by the Society for the Experimental Analysis of Behavior, Inc. Used by permission.

Another way to examine behavior change is by proportional or relative change. Ratio scales are well suited for displaying proportional change. On a **ratio scale,** equal vertical distances correspond to equal ratios of change in the variable being measured. Because behavior is measured and charted over time, which progresses in equal intervals, the horizontal axis is marked off in equal intervals and only the vertical axis has a ratio scaling. Hence, the term *ratio chart* refers to graphs where one axis is scaled proportionally.

Ratio charts offer a different perspective, namely, detecting relative behavior change as opposed to absolute change. For example, on a ratio chart a doubling of response rate from 4 to 8 per minute would appear the same as a doubling of 50 to 100 responses per minute. Likewise, a decrease in responding from 75 to 50 responses per minute (a decrease of one third) would occupy the same distance on the vertical axis as a change from 12 to 8 responses per minute (a decrease of one third).

Figure 6.15 shows the same data plotted on an equal-interval graph (sometimes called *linear, arithmetic,* or *add-subtract charts*) and on a ratio chart (sometimes called a *semilogarithmic chart*). The behavior change that appears as an

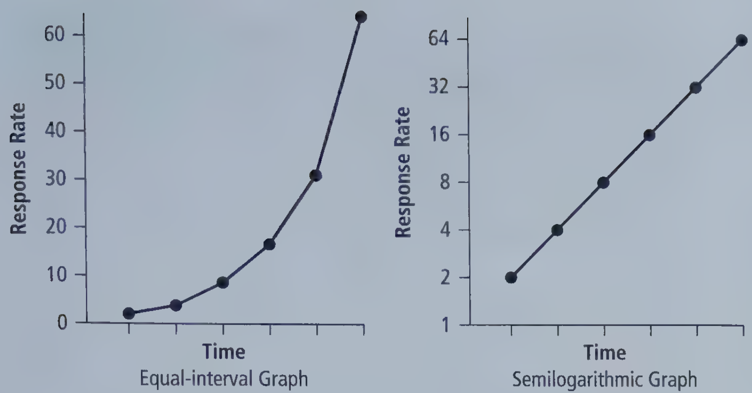

Figure 6.15 Same set of data plotted on equal-interval arithmetic scale (left) and on equal-proportion ratio scale (right).

exponential curve on the arithmetic chart is a straight line on the ratio chart. The vertical axis in the ratio chart in Figure 6.15 is scaled by log-base-2 or ×2 cycles, which means each cycle going up the vertical axis represents a times-2 increase (i.e., a doubling or 100% increase) of the cycle below it.

Standard Celeration Chart

Ogden Lindsley developed the **Standard Celeration Chart** to provide a standardized means of charting and analyzing how frequency of behavior changes over time (Lindsley, 1971). The Standard Celeration Chart is a standard ratio chart with six ×10 cycles on the vertical axis that can accommodate response rates as low as 1 per 24 hours (0.000695 per minute) or as high as 1000 per minute. There are four standard charts, differentiated from one another by the scaling on the horizontal axis: a daily chart with 140 calendar days, a weekly chart, a monthly chart, and a yearly chart. The daily chart shown in Figure 6.16 is used most often.

The size of the chart and the consistent scaling of the vertical axis and horizontal axis do not make the Standard Celeration Chart *standard*, as is commonly believed. What makes the Standard Celeration Chart standard is its consistent

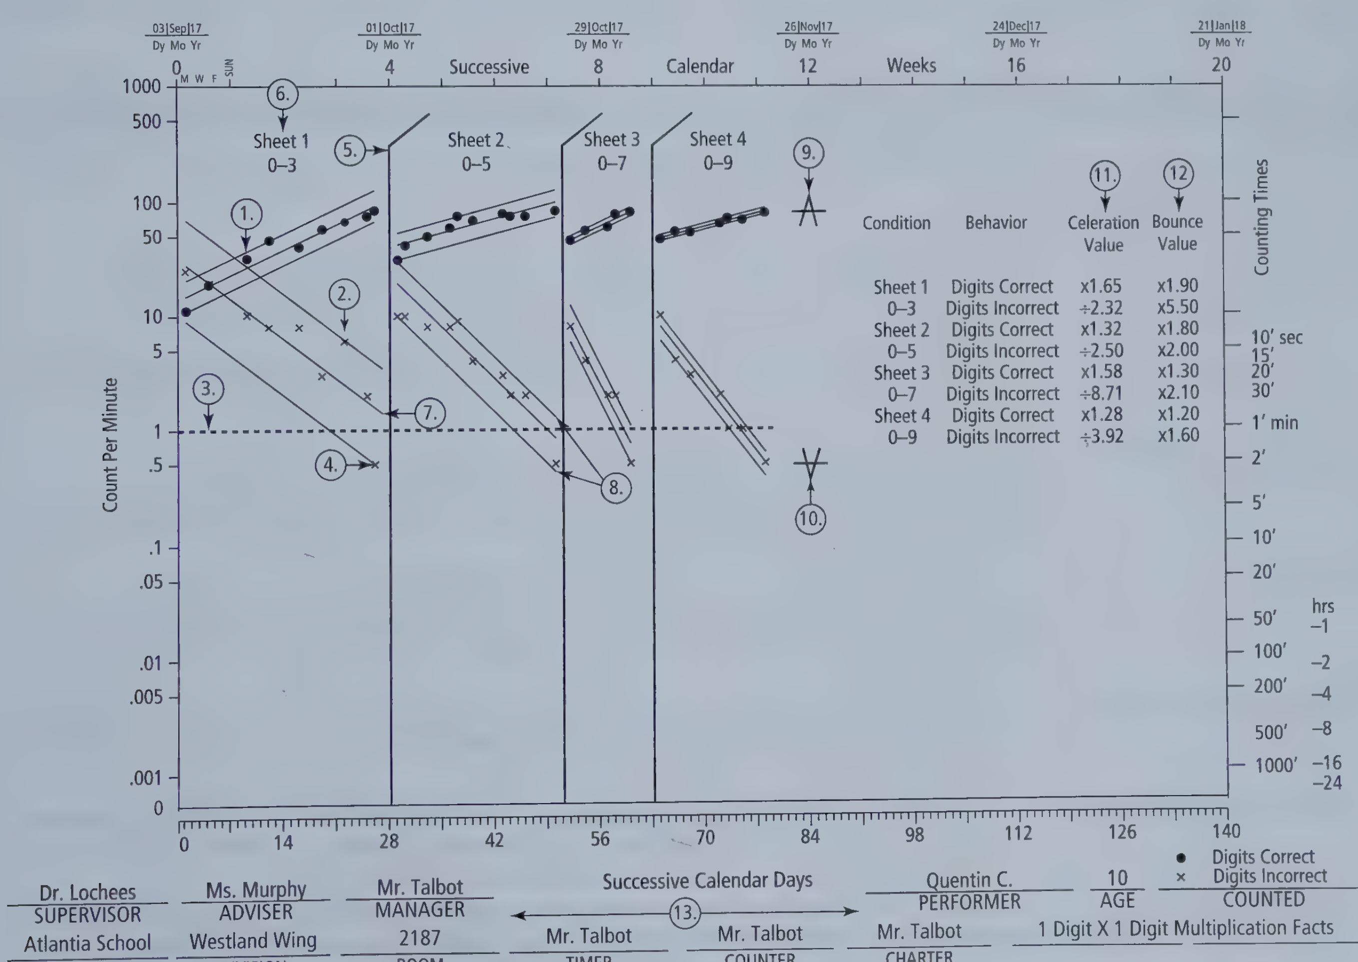

Figure 6.16 Standard Celeration Chart showing basic charting conventions. (See Table 6.1 for descriptions of numbered features.)

Model Standard Celeration Chart created by Douglas E. Kostewicz, Ph.D., BCBA-D, University of Pittsburgh. Used with permission.

display of *celeration*, a linear measure of frequency change across time, a factor by which frequency multiplies or divides per unit of time. The terms *acceleration* and *deceleration* are used to describe accelerating performances or decelerating performances.

A line drawn from the bottom left corner to the top right corner has a slope of 34° on all Standard Celeration Charts. The slope has a celeration value of ×2 (read as "times-2"). Celerations are expressed with a multiplication or division sign. A ×2 celeration represents a doubling in frequency per celeration period. The celeration period for the daily chart is per week; per month for the weekly chart, per 6 months for the monthly chart, and per 5 years for the yearly chart.

An instructional decision-making system, called **precision teaching**, has been developed for use with the Standard Celeration Chart. Precision teaching is predicated on the position that (a) learning is best measured as a change in response rate, (b) learning most often occurs through proportional changes in behavior, and (c) past changes in performance can project future learning. Figure 6.16 shows how precision teaching could be implemented to help a student working on 1-digit by 1-digit multiplication facts. Several times per week the student is given a worksheet of 1-digit by 1-digit multiplication problems and told to write the answer to as many problems as he can in 1 minute. Practice sheets during the initial phase consist of problems with digits 0 through 3 (e.g., 3×3, 2×1, 0×1). When the student attains the dual aims of 80 correct digits and 0 incorrect digits per minute, he starts practicing problems with increased range of digits and his performance is assessed with practice sheets sampling more diverse populations of problems. He completes the skill by reaching the aim on the final set of worksheets sampling all possible 1-digit by 1-digit multiplication problems. The Standard Celeration Chart shows the student took the longest to reach aim on the first set of sheets but attained each successive aim more quickly and with fewer errors. The reduced variability, called *bounce* by precision teachers, for corrects for each successive type of practice sheet suggests tighter stimulus control. Table 6.1 provides names and descriptions of chart features in Figure 6.16.[9]

Scatterplots

A **scatterplot** is a graphic display that shows the relative distribution of individual measures in a data set with respect to the variables depicted by the *x*- and *y*-axes. Data points on a scatterplot are unconnected. Scatterplots show how much changes in the value of the variable depicted by one axis correlate with changes in the value of the variable represented by the other axis. Patterns of data points falling along lines on the plane or clusters suggest certain relationships. For example, a scatterplot

TABLE 6.1 Features of the Standard Celeration Chart as Used by Precision Teaching (numbers refer to Figure 6.16)

Chart Feature	Description and Charting Convention
1. Acceleration target frequency	Responses to accelerate noted by a solid dot on the appropriate day line.
2. Deceleration target frequency	Responses to decelerate noted by an X on the appropriate day line.
3. Time bar	Amount of recording time per day noted by a solid horizontal line on the charted day.
4. No count (zero)	No behaviors intended to accelerate (i.e., dots) or decelerate (i.e., X) occurred during the recording period and charted at a distance ÷2 below the time bar.
5. Condition change line	Vertical line drawn between the last charted day of one intervention and the first charted day of a new intervention.
6. Condition change label	Brief description of condition/intervention.
7. Celeration lines	A straight line representing celeration or deceleration of five or more charted days with each condition. Drawn by free hand on paper charts; automatically calculated with linear regression algorithm and plotted on some digital charts.
8. Bounce lines	A measure of performance variability. Parallel straight lines above and below a celeration line that encompass the majority of performance. The up bounce line is placed through the upmost point (excluding outliers); the down bounce line is placed through the downmost point (excluding outliers).
9. Acceleration frequency aim	A symbol representing the desired frequency aim and date to achieve it for the behavior targeted for acceleration. Drawn with horizontal bar on the desired frequency and date and intersecting caret pointing up.
10. Deceleration frequency aim	A symbol representing the desired frequency aim and date to achieve it for the behavior targeted for deceleration. Drawn with horizontal bar on the desired frequency and date and intersecting caret pointing down.
11. Celeration value	A measure of performance change per minute per week. Accelerations (X) and decelerations (÷) represented on the chart or text show the change in performance.
12. Bounce values	The total amount of bounce (i.e., variability) around celeration and deceleration in a condition. Always written as an "X" value.

TABLE 6.1 (continued)

Chart Feature	Description and Charting Convention	
13. Charted blanks	Supervisor	Sees the chart monthly, advises the adviser or manager
	Adviser	Advises the manager or performer
	Manager	Works with the performer daily
	Organization	Where the recorded performance takes place
	Division	Location or subdivision within the organization
	Room	Room where the recording takes place
	Counter	Counts the performer's behavior
	Performer	Learner whose performance appears on the chart
	Charter	Person who creates chart with recorded performance data
	Counted	Description of performer's counted behavior
	Small Unlabeled Blanks	Optional: performer's age
	Large Unlabeled Blanks	Optional: additional relevant information

graph presented by Meindl et al. (2013) suggested that the more fluent a student's performance on a set of training flash cards, the greater the decrease in fluency with a generalization set of cards (see Figure 6.17). This finding supported the researchers' hypothesis that the student's responses to the training set flash-cards were controlled in part by irrelevant stimulus features of the cards (e.g., specific words in specific locations on the cards), which inhibited generalization to new cards.

Scatterplots can also reveal relationships among different subsets of data. For example, Boyce and Geller (2001) created the scatterplot shown in Figure 6.18 to see how the behavior of individuals from different demographic groups related to a ratio of driving speed and following distance that represents one element of safe driving (e.g., the proportion of data points for young males falling in the at-risk area of the graph compared to the proportion of drivers from other groups). Each data point

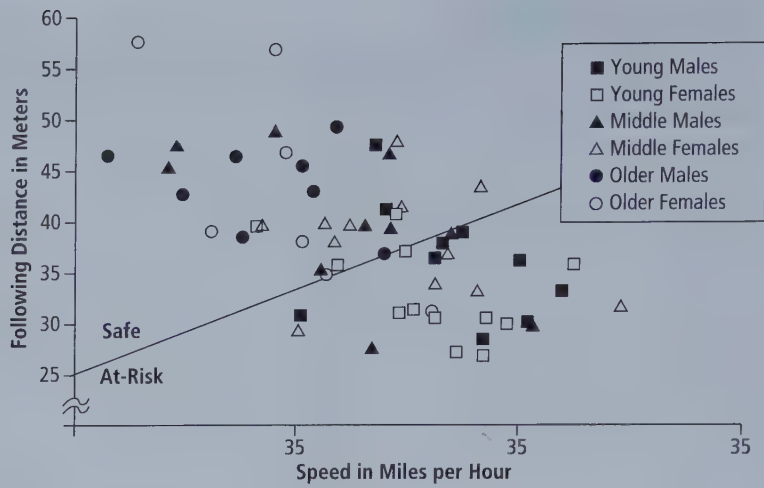

Figure 6.18 Scatterplot showing how the behavior of individuals from different demographic groups relates to a standard measure of safe driving.

Based on "A Technology to Measure Multiple Driving Behaviors without Self-Report or Participant Reactivity" by T. E. Boyce and E. S. Geller, 2001, *Journal of Applied Behavior Analysis, 34*, p. 49. Copyright 2001 by the Society for the Experimental Analysis of Behavior, Inc. Used by permission.

shows a single driver's behavior in terms of speed and following distance and whether the speed and following distance combination is considered safe or at risk for accidents. Such data could be used to target interventions for certain demographic groups.

Applied behavior analysts sometimes use scatterplots to discover the temporal distribution of a target behavior (e.g., Kahng et al., 1998; Symons, McDonald, & Wehby, 1998; Touchette, MacDonald, & Langer, 1985). Touchette and colleagues described a procedure for observing and recording behavior that produces a scatterplot that graphically shows whether the behavior's occurrence is typically associated with certain time periods. The use of scatterplot recording is described further in Chapter 27.

Other Graphic Displays

Applied behavior analysts have used a wide variety of other graphic formats to display and communicate behavioral data. For example, Raiff, Jarvis, and Dallery (2016) created a graphic display consisting of a horizontal sequence of boxes in different shades to illustrate patients' adherence to antidiabetic medication routines during baseline and treatment conditions. Romanowich and Lamb (2015) illustrated and compared participants' ratings on a treatment acceptability scale with a horizontal bar graph. Still other graphic formats are *bubble graphs* (e.g., Schultz, Kohn, & Musto, 2017), *dot charts* (see Figure A in Box 6.1), and *frequency profiles* (Epstein, Mejia, & Robertson, 2017).

Applied behavior analysis researchers have devised creative combinations of graphic devices to present data in ways that invite insights, understanding, and analyses of their findings. Interesting and effective examples can be found in Cammilleri and Hanley (2005 [Figure 29.10 in this text]; Fahmie, Iwata, and Mead (2016, Figure 1); Ingvarsson, Kramer, Carp, Pétursdóttir, and Macias (2016, Figures 1 and 2); Jessel et al. (2016, Figure 5); and Jones, Carr, and Feeley (2006, Figure 10).[10]

CONSTRUCTING LINE GRAPHS

The skills required for constructing effective, distortion-free graphic displays are as important as any in the behavior analyst's repertoire.[11] As applied behavior analysis has developed, so have certain stylistic conventions and expectations regarding the construction of graphs. An effective graph presents the data accurately, completely, and clearly, and makes the viewer's task of understanding the data as easy as possible. The graph maker must strive to fulfill each of these requirements while remaining alert to features in the graph's design or construction that might create distortion and bias—either the graph maker's or that of a future viewer when interpreting the extent and nature of the behavior change depicted by the graph.

Despite the graph's prominent role in applied behavior analysis, relatively few detailed treatments of how to construct behavioral graphs have been published. Notable exceptions have been chapters by Parsonson and Baer (1978, 1986) and by Spriggs, Lane, and Gast (2014); discussion of graphic display tactics by Johnston and Pennypacker (2009); and a recent critique of graphs published in behavior analytic journals by Kubina, Kostewicz, Brennan, and King (2015). Recommendations from these sources and others (American Psychological Association, 2009; Tufte, 2001) contributed to the preparation of this section. Additionally, hundreds of graphs published in applied behavior analysis journals were examined in an effort to discover those features that most clearly communicate the story told by the data.

Although there are few hard-and-fast rules for constructing graphs, adhering to the following conventions will result in clear, well-designed graphic displays consistent in format and appearance with current practice. Although most of the recommendations are illustrated by graphs presented throughout this text, we created Figures 6.19 and 6.20 to serve as models for most of the practices suggested here. The recommendations generally apply to all behavioral graphs. However, each data set and the conditions under which the data were obtained present their own challenges to the graph maker.

Drawing, Scaling, and Labeling Axes

Ratio of the Vertical and Horizontal Axes

The relative length of the vertical axis to the horizontal axis, in combination with the scaling of the axes, determines the degree

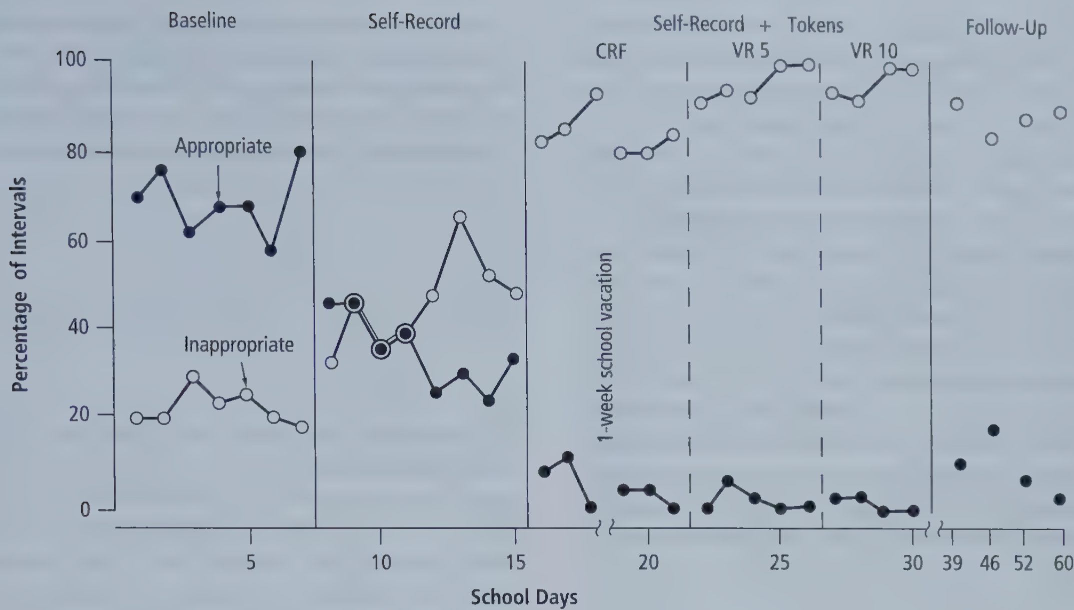

Figure 1. Percent of 10-second intervals of appropriate and inappropriate behavior by an 8-year-old boy. Each interval was scored as appropriate, inappropriate, or neither; thus the two behaviors do not always total 100%.

Figure 6.19 Graph of hypothetical data illustrating various conventions and guidelines for constructing behavioral graphs.

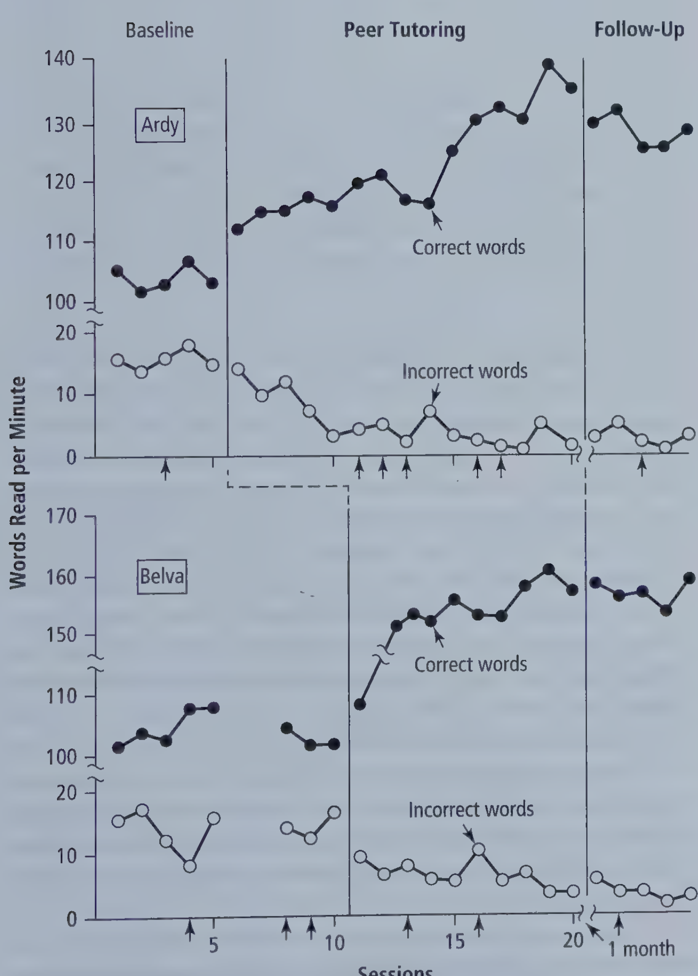

Figure 1. Number of words read correctly and incorrectly by Ardy and Belva during 1-min probes following each session. Arrows below horizontal axes indicate sessions in which student used reading material brought from home.

Figure 6.20 Graph of hypothetical data illustrating various conventions and guidelines for constructing behavioral graphs.

to which a graph will accentuate or minimize variability in a given data set. The legibility of a graph is enhanced by a balanced ratio between the height and width so that data points are neither too close together nor too spread apart. Recommendations in the behavioral literature for the ratio, or relative length, of the vertical axis to the horizontal axis range from 5:8 (Johnston & Pennypacker, 2009) to 3:4 (Katzenberg, 1975). Tufte (2001), whose book *The Visual Display of Quantitative Information* is a wonderful storehouse of guidelines and examples of effective graphing techniques, also recommends a vertical axis–to–horizontal axis ratio of 5:8.

A vertical axis approximately two-thirds the length of the horizontal axis works well for most behavioral graphs. When multiple sets of axes will be presented one atop another in a single figure and/or when the number of data points to be plotted on the horizontal axis is very large, the length of the vertical axis relative to the horizontal axis can be reduced (as shown in Figures 6.2 and 6.7).

Scaling the Horizontal Axis

The horizontal axis should be marked in equal intervals, with each unit representing from left to right the chronological succession of equal time periods or response opportunities in which the behavior was (or will be) measured and from which an interpretation of behavior change is to be made (e.g., days, sessions, trials). It is not necessary to mark each point on the *x*-axis. Avoid visual clutter by placing *tick marks* at regularly spaced increments on the outside of the axis and numbering them accordingly (e.g., by 5s, 10s, 20s).

When two or more sets of axes are stacked vertically, and each horizontal axis represents the same time frame, unnumbered tick marks on the horizontal axes of the upper tiers are permissible. However, each horizontal axis should have the tick marks corresponding to those on the bottom tier to facilitate comparison of performance across tiers at any given point in time (see Figure 6.4).

Representing Discontinuities of Time on the Horizontal Axis

Behavior change, its measurement, and all manipulations of treatment or experimental variables occur within and across time. Therefore, time is a fundamental variable in all experiments that should not be distorted or arbitrarily represented in a graphic display. Each equally spaced unit on the horizontal axis should represent an equal passage of time. Discontinuities in the progression of time should be indicated on the horizontal axis by a *scale break*: an open, unconnected portion of the axis with a squiggly line at each end. Scale breaks on the *x*-axis can also be used to signal periods when data were not collected or when otherwise regularly spaced data points represent consecutive measurements made at unequal intervals (see the numbering of school days for the follow-up condition in Figure 6.19).

When measurement occurs across consecutive observations of opportunities for the target behavior to occur (e.g., stories read, meals, tennis serves) rather than standard units of time, the horizontal axis still serves as a visual representation of the progression of time because the data plotted above it are recorded one after the other. The text accompanying such a figure should indicate the real time in which the consecutive measurements were made (e.g., "Two or three peer tutoring sessions were conducted each school week"), and any irregularities or discontinuities in that time context should be clearly indicated or marked with scale breaks (see Figure 6.20).

Labeling the Horizontal Axis

The dimension by which the horizontal axis is scaled is identified in a brief label centered below and parallel to the axis.

Scaling the Vertical Axis

The most significant feature of an equal-interval graph's representation of behavior change (or lack thereof) is its vertical axis scale. Common practice is to mark the origin at 0 (on cumulative graphs the bottom on the vertical axis must be 0) and then to mark off the vertical axis to accommodate all values represented in the data set and the range of socially important/desired performance. Increasing the distance on the vertical axis between each unit of measurement magnifies the variability in the data, whereas contracting the units of measurement on the vertical axis minimizes the portrayal of variability in the data set. The graph maker should plot the data set against several different vertical axis scales, watching for distortion of the graphic display that might lead to inappropriate interpretations (Dart & Radley, 2017).

When zero values make no sense, truncate the *y*-axis. "Charting is about being true to the data. Some data never fall to zero—the body temperature of a living person, for instance" (Yanofsky 2015). Edward Tufte (2017) agrees: "Don't spend a lot of empty vertical space trying to reach down to the zero point at the cost of hiding what is going on in the data line itself" (n.p.).

The social significance of various levels of behavior change for the behavior being graphed should be considered when scaling the vertical axis. If relatively small numerical changes in performance are socially significant, the *y*-axis scale should reflect a smaller range of values. For example, to display data most effectively from a training program in which an industrial employee's percentage of correctly executed steps in a safety checklist increased from an unsafe preintervention range of 85% to 90% to a nearly accident-free postintervention level of 98% to 100%, the vertical axis should focus on the 80% to 100% range. However, the scaling of the vertical axis should be contracted when small numerical changes in behavior are not socially important and the degree of variability obscured by the compressed scale is of little interest.

Horizontal numbering of regularly spaced tick marks on the outside of the vertical axis reduces visual clutter and facilitates reading the scale. The vertical axis should not be extended beyond the tick mark indicating the highest value on the axis scale.

When the data set includes several measures of 0, start the vertical axis at a point slightly above the horizontal axis to keep data points from falling directly on the axis. This produces a neater graph and helps the viewer discriminate 0-value data points from those representing measures close to 0 (see Figure 6.19).

In most instances, scale breaks should not be used on the vertical axis. However, when two sets of data with widely different and nonoverlapping ranges are displayed against the same *y*-axis, a scale break can be used to separate the range of measures encompassed by each data set (see Figure 6.20).

In multiple-tier graphs, equal distances on each vertical axis should represent equal changes in behavior to aid the comparison of data across tiers. Also, whenever possible, similar positions on each vertical axis of multiple-tier graphs should represent similar absolute values of the dependent variable. When the differences in behavioral measures from one tier to another would result in one or more overly long vertical axes, scale breaks can be used to highlight the difference in absolute values and aid point-to-point comparisons across tiers.

When the range values to be plotted on the vertical axis exceed what could be displayed on an axis of proportional length to the horizontal axis, it may be possible to split the range across two or more tired graphs. For example, in a study on compliance, Cook, Rapp, and Schulze (2015) presented their results in a three-tiered graph. (see Figure 9.11 this text). The vertical axis of the top tier is scaled in seconds, the middle tier in minutes, and the bottom tier in hours. The horizontal axis of each descending tier represented a continuation of time as measured by experimental trials.

Labeling the Vertical Axis

A brief label, printed and centered to the left and parallel to the vertical axis, should identify the dimension by which the axis is scaled. On multiple-tiered graphs, one label identifying the dimension portrayed on all of the vertical axes can be centered along the axes as a group. Additional labels identifying the different behaviors (or some other relevant aspect) graphed within each set of axes are sometimes printed to the left and parallel to each vertical axis. These individual tier labels should be printed to the right of and in smaller sized font than the label identifying the dimension by which all of the vertical axes are scaled.

Identify Experimental Conditions

Condition Change Lines

Vertical lines extending upward from the horizontal axis indicate changes in treatment or experimental procedures. Condition change lines should be placed after (to the right of) the data point representing the last measure prior to the change in conditions signified by the line and before (to the left of) the data point representing the first measure obtained after the change in procedure. In this way, data points fall clearly on either side of change lines and never on the lines themselves. Drawing condition change lines to a height equal to the height of the vertical axis helps the viewer estimate the value of data points near the top of the vertical axis range.

Condition change lines can be drawn with either solid or dashed lines. However, when an experiment or a treatment program includes relatively minor changes within an ongoing condition, a combination of solid and dashed lines should be used to distinguish the major and minor changes in conditions. For example, the solid lines in Figure 6.19 change from baseline, to Self-Record, to Self-Record+Tokens, to Follow-Up conditions, and dashed lines indicate changes in the schedule of reinforcement from CRF, to VR 5, to VR 10 within the Self-Record+Tokens condition (CRF and VR schedules of reinforcement are described in Chapter 13).

When the same manipulation of an independent variable occurs at different points along the horizontal axes of multiple-tiered graphs, a dog-leg connecting the condition change lines from one tier to the next makes it easy to follow the sequence and timing of events in the experiment (see Figure 6.20).

Unplanned events that occur during an experiment or treatment program, as well as minor changes in procedure that do not warrant a condition change line, can be indicated by placing small arrows, asterisks, or other symbols next to the relevant data points (see Figure 6.6) or just under the *x*-axis (see Figure 6.20). The figure caption should explain any special symbols.

Condition Labels

Labels identifying the conditions in effect during each period of an experiment are centered above the space delineated by the condition change lines. Whenever space permits, condition labels should be parallel to the horizontal axis. Labels should be brief but descriptive (e.g., *Contingent Praise* is preferable to *Treatment*), and the labels should use the same terms or phrases used in the accompanying text describing the condition. Abbreviations may be used when space or design limitations prohibit printing the complete label. A single condition label should be placed above and span across labels identifying minor changes within that condition (see Figure 6.19). Numbers are sometimes added to condition labels to indicate the number of times the condition has been in effect during the study (e.g., Baseline 1, Baseline 2).

Plot Data Points and Draw Data Paths

Data Points

When graphing data by hand, behavior analysts must take great care to ensure that they plot each data point exactly on the coordinate of the horizontal and vertical axis values of the measurement it represents. The inaccurate placement of data points is an unnecessary source of error in graphic displays, which can lead to mistakes in clinical judgment and/or experimental method. Accurate placement is aided by careful selection of graph paper with grid lines sized and spaced appropriately for the data to be plotted. When many different values must be plotted within a small distance on the vertical axis, a graph paper with many grid lines per inch should be used.

Should a data point fall beyond the range of values described by the vertical axis scale, it is plotted just above the scale it transcends, with the actual value of the measurement printed in parentheses next to the data point. Breaks in the data path leading to and from the off-the-scale data point also help to highlight its discrepancy (see Figure 6.20, Session 19).

Data points should be marked with bold symbols that are easily discriminated from the data path. When only one set of data is displayed on a graph, solid dots are most often used. When multiple data sets are plotted on the same set of axes, a different geometric symbol should be used for each set of data.

The symbols for each data set should be selected so that the value of each data point can be determined when data points fall near or on the same coordinates on the graph (see Figure 6.19, Sessions 9–11).

Data Paths

Data paths are created by drawing a straight line from the center of each data point in a given data set to the center of the next data point in the same set. All data points in a given data set are connected in this manner with the following exceptions:

- Data points falling on either side of a condition change line are not connected.
- Data points should not be connected across a significant span of time in which behavior was not measured. To do so implies that the resultant data path represents the level and trend of the behavior during the span of time in which no measurement was conducted.
- Data points should not be connected across discontinuities of time in the horizontal axis (see Figure 6.19, 1-week school vacation).
- Data points on either side of a regularly scheduled measurement period in which data were not collected or were lost, destroyed, or otherwise not available (e.g., participant's absence, recording equipment failure) should not be joined together (see Figure 6.20, Belva's graph, baseline condition).
- Follow-up or postcheck data points should not be connected with one another (see Figure 6.19) unless they represent successive measures spaced in time in the same manner as measures obtained during the rest of the experiment (see Figure 6.20).

When multiple data paths are displayed on the same graph, different styles of lines, in addition to different symbols for the data points, may be used to help distinguish one data path from another (see Figure 6.19). The behavior represented by each data path should be clearly identified, either by printed labels with arrows drawn to the data path (see Figures 6.19 and 6.20) or by a legend showing models of the symbols and line styles (see Figure 6.13). When two data sets travel the same path, their lines should be drawn close to and parallel with one another to help clarify the situation (see Figure 6.19, Sessions 9–11).

Write Figure Caption

Printed below the graph, the figure caption should give a concise but complete description of the figure. The caption should also direct the viewer's attention to any features of the graph that might be overlooked (e.g., scale changes) and should explain the meaning of any added symbols representing special events.

Print Graph

Graphs should be printed in only one color—black. Although the use of color can enhance the attractiveness of a visual display and highlight certain features, it is discouraged in the scientific presentation of data. Every effort must be made to let the data stand on their own. The use of color can encourage perceptions of performance or experimental effects that differ from perceptions of the same data displayed in black. The fact that graphs and charts may be reproduced in journals and books is another reason for using black only.

Constructing Graphs with Computer Software

Software programs for producing computer-generated graphs are available and becoming both increasingly sophisticated and easier to use. Most of the graphs displayed throughout this book were constructed with computer software. Even though computer graphics programs offer a tremendous time savings over hand-plotted graphs, careful examination should be made of the range of scales available and the printer's capability for both accurate data point placement and precise printing of data paths.

Most computer generated graphs are produced with Microsoft Excel software. Detailed task analyses and step-by-step instructions for creating behavioral graphs using Microsoft Excel are available (e.g., Cole & Witts, 2015; Deochand, 2017; Deochand, Costello, & Fuqua, 2015; Dixon et al., 2009; Lo & Konrad, 2007). Vanselow and Bourret (2012) developed an online interactive tutorial for creating graphs with Excel.

Software programs that automatically create graphs from digitally collected or practitioner-uploaded data save time that can be devoted to other clinical or instructional activities. Autographing software can help clinicians keep graphs of client performance current, enabling more frequent data-based decisions (e.g., Pinkelman & Horner, 2016; Sleeper et al., 2017).

INTERPRETING GRAPHICALLY DISPLAYED BEHAVIORAL DATA

The effects of an intervention that produces dramatic, replicable changes in behavior that last over time are readily seen in a well-designed graphic display. People with little or no formal training in behavior analysis can read the graph correctly in such cases. Many times, however, behavior changes are not so large, consistent, or durable. Behavior sometimes changes in sporadic, temporary, delayed, or seemingly uncontrolled ways; and sometimes behavior may hardly change at all. Graphs displaying these kinds of data patterns often reveal equally important and interesting subtleties about behavior and its controlling variables.

Behavior analysts employ a systematic form of examination known as **visual analysis** to interpret graphically displayed data. Visual inspection of graphs showing behavior change in relation to the presence or absence of environmental variables is the primary method of data analysis in behavior analysis. Visual analysis of data from an applied behavior analysis experiment is conducted to answer two questions: (a) Did behavior change in a meaningful way? and (b) if so, to what extent can that behavior change be attributed to the independent variable? Although there are no formalized rules for visual analysis, the dynamic nature of behavior, the scientific and technological necessity of discovering effective interventions, and the applied requirement of producing socially meaningful levels of performance all combine to focus the behavior analyst's interpretive attention on certain properties common to all behavioral data: (a) variability,

(b) level, and (c) trend. Visual analysis entails examining each of these characteristics both within and across the conditions and phases of an experiment.[12]

Before attempting to interpret the data displayed in a graph, the viewer should carefully examine the graph's overall construction. First, read the figure legend, axis labels, and all condition labels to obtain a basic understanding of what the graph is about. The viewer should then look at the scaling of each axis, taking note of the location, numerical value, and relative significance of any scale breaks. Did the graph maker truncate the vertical axis scale to emphasize behavior change?

> A common complaint of this is that it gives the appearance of severity when none exists. First, this is why charts have scales. Blaming a chart's creator for a reader who doesn't look at clearly labeled axes is like blaming a supermarket for selling someone food he's allergic to.
>
> Second, the degree to which the chart emphasizes certain aspects of the data is a judgment of storytelling not chart-making. Sure, this mindset can yield misleading displays, but how is that different than words? Charts should be fair, not impartial. (Yanofsky, 2015, n.p.)

Next, visually track each data path to determine that the data points are properly connected. Does each data point represent a single measurement or observation, or are the data "blocked" such that each data point represents an average or some other summary of multiple measurements? Do the data show the performance of an individual subject or the average performance of a group of subjects? If blocked or group data are displayed, is a visual representation of the range or variation of scores provided; or do the data themselves allow determination of the amount of variability that was collapsed in the graph? For example, if the horizontal axis is scaled in weeks and each data point represents a student's average score for a week of daily five-word spelling tests, data points falling near 0 or at the top end of the closed scale, such as 4.8, pose little problem because they can be the result of only minimal variability in the daily scores for that week. However, data points near the center of the scale, such as 2 to 3, can result from either stable or highly variable performance.

Only when satisfied that a graph is properly constructed and does not distort the events it represents, should the viewer examine the data to discover what they reveal about the behavior during each condition of the study. If the viewer suspects the graph's construction distorts, overstates, or hides important features, interpretive judgments of the data should be withheld (see Box 6.2).

BOX 6.2

Don't Be Fooled by a Pretty Graph

Graphic displays tell visual stories of the data they represent. But just as storytellers can conceal, distort, and mislead by selecting and sequencing biased words and phrases, graph makers can make certain interpretations of the data more or less likely by manipulating chart features. When looking at a graphic display, ask yourself whether it has been designed to tell a story that accurately reflects the underlying data, or whether it has been designed to tell a story more closely aligned with what the designer would like you to believe. Truncated or expanded axes with questionable scaling; extraneous color and depth cues; misleading labels, legends, and captions; and bar graphs with y-axes that do not include 0 are common forms of graphic foolery (Bergstrom & West, 2018a).

Why does a bar graph need to include 0 on the dependent axis, whereas a line graph need not do so? Our view is that the two types of graphs are telling different stories. By its design, a bar graph emphasizes the *absolute magnitude* of values associated with each category, whereas a line graph emphasizes the *change* in the dependent variable (usually the y value) as the independent variable (usually the x value) changes.

For a bar graph to provide a representative impression of the values being plotted, the visual weight of each bar—the amount of ink on the page, if you will—must be proportional to the value of that bar. Setting the axis above zero interferes with this. For example, if we create a bar graph with values 15 and 20 but set the axis at 10, the bar corresponding to 20 has twice the visual weight of the bar corresponding to 15, despite the value 20 being only 4/3 of the value 15. (Bergstrom & West, 2018b, n.p.)

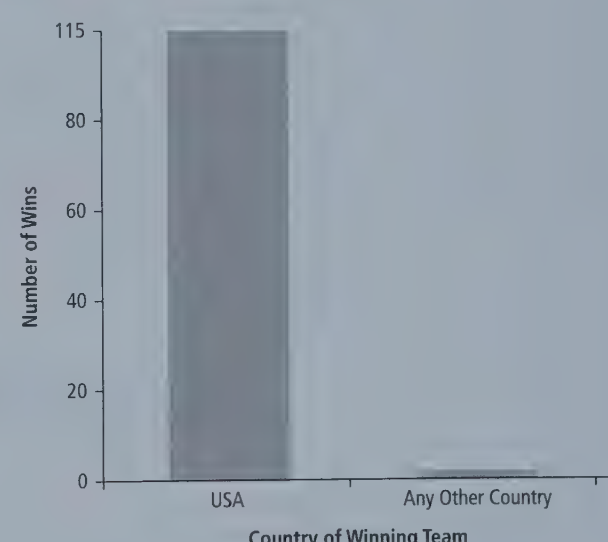

Figure A Country of Baseball's World Series–Winning Teams (1903–2017).

Don't be fooled by graphs comparing data sets that have no logical or possible relation to one another. Figure A, for example, compares the number of baseball teams located

(continued)

BOX 6.2 (continued)

in the United States who have won baseball's World Series with the number of World Series winners from outside the United States. The story told by this graph is U.S. dominance over the rest of the baseball-playing world. Although the data depicted are accurate, they represent dramatically different opportunities. From the first World Series in 1903 through 1968 there were 0 non-U.S. major league teams. The Montreal Expos competed in the National League from 1969 to 2004. The Toronto Blue Jays, World Series winners in 1992 and 1993, have played in the American League since 1977.

Comparing multiple data sets with different scales for each set can create even more deceptive graphs. One must be especially careful comparing multiple data series on the graph, with different scales for each series. Figure B shows a correlation between the use of the herbicide glyphosate (trade name Roundup) on corn and soybean crops and the increasing incidence of cancer. The authors reported: "We found strong correlations for cancers of the liver, kidney, bladder/urinary and thyroid. . . . Thyroid and bladder cancers especially seem to track with the advent of GE [genetically engineered] crops and associated glyphosate applications" (Swanson, Leu, Abrahamson, & Wallet, 2014, p. 16, words in brackets added).

Exposure to Roundup may well have serious health consequences, but whatever they may be, this particular graph is not persuasive. First of all, there's the obvious point that correlation is not causation. One would find a similar correlation between cell phone usage and hypertension, for example—or even between cell phone usage and Roundup usage! The authors make no causal claims, but we fail to see the value in fishing for correlations.

The left-hand axis doesn't go to zero. We've already noted why this is problematic. But it gets worse. Both the scale and *the intercept* of the other vertical axis, at right, have been adjusted so that the red curve traces the peaks of the yellow bars. Most remarkably, to make the curves do this, the axis has to go all the way to *negative* 10% GE corn planted and *negative* 10,000 tons glyphosate used! We've noted that the *y*-axis need not go to zero, but if it goes to a negative value for a quantity (percentage or tonnage) that can only take on positive values, this should set off alarm bells. (Bergstrom & West, 2018b, emphasis in original, n.p.)

While a challenge to everyone, detecting graphic sleight of hand is particularly important for applied behavior analysts, who rely on visual analysis of graphed data to determine the story of behavior change. Fortunately, transparency is a characteristic of behavior analytic research and practice. Many graphic displays used in behavior analysis provide direct access to the original data, which allows the inquisitive or skeptical viewer to replot the data on a new set of axes.

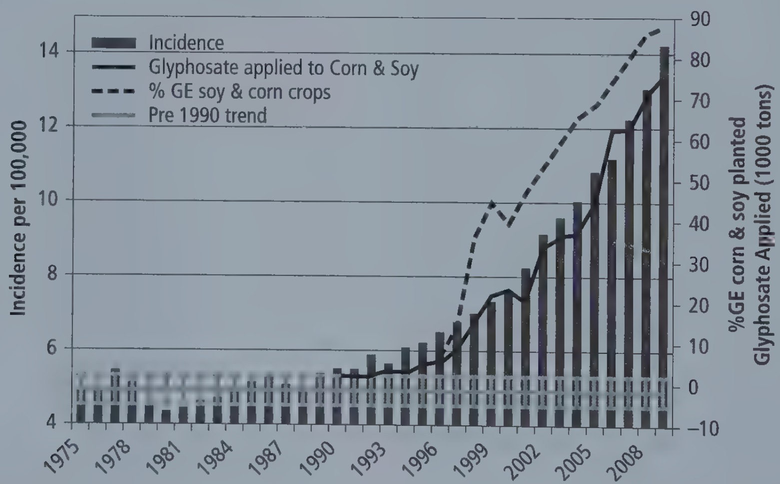

Figure B Graph suggesting correlation between rising incidence of thyroid cancer and use of herbicide glyphosate on U.S. corn and soy crops that are genetically engineered.

Visual Analysis Within Conditions

Data within a given condition are examined to determine (a) the number of data points, (b) the nature and extent of variability in the data, (c) the absolute and relative level of the behavioral measure, and (d) the direction and degree of any trend(s) in the data.[13]

Number of Data Points

First, the viewer should determine the quantity of data reported during each condition. This entails a simple counting of data points. As a general rule, the more measurements of the dependent variable per unit of time and the longer the period of time in which measurement occurred, the more confidence one can have in the data

path's estimation of the true course of behavior change (given, of course, a valid and accurate observation and measurement system).

The number of data points needed to provide a believable record of behavior during a given condition also depends on how many times the same condition has been repeated during the study. As a rule, fewer data points are needed in subsequent replications of an experimental condition if the data depict the same level and trend in performance that were noted in earlier applications of the condition.

The published literature of applied behavior analysis also plays a part in determining how many data points are sufficient. In general, briefer phases are required of experiments investigating relations between previously studied and well-established variables if the results are also similar to those of the previous studies. More data are needed to demonstrate new findings, whether or not new variables are under investigation.

There are other exceptions to the rule of the-more-data-the-better. Ethical concerns do not permit the repeated measurement of certain behaviors (e.g., self-injurious behavior) under an experimental condition in which there is little or no expectation for improvement (e.g., during a no-treatment baseline condition or a condition intended to reveal variables that exacerbate problem behavior). Also, there is little purpose in repeated measurement in situations in which the subject cannot logically perform the behavior (e.g., measuring the number of correct answers to long division problems when concurrent observations indicate that the student has not learned the necessary component skills of multiplication and subtraction). Nor are many data points required to demonstrate that behavior did not occur when in fact it had no opportunity to occur.

Familiarity with the response class measured and the conditions under which it was measured may be the graph viewer's biggest aid in determining how many data points constitute believability. The quantity of data needed in a given condition or phase is also partly determined by the analytic tactics employed in a given study. Experimental design tactics are described in Chapters 7 through 10.

Variability

How often and the extent to which repeated measures of behavior yield different outcomes is called **variability**. A high degree of variability (or "bounce") within a given condition usually indicates that the researcher or practitioner has achieved insufficient control over the factors influencing the behavior. (An important exception is when the purpose of an intervention is to produce a high degree of variability.) In general, the greater the variability within a given condition, the greater the number of data points that are necessary to establish a predictable pattern of performance. By contrast, fewer data points are required to present a predictable pattern of performance when those data reveal relatively little variability.

Practitioners and researchers should also look for variability in the form of cyclical patterns, such as those shown in the bottom panel of Figure 6.1.

Level

The value on the vertical axis scale around which a set of behavioral measures converge is called **level**. In the visual analysis of behavioral data, level is examined within a condition in terms of its absolute value on the *y*-axis (mean, median, and/or range), the degree of stability or variability, and the extent of change from one level to another. The graphs in Figure 6.21 illustrate four different combinations of level and variability.

The mean level of a series of behavioral measures within a condition can be graphically illustrated by the addition of a *mean level line*: a dashed horizontal line drawn through a series of data points within a condition at that point on the vertical axis equaling the average value of the series of measures. Although mean level lines provide an easy-to-see summary of average performance within a given condition or phase, they should be used and interpreted with caution. With highly stable data paths, mean level lines pose no serious drawbacks. However, the less variability there is within a series of data points, the less need there is for a mean level line. For instance, a mean level line would serve little

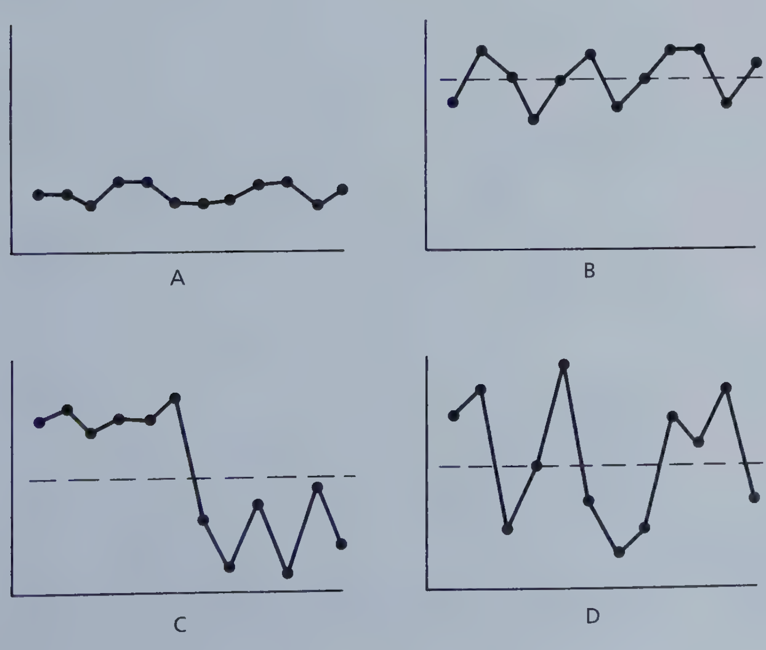

Figure 6.21 Four data paths illustrating (A) a low, stable level of responding; (B) a high, variable level of responding; (C) an initially high, stable level of responding followed by a lower, more variable level of responding; and (D) an extremely variable pattern of responding not indicative of any overall level of responding. Dashed horizontal lines on graphs B, C, and D represent the mean levels of responding.

purpose in Graph A in Figure 6.21. And although mean level lines have been added to Graphs B, C, and D in Figure 6.21, Graph B is the only one of the three for which a mean level line provides an appropriate visual summary of level. The mean level line in Graph C is not representative of any measure of behavior taken during the phase. The data points in Graph C show a behavior best characterized as occurring at two distinct levels during the condition and beg for an investigation of the factor(s) responsible for the clear change in levels. The mean level line in Graph D is inappropriate because the variability in the data is so great that only 4 of the 12 data points fall close to the mean level line.

A *median level line* is another method for visually summarizing the overall level of behavior in a condition. Because a median level line represents the most typical performance within a condition, it is not so influenced by one or two measures that fall far outside the range of the remaining measures. Therefore, one should use a median level line instead of a mean level line to graphically represent the central tendency of a series of data points that include several outliers, either high or low.

Change in level within a condition is determined by calculating the difference in absolute values on the *y*-axis between the first and last data points within the condition. Another method, somewhat less influenced by variability in the data, is to compare the difference between the median value of the first three data points in the condition with the median value of the final three data points in the condition (Koenig & Kunzelmann, 1980).

Trend

The overall direction taken by a data path is its **trend**. Trends are described in terms of their direction (increasing, decreasing, or zero trend), degree or magnitude, and extent of variability of data points around the trend. The graphs in Figure 6.22 illustrate a variety of trends. The direction and degree of trend in a series of graphed data points can be visually represented by a straight line drawn through the data. called a *trend line* or *line of progress*. Several methods for calculating and fitting trend lines to a series of data have been developed. One can simply inspect the graphed data and draw a straight line that visually provides

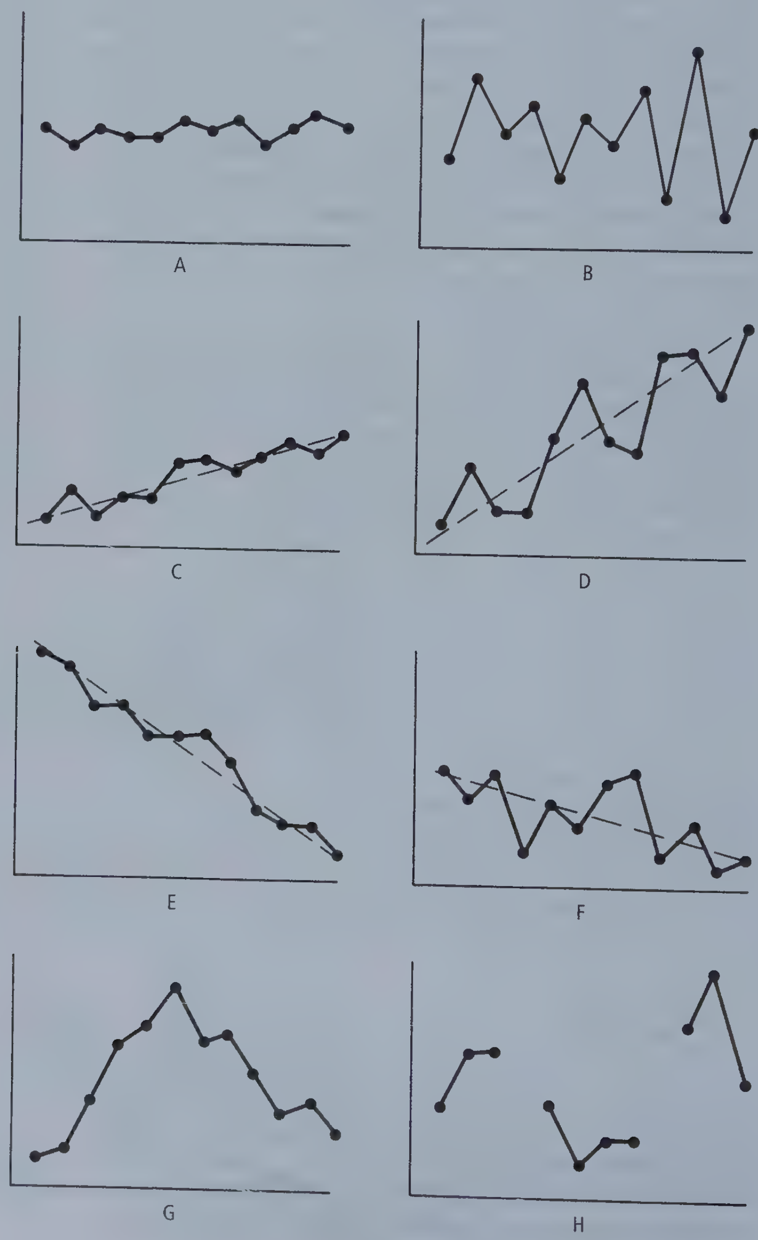

Figure 6.22 Data patterns indicating various combinations of trend direction, degree, and variability: (A) zero trend, high stability; (B) zero trend, high variability; (C) gradually increasing stable trend; (D) rapidly increasing variable trend; (E) rapidly decreasing stable trend; (F) gradually decreasing variable trend; (G) rapidly increasing trend followed by rapidly decreasing trend; (H) no meaningful trend, too much variability and missing data. Split-middle lines of progress have been added to Graphs C–F.

the best fit through the data. For this freehand method, Lindsley (1985) suggested ignoring one or two data points that fall well beyond the range of the remaining values in a data series and fitting the trend line to the remaining scores. Although the freehand method is the fastest way of drawing trend lines and can be useful for the viewer of a published graph, hand-drawn trend lines may not always result in an accurate representation of trend and are typically not found in graphs of published studies.

Trend lines can also be calculated using a mathematical formula called the ordinary least-squares linear regression equation (McCain & McCleary, 1979; Parsonson & Baer, 1978). Trend lines determined in this fashion have the advantage of complete reliability: The same trend line will always result from the same data set. The disadvantage of this method is the many mathematical operations that must be performed to calculate the trend line. A computer program that can perform the equation eliminates the time concern in calculating a least-squares trend line.

A method of calculating and drawing lines of progress that is more reliable than the freehand method and much less time consuming than linear regression methods is the **split-middle line of progress**. White (2005) developed the split-middle technique for use with rate data plotted on semilogarithmic charts, and it has proven a useful technique for predicting future behavior from such data. Split-middle lines of progress can also be drawn for data plotted against an equal-interval vertical axis, but it must be remembered that such a line is only an estimate that summarizes the overall trend (Bailey, 1984). A trend line cannot be drawn by any method through a series of data points spanning a scale break in the vertical axis and generally should not be drawn across scale breaks in the horizontal axis.

The specific degree of acceleration or deceleration of trends in data plotted on semilogarithmic charts can be quantified in numerical terms. For example, on the daily Standard Celeration Chart, a "times-2" celeration means that the response rate is doubling each week, and a "times-1.25" means that the response rate is accelerating by a factor of one fourth each week. A "divide-by-2" celeration means that each week the response rate will be one half of what it was the week before, and a "divide-by-1.5" means that the frequency is decelerating by one third each week.

There is no direct way to determine visually from data plotted on equal-interval charts the specific rates at which trends increase or decrease. But visual comparison of trend lines drawn through data on equal-interval charts can provide important information about the relative rates of behavior change.

A trend may be highly stable with all of the data points falling on or near the trend line (see Figure 6.22, Graphs C and E). Data paths can also follow a trend even though a high degree of variability exists among the data points (see Figure 6.22, Graphs D and F).

Visual Analysis Between Conditions

After inspection of the data within each condition or phase of a study, visual analysis proceeds with a comparison of data between conditions. Drawing proper conclusions entails comparing the previously discussed properties of behavioral data—level, trend, and variability between different conditions and among similar conditions.

A condition change line indicates that an independent variable was manipulated at a given point in time. To determine whether an immediate change in behavior occurred at that point in time, one needs to examine the difference between the last data point before the condition change line and the first data point in the new condition.

The data are also examined in terms of the overall level of performance between conditions. In general, when all data points in one condition fall outside the range of values for all data points in an adjacent condition (i.e., there is no overlap of data points between the highest values obtained in one condition and the lowest values obtained in the other condition), there is little doubt that behavior changed from one condition to the next. When many data points in adjacent conditions overlap one another on the vertical axis, less confidence can be placed in the effect of the independent variable associated with the change in conditions.[14]

Mean or median level lines can be helpful in examining the overall level between conditions. However, using mean or median level lines to summarize and compare the overall central tendency of data across conditions poses two serious problems. First, the viewer of such a visual display must guard against letting "apparently large differences among measures of central tendency visually overwhelm the presence of equally large amounts of uncontrolled variability" (Johnston & Pennypacker, 1980, p. 351). Emphasizing mean changes in performance in a graphic display can suggest a greater degree of experimental control was obtained than is warranted by the data. In the top graph of Figure 6.23, half of

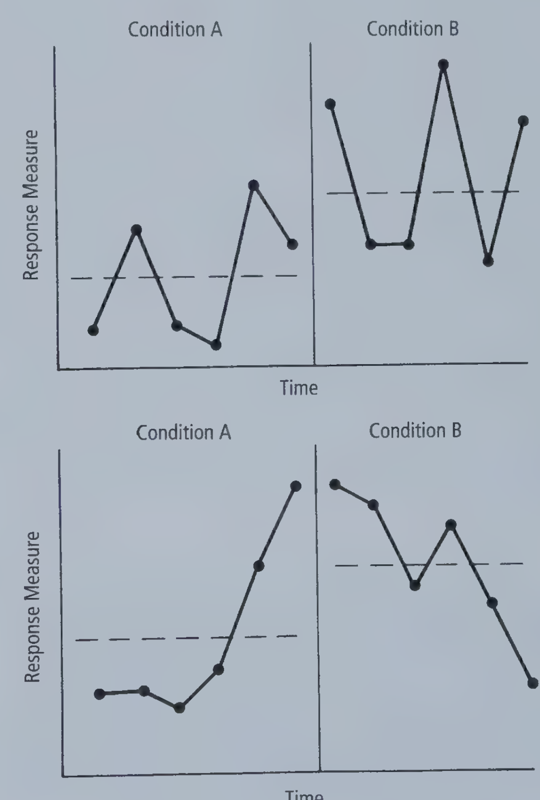

Figure 6.23 Inappropriate use of mean level lines, encouraging interpretation of a higher overall level of responding in Condition B when extreme variability (top graph) and trends (bottom graph) warrant different conclusions.

the data points in Condition B fall within the range of values of the measures taken during Condition A, but the mean level lines suggest a clear change in behavior. Second, measures of central tendency can obscure important trends in the data that warrant interpretations other than those suggested by the central tendency indicators. Although a mean or median line accurately represents the average or typical performance, neither provides any indication of increasing or decreasing performance. In the bottom graph of Figure 6.23, for example, the mean line suggests a higher level of performance in Condition B than in Condition A, but an examination of trend yields a very different picture of behavior change within and between Conditions A and B.

Those analyzing behavioral data should also note any changes in level that occur after a new condition has been in place for some time and any changes in level that occur early in a new condition but are later lost. Such delayed or temporary effects can indicate that the independent variable must be in place for some time before behavior changes, or that the temporary level change was the result of an uncontrolled variable. Either case calls for further investigation in an effort to isolate and control relevant variables.

Visual analysis of data between adjacent conditions includes an examination of the trends exhibited by the data in each condition to determine whether the trend found in the first condition changed in direction or slope during the subsequent condition. In practice, because each data point in a series contributes to level and trend, the two characteristics are viewed in conjunction with one another. Figure 6.24 presents stylized data paths illustrating four basic combinations of change or lack of change in level and trend between adjacent conditions. Of course, many other data patterns could display the same characteristics. Idealized, straight-line data paths that eliminate the variability found in most repeated measures of behavior have been used to highlight level and trend.

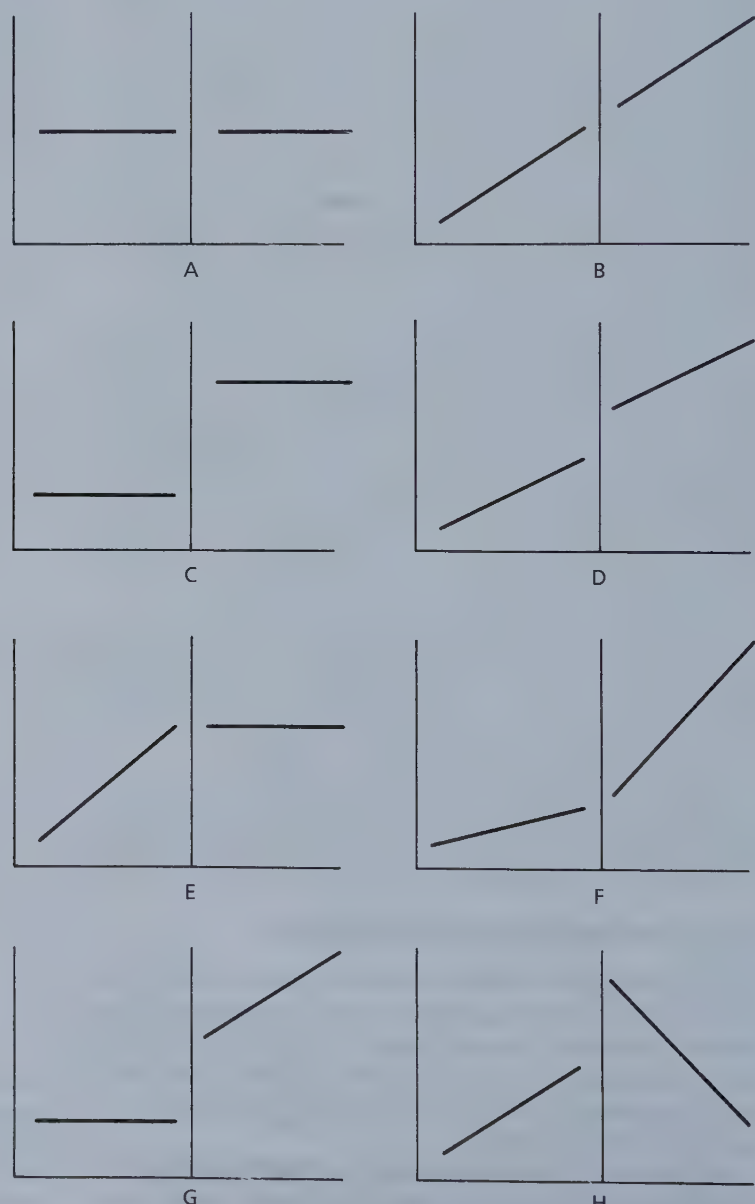

Figure 6.24 Stylized data paths illustrating the different combinations of change or lack of change in level and trend between two adjacent conditions: Graphs A and B show no change in either level or trend between the two conditions, Graphs C and D show changes in level and no change in trend, Graphs E and F depict no immediate change in level and a change in trend, and Graphs G and H reveal change in both level and trend.

From "Time-Series Analysis in Operant Research," by R. R. Jones, R. S. Vaught, and M. R. Weinrott, 1977, *Journal of Applied Behavior Analysis*, 10, p. 157. Copyright 1977 by the Society for the Experimental Analysis of Behavior, Inc. Adapted by permission.

Visual analysis includes not only an examination and comparison of changes in level and trend between adjacent conditions, but also an examination of performance across similar conditions. Interpreting what the data from an applied behavior *analysis* mean requires more than visual analysis and the identification and description of level, trend, and variability. When behavior change is demonstrated over the course of a treatment program or research study, the next question to be asked is, Was the change in behavior a function of the treatment or experimental variable? The remaining chapters of Part Three describe strategies and tactics of experimental design used by applied behavior analysts in an effort to provide a meaningful answer.

SUMMARY

1. Applied behavior analysts document and quantify behavior change by direct and repeated measurement of behavior, and the product of those measurements is called *data*.
2. Graphs are relatively simple formats for visually displaying relationships among and between a series of measurements and relevant variables.

Purpose and Benefits of Graphic Displays of Behavioral Data

3. Graphing each measure of behavior as it is collected provides the practitioner or researcher with an immediate and ongoing visual record of the participant's behavior, allowing treatment and experimental decisions to be responsive to the participant's performance.
4. Direct and continual contact with the data in a readily analyzable format enables the practitioner or researcher to identify and investigate interesting variations in behavior as they occur.
5. As a judgmental aid for interpreting experimental results, graphic display is a fast, relatively easy-to-learn method that imposes no arbitrary levels of significance for evaluating behavior change.
6. Visual analysis of graphed data is a conservative method for determining the significance of behavior change; only variables able to produce meaningful effects repeatedly are considered significant, and weak and unstable variables are screened out.
7. Graphs enable and encourage independent judgments of the meaning and significance of behavior change by others.
8. Graphs can serve as effective sources of feedback to the people whose behavior they represent.

Graphs Used by Applied Behavior Analysts

9. Line graphs, the most commonly used format for the graphic display of behavioral data, are based on the Cartesian plane, a two-dimensional area formed by the intersection of two perpendicular lines.
10. Major parts of the simple line graph are the horizontal axis (also called the x-axis), the vertical axis (also called the y-axis), condition change lines, condition labels, data points, the data path, and the figure caption.
11. Graphs with multiple data paths on the same set of axes are used in applied behavior analysis to show (a) two or more dimensions of the same behavior, (b) two or more different behaviors, (c) the same behavior under different and alternating experimental conditions, (d) changes in target behavior relative to the changing values of an independent variable, and (e) the behavior of two or more participants.
12. A second vertical axis, which is drawn on the right-hand side of the horizontal axis, is sometimes used to show different scales for multiple data paths.
13. Bar graphs are used for two primary purposes: (a) to display discrete data not related by an underlying dimension that can be used to scale the horizontal axis and (b) to summarize and enable easy comparison of the performance of a participant or group of participants during the different conditions of an experiment.
14. Each data point on a cumulative record represents the total number of responses emitted by the subject since measurement began. The steeper the slope of the data path on a cumulative graph, the higher the response rate.
15. Overall response rate refers to the average rate of response over a given time period; a local response rate refers to the rate of response during a smaller period within a larger period for which an overall response rate has been given.
16. Cumulative records are especially effective for displaying data when (a) the total number of responses made over time is important, (b) the graph is used as a source of feedback to the subject, (c) the target behavior can occur only once per measurement period, and (d) a fine analysis of a single instance or portions of data from an experiment is desired.
17. Ratio charts use a logarithmic-scaled y-axis so that changes in behavior that are of equal proportion (e.g., doublings of the response measure) are represented by equal distances on the vertical axis.
18. The Standard Celeration Chart is a six-cycle multiply-divide graph that enables the standardized charting of celeration, a linear measure of frequency change across time, a factor by which frequency multiplies or divides per unit of time.
19. A scatterplot shows the relative distribution of individual measures in a data set with respect to the variables depicted by the x- and y-axes.

Constructing Line Graphs

20. The vertical axis is drawn to a length approximately two-thirds that of the horizontal axis.

21. The horizontal axis is marked in equal intervals, each representing, from left to right, the chronological succession of equal time periods within which behavior was measured.

22. Scale breaks on the horizontal axis indicate discontinuities of time.

23. The vertical axis is scaled relative to the dimension of behavior measured, the range of values of the measures obtained, and the social significance of various levels of change in the target behavior.

24. Condition change lines indicate changes in the treatment program or manipulations of an independent variable and are drawn to the same height as the vertical axis.

25. A brief, descriptive label identifies each condition of an experiment or behavior change program.

26. Data points should be accurately placed with bold, solid dots. When multiple data paths are used, different geometric symbols are used to distinguish each data set.

27. Data paths are created by connecting successive data points with a straight line.

28. Successive data points should not be connected when (a) they fall on either side of a condition change line; (b) they span a significant period in which behavior was not measured; (c) they span discontinuities of time on the horizontal axis; (d) they fall on either side of a regularly scheduled measurement period in which data were not collected or were lost, destroyed, or otherwise not available; (e) they fall in a follow-up or postcheck period that is not regularly spaced in time in the same manner as the rest of the study; or (f) one member of the pair falls outside the range of values described by the vertical axis.

29. The figure caption provides a concise but complete description of the graph, giving all of the information needed to interpret the display.

30. Graphs should be printed in black ink only.

Interpreting Graphically Displayed Behavioral Data

31. Visual analysis of graphed data attempts to answer two questions: (a) did a socially meaningful change in behavior take place and (b) if so, can the behavior change be attributed to the independent variable?

32. Before beginning to evaluate the data displayed in a graph, a careful examination of the graph's construction should be undertaken. If distortion is suspected from the features of the graph's construction, the data should be replotted on a new set of axes before interpretation is attempted.

33. Blocked data and data representing the average performance of a group of subjects should be viewed with the understanding that significant variability may have been lost in the display.

34. Visual analysis of data within a given condition focuses on the number of data points, the variability of performance, the level of performance, and the direction and degree of any trends in the data.

35. As a general rule, the more data in a condition and the greater the stability of those data, the more confidence one can place in the data path's estimate of behavior during that time. The more variability in the behavioral measures during a condition, the greater the need for additional data.

36. *Variability* refers to the frequency and degree to which multiple measures of behavior yield different outcomes. A high degree of variability within a given condition usually indicates that little or no control has been achieved over the factors influencing the behavior.

37. *Level* refers to the value on the vertical axis around which a series of data points converges. When the data in a given condition all fall at or near a specific level, the behavior is considered stable with respect to level; to the extent that the behavioral measures vary considerably from one to another, the data are described as showing variability with respect to level. In cases of extreme variability, no particular level of performance is evidenced.

38. Mean or median level lines are sometimes added to graphic displays to represent the overall average or typical performance during a condition. Mean and median level lines should be used and interpreted with care because they can obscure important variability and trends in the data.

39. *Trend* refers to the overall direction taken by a data path; trends are described in terms of their direction (increasing, decreasing, or zero trend), degree (gradual or steep), and the extent of variability of data points around the trend.

40. Trend direction and degree can be visually represented by drawing a trend line, or line of progress, through a series of data points. Trend lines can be drawn freehand, using the least-squares regression equation, or using a method called the split-middle line of progress. Split-middle lines of progress can be drawn quickly and reliably and have proven useful in analyzing behavior change.

41. Visual analysis of data across conditions determines whether change in level, trend, and/or variability occurred and to what extent any changes were significant.

MULTIPLE-CHOICE QUESTIONS

1. Visual analysis is considered a(n) ________ method for determining the social significance of behavior change.
   a. Temporary
   b. Arrangement
   c. Subjective
   d. Conservative
   Hint: (See "Purpose and Benefits of Graphic Displays of Behavioral Data")
2. Graphic displays of behavioral data are considered simple formats for visually displaying ________ among and between a series of measurements and relevant variables.
   a. Time series
   b. Data
   c. Relationships
   d. Graphs
   Hint: (See "Purpose and Benefits of Graphic Displays of Behavioral Data")
3. This type of graph is also known as a histogram and is useful in summarizing behavioral data allowing for a quick comparison of performance across participants and/or conditions.
   a. Line graph
   b. Scatterplot
   c. Cumulative Record
   d. Bar graph
   Hint: (See "Graphs Used by Applied Behavior Analysts")
4. This is the most commonly used graph in applied behavior analysis.
   a. Line graph
   b. Scatterplot
   c. Cumulative Record
   d. Bar graph
   Hint: (See "Graphs Used by Applied Behavior Analysts")
5. You are interested in the total number of sight words accurately read since your data collection began last week. Which graphing convention allows you to most efficiently answer your inquiry?
   a. Line graph
   b. Scatterplot
   c. Cumulative Record
   d. Bar graph
   Hint: (See "Graphs Used by Applied Behavior Analysts")
6. You are interested in displaying the mean score for both your baseline and experimental condition. For this summary, you are willing to sacrifice the presentation and detection of variability and trends.
   a. Line graph
   b. Scatterplot
   c. Cumulative Record
   d. Bar graph
   Hint: (See "Graphs Used by Applied Behavior Analysts")
7. A ________ is depicted on a line graph by an open spot in the axis with a squiggly line at each end.
   a. Condition line
   b. Data set
   c. Scale break
   d. Horizontal axis
   Hint: (See "Line Graphs")
8. This part of a line graph is printed below the graph and gives a concise but complete description of the figure.
   a. Figure caption
   b. Data set
   c. Scale break
   d. Condition label
   Hint: (See "Line Graphs")

9. A ________ chart is a type of semilogarithmic chart useful for charting accelerating and decelerating performances over time.

   a. Cumulative time
   b. Standard celebration
   c. Scatter plot
   d. Bar graph

   Hint: (See "Graphs Used by Applied Behavior Analysts")

10. In order to produce a visual representation of an overall rate on a cumulative graph, the first and last data points of a given series of observations should be:

   a. Plotted bilaterally
   b. Plotted using different symbols
   c. Drawn simultaneously
   d. Connected with a straight line

   Hint: (See "Graphs Used by Applied Behavior Analysts")

11. The ________ of each data path on a cumulative record represents the different rates of acquisition.

   a. Position
   b. Slope
   c. Scatter
   d. Slant

   Hint: (See "Graphs Used by Applied Behavior Analysts")

12. A scatterplot shows the ________ distribution of individual measures in a data set with respect to the variables depicted by the both the x- and y-axes.

   a. Exact
   b. Scattered
   c. Relative
   d. Standard

   Hint: (See "Graphs Used by Applied Behavior Analysts")

13. Scatterplots are useful when applied behavior analysts are interested in finding out the ________ distribution of the target behavior. In other words, a scatterplot illustrates whether the behavior's occurrence is typically associated with certain time periods.

   a. Temporal
   b. Independent
   c. Dependent
   d. False

   Hint: (See "Graphs Used by Applied Behavior Analysts")

14. Which part of the line graph is the arrow pointed at?

   a. X-axis
   b. Condition change line
   c. Y-axis
   d. Data path

   Hint: (See "Line Graphs")

15. The type of graph illustrated in this example has disconnected data points and is used primarily to depict temporal distributions and reveal correlations between variables depicted on the y-axis with variables depicted on the x-axis.

   a. Cumulative record
   b. Line graph
   c. Bar graph
   d. Scatterplot

   Hint: (See "Line Graphs")

16. You are interested in beginning a self-management program to help you save money for a new car. Which type of graph would provide the most appropriate feedback and display your progress toward your goal?

   a. Cumulative record
   b. Line graph
   c. Bar graph
   d. Scatterplot

   Hint: (See "Graphs Used by Applied Behavior Analysts")

17. You are interested in comparing the effects of two different interventions on a single target behavior. You have decided to present each of the interventions in an alternating fashion and measure the changes in the value of your dependent variable. You would like to plot the results of both interventions on one graph. Which would be the best format to display your results?

   a. Cumulative record
   b. Line graph
   c. Bar graph
   d. Scatterplot

   Hint: (See "Graphs Used by Applied Behavior Analysts")

18. Which of the following best describes the direction, degree, and variability of the data path depicted in this graph?

   a. Rapidly increasing, variable trend
   b. Zero trend
   c. Gradually decreasing, variable trend
   d. Rapidly decreasing, stable trend

   Hint: (See "Interpreting Graphically Displayed Behavioral Data")

19. Which of the following best describes the direction, degree, and variability of the data path depicted in this graph?

   a. Rapidly increasing, variable trend
   b. Cannot be determined
   c. Gradually decreasing, variable trend
   d. Rapidly decreasing, stable trend

   Hint: (See "Interpreting Graphically Displayed Behavioral Data")

ESSAY-TYPE QUESTIONS

1. State a purpose and a benefit of using graphic displays of behavioral data for decision-making over listing a series of numbers in a tabular format.

   Hint: (See "Purpose and Benefits of Graphic Displays of Behavioral Data")

2. Describe a benefit of using visual analysis over statistical analysis in interpreting the social significance of behavior change.

   Hint: (See "Purpose and Benefits of Graphic Displays of Behavioral Data")

3. List and describe the parts of a basic line graph.

   Hint: (See "Parts of a Basic Line Graph")

4. Discuss why a line graph is often the most appropriate format for communicating changes in level, trend, and the variability of behavioral data when comparing the effects of intervention A to intervention B.

   Hint: (See "Graphs Used by Applied Behavior Analysts")

5. Discuss a situation in which a cumulative record would be preferable to a basic line graph.

   Hint: (See "Graphs Used by Applied Behavior Analysts")

6. Discuss a situation in which a scatterplot would be the most appropriate graphic format.

   Hint: (See "Graphs Used by Applied Behavior Analysts")

7. Which type of graph would you select to communicate changes in behavior when the behavior can only occur or not occur one time during a measurement period?

   Hint: (See "Graphs Used by Applied Behavior Analysts")

8. Define the following fundamental properties of behavior change: variability, level, and trend.

   Hint: (See "Interpreting Graphically Displayed Behavioral Data")

NOTES

1. Although often used as a singular construction (e.g., "The data *shows* that . . ."), *data* is the plural form of *datum*, noun of Latin origin; thus, *data* is used correctly with plural verbs (e.g., "These data *are* . . .").
2. Skillful visual analysis is not quite so simple, as will become evident later in this chapter and in Chapter 10.
3. A comparison of the visual analysis of graphed data and inferences based on statistical tests of significance is presented in Chapter 10.
4. Graphs, like statistics, can also be manipulated to make certain interpretations of the data more or less likely. Unlike statistics, however, most graphic displays used in behavior analysis provide direct access to the original data, which allows the inquisitive or doubtful reader to regraph the data and have another look.
5. The terms *condition* and *phase* are related but not synonymous. Properly used, *condition* indicates the environmental arrangements in effect; *phase* refers to a period within a study or behavior change program.
6. Functional communication training is described in Chapter 26.
7. To learn the interesting history and role of the cumulative recorder in the development of behavior analysis, see Lattal (2004) and Morris and Smith (2004).
8. Technically, Figure 6.12 does not represent true rates of response because the number of words spelled correctly was measured and not the rate, or speed, at which they were spelled. However, the slope of each data path represents the "rate" of mastering the spelling words in each session within the context of a total of 10 new words presented per session.
9. For detailed explanations of the Standard Celeration Chart and its use by precision teachers see Cooper, Kubina, and Malanga (1998); Graf and Lindsley (2002); Johnson and Street (2014); Kubina and Yurich 2012); Lindsley (1990, 1992, 1996); and Pennypacker, Gutierrez, and Lindsley (2003).
10. Perhaps the ultimate example of combining visual display techniques is Charles Minard's use of space-time-story graphics to illustrate the interrelations of six variables during Napoleon's ill-fated Russian campaign of 1812–1813 (see Tufte, 1983, p. 41). Tufte called Minard's graph perhaps "the best statistical graphic ever drawn"(p. 40).
11. Although most graphs published in behavior analysis journals since the mid-1990s and many graphs used by practitioners are constructed with computer software, we believe it is essential that applied behavior analysts know how to construct graphs by hand. The knowledge and skills required to create proper graphs by hand enable effective use of graphing software (cited later in this chapter).
12. Several studies have evaluated methods for training visual data analysis skills to behavior analysis students and practitioners (e.g., Kahng et al., 2010; Stewart, Carr, Brandt, & McHenry, 2007; Vanselow, Thompson, & Karsina, 2011; Wolfe & Slocum, 2015; Young & Daly, 2016).
13. When each data point represents multiple measures, a within-session analysis of the data may be warranted to detect behavioral functions and trends not apparent in aggregated data displays (Fahmie & Hanley, 2008). See Figure 6.14 for an example.
14. Whether a documented change in behavior should be interpreted as a function of the independent variable depends on the experimental design used in the study. Strategies and tactics for designing experiments are presented in Chapters 7 through 10.

CHAPTER 7

Analyzing Behavior Change: Basic Assumptions and Strategies

LEARNING OBJECTIVES

- Define and give examples of the basic assumptions underlying the analysis of behavior.
- List and describe the three levels of scientific understanding.
- Define and give examples of functional relations.
- Outline how experiments should be conducted to control for various threats to internal validity.
- Compare and contrast the role of variability in single-subject versus group research designs.
- List and define the essential components of experiments in applied behavior analysis research.
- Write a specific research question given a behavioral phenomenon of interest.
- Define and identify steady or stable rate responding.
- List and define the three elements of baseline logic.
- Discuss the value of establishing a steady baseline in applied behavior analysis.
- Outline guidelines for establishing a steady baseline in applied behavior analysis research.
- Identify four types of baseline data patterns.
- Discuss how single-subject research employs the inductive logic known as "affirmation of the consequent."
- Systematically manipulate independent variables and analyze their effects on treatment.

> Our technology of behavior change is also a technology of behavior measurement and of experimental design; it developed as that package, and as long as it stays in that package, it is a self-evaluating enterprise. Its successes are successes of known magnitude; its failures are almost immediately detected as failures; and whatever its outcomes, they are attributable to known inputs and procedures rather than to chance events or coincidences.
>
> —Donald M. Baer (personal communication, October 21, 1982)

Measurement shows whether, when, and how much behavior has changed, but measurement alone does not reveal why, or more accurately *how*, behavior change occurred. A useful technology of behavior change depends upon knowing the specific arrangements of environmental variables that produced behavior change. Without this knowledge, practitioners' efforts to change behavior would consist of procedures selected from a bag of tricks with little or no generality from one situation to the next.

The search for and demonstration of functional and reliable relations between socially important behavior and its controlling variables is a defining characteristic of applied behavior analysis. As articulated by Don Baer's chapter-opening statement, a major strength of applied behavior analysis is its insistence on experimentation as its method of proof, which enables and demands an ongoing, self-correcting search for effectiveness.

An experimental analysis must be accomplished to determine if and how a given behavior functions in relation to specific changes in the environment. This chapter introduces basic concepts and strategies that underlie the *analysis* in applied behavior analysis.[1] First, we briefly review some general conceptions of science and then continue with a discussion of two defining features and two assumptions about behavior that dictate the experimental methods most conducive to the subject matter. We identify the essential components of an experiment in applied behavior analysis and describe the basic logic that guides experimental methods in applied behavior analysis.

CONCEPTS AND ASSUMPTIONS UNDERLYING THE ANALYSIS OF BEHAVIOR

As discussed in Chapter 1, scientists share a set of common perspectives that include assumptions about the nature of the phenomena they study (determinism), the kind of information that should be gathered on the phenomena of interest (empiricism), the way questions about the workings of nature are most effectively examined (experimentation), and how an experiment's results should be judged (with parsimony and philosophic doubt). As Skinner (1953) noted, these attitudes apply to

all scientific disciplines: "The basic characteristics of science are not restricted to any particular subject matter" (p. 11).

The overall goal of science is complete understanding of the phenomena under study—socially significant behavior, in the case of applied behavior analysis. Scientists use a wide variety of methods that yield understanding at three levels: description, prediction, and control. First, systematic observation enables scientists to describe natural phenomena accurately. Descriptive knowledge of this type yields a collection of facts about the observed events—facts that can be quantified and classified, a necessary and important element of any scientific discipline.

A second level of scientific understanding is achieved when repeated observation shows that two events consistently covary. That is, the occurrence of one event (e.g., marriage) is associated with the occurrence of another event at some reliable degree of probability (e.g., longer life expectancy). The systematic covariation between two events—termed a *correlation*—can be used to predict the probability that one event will occur based on the presence of the other event.

The ability to predict successfully is a useful result of science; prediction allows preparation. However, the greatest potential benefits of science are derived from the third, and highest, level of scientific understanding, which comes from establishing experimental control. "The experimental method is a method for isolating the relevant variables within a pattern of events. Methods that depend merely on observed correlations, without experimental intervention, are inherently ambiguous" (Dinsmoor, 2003, p. 152).

Experimental Control: The Path to and Goal of Behavior Analysis

Behavior—the interaction between an organism and its environment—is best analyzed by measuring behavior change produced by imposed variations on the environment. This statement embodies the general strategy and the goal of behavior analytic research: to demonstrate that changes in the target behavior occurred *because of* experimentally manipulated changes in the environment.

Experimental control is achieved when a predictable change in behavior (the dependent variable) is reliably produced by the systematic manipulation of some aspect of the environment (the independent variable). Experimentally determining the effects of environmental manipulation on behavior and demonstrating that those effects can be reliably produced constitute the *analysis* in applied behavior analysis. An analysis of a behavior has been achieved when a reliable functional relation between the behavior and some specified aspect of the environment has been demonstrated convincingly. Knowledge of functional relations enables practitioners trained in applied behavior analysis to reliably alter behavior in meaningful ways.

An analysis of behavior "requires a believable demonstration of the events that can be responsible for the occurrence or nonoccurrence of that behavior. An experimenter has achieved an analysis of a behavior when he can exercise control over it" (Baer, Wolf, & Risley, 1968, p. 94).[2] That behavior analysts seek and value the experimental isolation of a given environmental variable of which a behavior is shown to be a function is often misinterpreted as support for a simplistic conception of behavioral causality. The fact that a behavior varies as a function of a given variable does not preclude that behavior also varying as a function of other variables. Thus, Baer and colleagues described an experimental analysis as a convincing demonstration that a variable *can* be responsible for the observed behavior change. Although a complete analysis (i.e., understanding) of a behavior requires an accounting of all of its multiple causes, an *applied* (i.e., technologically useful) analysis has been accomplished when the investigator has isolated an environmental variable (or group of variables that operate together as a treatment package) that reliably produces socially significant behavior change. An *applied* analysis also requires the target behavior to be a function of an environmental event that can be practically and ethically manipulated.

An experiment that shows convincingly that changes in the dependent variable are a function of the independent variable and not the result of uncontrolled or unknown variables is said to have a high degree of **internal validity**. A study with questionable internal validity yields no meaningful statements regarding functional relations between the variables examined in the experiment. Nor can a study without convincing internal validity be used as the basis for statements claiming generality of the findings to other persons, settings, and/or behaviors. **External validity** refers to the degree to which a study's results are generalizable to other subjects, settings, and/or behaviors. Strategies for assessing and extending the external validity of experimentally demonstrated functional relations are discussed in Chapter 10.

When planning an experiment and later when examining data from an ongoing study, investigators must always look out for threats to internal validity. Uncontrolled variables known or suspected to exert an influence on the dependent variable are called **confounding variables**. For example, suppose a researcher wants to analyze the effects of guided lecture notes on high school biology students' scores on next-day quizzes. Just one of many potential confounding variables the researcher would need to take into account would be each student's changing level of interest in and background knowledge about the specific curriculum content (e.g., a student's high score on a quiz following a lecture on sea life may be due to his prior knowledge about fishing, not the guided notes provided during that lecture).

A primary factor in evaluating the internal validity of an experiment is the extent to which it eliminates or controls the effects of confounding variables while still investigating the research questions of interest. Eliminating every possible source of uncontrolled variability in an experiment is an impossible ideal, but one all researchers should strive to attain. In reality, the goal of experimental design is eliminating as many uncontrolled variables as possible while holding constant the influence of all other variables except the independent variable, which is purposefully manipulated to determine its effects.

Behavior: Defining Features and Assumptions that Guide Its Analysis

Behavior is a difficult subject matter, not because it is inaccessible, but because it is extremely complex. Since it is a

> process, rather than a thing, it cannot easily be held still for observation. It is changing, fluid, evanescent, and for this reason it makes great technical demands upon the ingenuity and energy of the scientist.
>
> —B. F. Skinner (1953, p. 15)

How a scientific discipline defines its subject matter exerts profound influence and imposes certain constraints on the experimental strategies that will be most effective in an understanding of it. Experimental methods in behavior analysis are guided by two defining features of behavior: (a) Behavior is an individual phenomenon and (b) behavior is dynamic and continuous; and two assumptions concerning its nature: (a) behavior is determined and (b) behavioral variability is extrinsic to the organism.

Behavior Is an Individual Phenomenon

If behavior is defined as a person's interaction with the environment, it follows that a science seeking to discover general principles or laws that govern behavior must study the behavior of individuals. Groups of people do not behave; individual people do. Thus, the experimental strategy of behavior analysis uses within-subject (or single-case) methods of analysis.

The average performance of a group of individuals often yields interesting and useful information and may, depending on the methods by which individuals were selected to be in the group, enable probability statements about the average performance within the larger population represented by the group. However, "group data" provide no information about the behavior of any individual or how any individual might perform in the future. For example, although administrators and taxpayers may be justifiably interested in the average increase in students' reading comprehension from grade level to grade level, such information is of little use to the classroom teacher who must decide how to improve a given student's comprehension skills.

Nonetheless, learning how behavior–environment relations work with many individuals is vital. A science of behavior contributes to a useful technology of behavior change only to the extent that it discovers functional relations with generality across individuals. The issue is how to achieve that generality. Behavior analysts have found that discovery of behavioral principles with generality across persons is best accomplished by replicating demonstrated functional relations with additional subjects.

Behavior Is Dynamic and Continuous

Just as behavior cannot take place in an environmental void, so must behavior occur in time. "Behavior is a continuous process, from birth through to death. The problem is that this stream of change cannot be stopped for scientific purposes" (Keenan & Dillenburger, 2000, p. 26). Measuring behavior as it changes over time is a fundamental feature of applied behavior analysis. Therefore, single measures, or even multiple measures sporadically dispersed over time, cannot provide an adequate description of behavior change. Only continuous measurement yields a complete record of behavior as it occurs in context with its environmental influences. Because true continuous measurement is seldom feasible in applied settings, systematic repeated measurement of behavior (as described in Chapters 4 and 5) is the hallmark of applied behavior analysis.

Behavior Is Determined

As discussed in Chapter 1, all scientists assume that the universe is a lawful and orderly place and that natural phenomena occur in relation to other natural events.

> The touchstone of all scientific research is order. In the experimental analysis of behavior, the orderliness of relations between environmental variables and the subject's behavior is at once the operating assumption upon which the experimenter proceeds, the observed fact that permits doing so, and the goal that continuously focuses experimental decisions. (Johnston & Pennypacker, 1993a, p. 238)

Behavior analysts consider behavior to be a natural phenomenon that, like all natural phenomena, is determined. Although determinism must always remain an assumption—it cannot be proven—it is an assumption with strong empirical support.

> Data gathered from all scientific fields indicate that *determinism* holds throughout nature. It has become clear that the *law of determinism*, that is, that all things are determined, holds for the behavioral area also. . . . When looking at actual behavior we've found that in situation 1, behavior is caused; in situation 2, behavior is caused; in situation 3, behavior is caused; . . . and in situation 1001, behavior is caused. Every time an experimenter introduces an independent variable that produces some behavior or some change in behavior, we have further *empirical* evidence that behavior is caused or deterministic. (Malott, General, & Snapper, 1973, pp. 170, 175)

Behavioral Variability Is Extrinsic to the Organism

When repeated measures reveal inconsistent responding by a subject when environmental conditions are held constant, the data are said to display variability. The experimental approach most commonly used in psychology and other social and behavioral sciences (e.g., education, sociology, political science) makes two assumptions about such variability: (a) Behavioral variability is an intrinsic characteristic of the organism, and (b) behavioral variability is distributed randomly among individuals in any given population. These assumptions have critical methodological implications: (a) Attempting to control or investigate variability is a waste of time—it simply exists, it's a given; and (b) by averaging the performance of individual subjects within large groups, the random nature of variability can be statistically controlled or canceled out. Both assumptions about behavioral variability are likely false (empirical evidence points in the opposite direction), and the methods they encourage are detrimental to a science of behavior. "Variables are not canceled statistically. They are simply buried so their effects are not seen" (Sidman, 1960, p. 162).[3]

Behavior analysts approach variability in their data quite differently. A fundamental assumption underlying the design and guiding the conduct of experiments in behavior analysis is that, rather than being an intrinsic characteristic of the organism, behavioral variability is the result of environmental influence: the

independent variable with which the investigator seeks to produce change, an uncontrolled aspect of the experiment itself, and/or an uncontrolled or unknown factor outside the experiment.

The assumption of extrinsic variability yields the following methodological implication: Instead of averaging the performance of many subjects in an attempt to mask variability (and forfeiting the opportunity to understand and control it), behavior analysts experimentally manipulate factors suspected of causing the variability. Searching for the causal factors contributes to the scientific understanding of behavior, because experimentally demonstrating a source of variability suggests another functional relation. In some studies, "tracking down these answers may even turn out to be more rewarding than answering the original experimental question" (Johnston & Pennypacker, 1980, p. 226).

From a purely scientific viewpoint, experimentally tracking down sources of variability is always the preferred approach. However, the applied behavior analyst, with a problem to solve, must often take variability as it presents itself (Sidman, 1960). Sometimes the applied researcher has neither the time nor the resources to experimentally manipulate even suspected and likely sources of variability (e.g., a teacher who interacts with a student for only part of the day has no hope of controlling the many variables outside the classroom that influence the student's behavior). In most settings, applied behavior analysts seek treatment variables robust enough to overcome variability induced by uncontrolled factors (Baer, 1977b).

COMPONENTS OF APPLIED BEHAVIOR ANALYSIS EXPERIMENTS

> Nature to be commanded must be obeyed. . . . But, that coin has another face. Once obeyed, nature can be commanded.
>
> —B. F. Skinner (1956, p. 232)

Experimentation is the scientist's way of discovering nature's rules. Discoveries that prove valid and reliable can contribute to a technology of effective behavior change. Experiments in applied behavior analysis include these essential components:

- Research question
- At least one participant (subject)
- At least one behavior (dependent variable)
- At least one setting
- A system for measuring the behavior and ongoing visual analysis of the data
- At least one intervention or treatment condition (independent variable)
- Manipulation of the independent variable to determine its effects on the dependent variable (experimental design)

Research Question

> We conduct experiments to find out something we do not know.
>
> —Murray Sidman (1960, p. 214)

For the applied behavior analyst, Sidman's "something we do not know" is cast in the form of a question about the existence and/or specific nature of a functional relation between meaningful improvement in socially significant behavior and one or more of its controlling variables. A **research question** specifies what the investigator wants the experiment to answer. Research questions in applied behavior analysis take many forms; most questions are one of four types:

- ***Demonstration***—to what extent will this intervention work (i.e., change the behavior of interest)?
- ***Parametric***—does more or less of the intervention work better?
- ***Component***—how effective is the intervention when various components are added or subtracted?
- ***Comparative***—does one intervention work better than another? (adapted from Wolery, Lane, & Common, 2018)

In some published reports of applied behavior analysis studies, the investigators state their research question(s) explicitly, as in these examples:

- The research questions were as follows: 1. What are the effects of a self-monitoring package with conferencing on the completion of spelling and math homework for students with disabilities in an inclusive general education classroom? 2. What are the effects of a self-monitoring package with conferencing on the accuracy of spelling and math homework for students with disabilities in an inclusive general education classroom? 3. If gains are made in completion and accuracy of spelling and math homework, will students maintain them 2 and 3 weeks after the intervention has ended? (Falkenberg & Barbetta, 2013, pp. 191–192)
- Four primary research questions were addressed: What are the effects of training middle school students with learning disabilities to recruit teacher attention in the special education classroom on (a) the number of recruiting responses they emit in the general education classroom, (b) the number of teacher praise statements received by the students in the general education classroom, (c) the number of instructional feedback statements received by the students in the general education classroom, and (d) the students' academic productivity and accuracy in the general education classroom? (Alber, Heward, & Hippler, 1999, p. 255)
- Experiment 1—What are the differences in responding under the "no programmed consequence," "praise," and "known reinforcer" conditions? To what extent will 3 to 5 "pairing" sessions per day affect responding during "praise" sessions conducted at the beginning and end of each day? (Axe & Laprime, 2017, p. 330)

More often, however, the research question is implicit within a statement of the study's purpose. For example:

- [T]he purpose of this study was to determine the effects of self-graphing on the quantity and quality of writing for students with high-incidence disabilities. (Stolz, Itoi, Konrad, & Alber-Morgan, 2008, p. 174)
- [T]he purpose of this study was to evaluate the extent to which lag schedules of reinforcement produced responses

that were already in the existing repertoires of three children diagnosed with autism, as well as the extent to which lag schedules produced novel responses. (Contreras & Betz, 2016, p. 5)

- [T]he purpose of this study was to examine the use of habit reversal to decrease filled pauses that occur during public speaking. (Mancuso & Miltenberger, 2016, p. 188)
- [W]e sought to determine if teaching three children with autism to monitor their peers' reading responses would lead to the acquisition of sight words. (Taylor, DeQuinzio, & Stine, 2012, p. 815)
- The purpose of this study was to determine whether naturally occurring meals would affect performance adversely during postmeal sessions in which highly preferred food was used as reinforcement. (Zhou, Iwata, & Shore, 2002, pp. 411–412)

Whether the research question is stated explicitly in the form of a question or implicit within a statement of purpose, all aspects of the experiment's design and conduct should follow from it.

> A good design is one that answers the question convincingly, and as such needs to be constructed in reaction to the question and then tested through arguments in that context (sometimes called "thinking through"), rather than imitated from a textbook. (Baer, Wolf, & Risley, 1987, p. 319)

Participant

Experiments in applied behavior analysis are most often referred to as *single-subject* or **single-case designs**. These terms do not mean that applied behavior analysis studies are conducted with only one subject (though some are); they denote an experimental logic for detecting and analyzing functional relations between environmental variables and behavior change that employs each subject as her own control.[4] Repeated measures of each subject's behavior are obtained as she is exposed to each condition of the study (e.g., the presence and absence of the independent variable). A subject is often exposed to each condition several times over the course of an experiment. Measures of the subject's behavior during each phase of the study provide the basis for comparing the effects of experimental variables as they are presented or withdrawn in subsequent conditions.

Although most applied behavior analysis studies involve more than one subject, each subject's data are graphed and analyzed separately.[5] Instead of using *single-case* or *single-subject design* to refer to an experiment in which each subject serves as his or her own control, some authors use more aptly descriptive terms such as *within-subject design*, *intrasubject design*, and *repeated-measures design*.[6]

Sometimes the applied behavior analyst is interested in assessing the overall effect of a treatment variable within a group of subjects—for example, the number of homework assignments completed by members of a class of fifth-grade students. In such a case, the total number of assignments completed may be measured, graphed, and analyzed as a dependent variable. However, unless each student's data are individually graphed and interpreted, no individual student's behavior has been analyzed, and the data for the group may not be representative of any individual subject.

Use of a single participant, or a small number of participants, each of whom is considered an intact experiment, stands in sharp contrast to the between-group designs traditionally used in psychology and the other social sciences that employ large numbers of subjects. Proponents of between-group designs contend that using a large number of subjects controls for the variability discussed earlier and increases the generality (or external validity) of any findings to the population from which the subjects were selected. The advantages and disadvantages of an experimental approach based on within-subject comparisons of the behavior of individual subjects versus comparisons of the average performance of different groups of subjects is discussed in Chapter 10.

Behavior: Dependent Variable

The target behavior in an applied behavior analysis experiment, or more precisely a measurable dimensional quantity of that behavior (e.g., rate, duration), is called the **dependent variable**. It is so labeled because the experiment is designed precisely to determine whether the behavior is, in fact, *dependent on* (i.e., a function of) the independent variable(s) manipulated by the investigator. (Criteria and procedures for selecting and defining response classes that meet the *applied* requirements as dependent variables in applied behavior analysis are described in Chapter 3.)

In some studies multiple behaviors are measured. One reason for measuring multiple behaviors is to provide data patterns that can serve as controls for evaluating and replicating the effects of an independent variable as it is applied sequentially to each of the behaviors.[7] A second reason for multiple dependent measures is to assess the presence and extent of the independent variable's effects on behaviors other than the response class to which it was applied directly. This strategy can reveal whether the independent variable has collateral effects—either desired or undesired—on other behaviors of interest. Such behaviors are referred to as secondary dependent variables. The experimenter obtains regular measures of their rate of occurrence, though perhaps not as often as measures of the primary dependent variable are recorded.

Still another reason for measuring multiple behaviors is to determine whether changes in the behavior of a person other than the subject occur during the course of an experiment and whether such changes might in turn explain observed changes in the subject's behavior. This strategy is implemented primarily to assess the effects of a suspected confounding variable: The additional behavior or behaviors measured are not true dependent variables in the sense of undergoing analysis. For example, in a classic study analyzing the effects of the self-recording by a junior high school girl on her classroom study behavior, Broden, Hall, and Mitts (1971) observed and recorded the number of times the girl's teacher paid attention to her throughout the experiment. If the frequency of teacher attention had covaried with changes in the girl's study behavior, a functional relation between self-recording and study behavior would not have been demonstrated. In that case, teacher attention would likely have been identified as a potential confounding variable,

and the focus of the investigation shifted to include efforts to experimentally control it (i.e., to hold teacher attention constant) or to systematically manipulate and analyze its effects. However, the data revealed no correlation between teacher attention and study behavior during the first four phases of the experiment, when concern was highest that teacher attention may have been a confounding variable.

Setting

> Control the environment and you will see order in behavior.
> —B. F. Skinner (1967, p. 399)

Functional relations are demonstrated when observed variations in behavior can be attributed to specific operations imposed on the environment. *Experimental control* is achieved when the systematic manipulation of some aspect of the subject's environment (the independent variable) reliably produces a predictable change in behavior (the dependent variable). To make such an attribution, the investigator must, among other things, control two sets of environmental variables. First, the investigator must control the presence, absence, or value of the independent variable in every phase of the experiment. Second, the investigator must control, by holding constant, all other aspects of the experimental setting—**extraneous variables**—to prevent unplanned environmental variation. These two operations—precisely manipulating the independent variable and maintaining the constancy of every other relevant aspect of the experimental setting—define the second meaning of *experimental control.*

In basic laboratory research, experimental space is designed and furnished to maximize experimental control. Lighting, temperature, and sound, for example, are all held constant, and programmed apparatus virtually guarantee the presentation of antecedent stimuli and the delivery of consequences as planned. Applied behavior analysts carry out research where socially important behaviors naturally occur—classrooms, homes, workplaces, and community settings. It is impossible to control every feature of an applied environment, and to add to the difficulty, subjects are typically in the experimental setting for a small portion of each day, bringing with them the influences of events and contingencies operating in other settings.

In spite of the complexity and ever-changing nature of applied settings, the behavior analyst must make every effort to hold constant all seemingly relevant aspects of the environment. When unplanned variations are noted, the investigator must wait out their effects or try to incorporate them into the design of the experiment. In any event, repeated measures of the subject's behavior provide the barometer for assessing whether unplanned environmental changes are of concern.

Applied studies are often conducted in more than one setting. Researchers sometimes use concurrent measures of the same behavior obtained across settings as controls for analyzing the effects of an independent variable that is sequentially applied to the behavior in each setting.[8] Data are also collected in multiple settings to assess the extent to which behavior changes observed in the primary setting have occurred in the other setting(s).

Measurement System and Ongoing Visual Analysis

Beginning students of behavior analysis sometimes believe the discipline is preoccupied with issues and procedures related to the observation and measurement of behavior. They want to get on with the analysis. Measuring behavior change over time is the principal feature of single-case experimental method. The results of any experiment can be presented and interpreted only in terms of what was measured, and the observation and recording procedures used in the study determine not only what was measured but also how well it was measured (i.e., how representative of the subject's actual behavior is the estimate provided by the experimental data—all measurements of behavior, no matter how frequent and technically precise, are estimates of true values).

Observation and recording procedures must be conducted in a standardized manner throughout each session of an experiment. Standardization involves every aspect of the measurement system, from the definition of the target behavior (dependent variable) to the scheduling of observations to the manner in which the raw data are transposed from recording sheets to session summary sheets to the way the data are graphed. As detailed in Chapter 5, unintended or imposed changes in measurement tactics can result in unwanted variability or confounded treatment effects.

The previous chapter outlined advantages that accrue to the behavioral researchers and practitioners who maintain direct contact with the experimental data by ongoing visual inspection of graphic displays. Behavior analysts must recognize changes in level, trend, and degree of variability as these changes develop in the data. Because behavior is a continuous, dynamic phenomenon, experiments designed to discover its controlling variables must enable the investigator to inspect and respond to the data continuously as the study progresses. Only in this way can the behavior analyst be ready to manipulate features of the environment at the time and in the manner that will best reveal functional relations and minimize the effects of confounding variables.

Intervention or Treatment: Independent Variable

Behavior analysts seek functional relations between behavior change and environmental variables. The particular aspect of the environment that the experimenter manipulates to find out whether it affects the subject's behavior is called the **independent variable**. Sometimes called the *experimental variable*, *intervention*, or *treatment*, this component of an experiment is called the independent variable because the researcher controls or manipulates it independent of the subject's behavior or any other event. (As we will soon see, though, manipulating the independent variable without regard to measures of the dependent variable is unwise.) Whereas changes in the experimental setting required to conduct the study (e.g., the presence of observers to measure behavior) are made with the goal of minimizing their effects on the dependent variable, "changes in the independent variable are arranged by the experimenter in order to maximize . . . its influence on responding" (Johnston & Pennypacker, 1980, p. 260).

Manipulation of the Independent Variable: Experimental Design

Experimental design refers to the particular arrangement of conditions in a study so that meaningful comparisons of the effects of the presence, absence, or different values of the independent variable can be made. Independent variables can be introduced, withdrawn, increased or decreased in value, or combined across behaviors, settings, and/or subjects in an infinite number of ways.[9] However, with respect to the behavior of a given subject, at a given point in time in a given setting, an experimenter can make only two basic kinds of independent variable changes: introduce a new condition or reinstate an old condition. In essence, "Experimental designs are merely temporal arrangements of various new and old conditions across behaviors and settings in ways that produce data that are convincing to the investigator and the audience" (Johnston & Pennypacker, 1980, p. 270).

In the simplest case—from an analytic perspective, but not necessarily a practical point of view—an independent variable can be either present or absent during each time period or phase of a study. When the independent variable is in either of these conditions during a study, the experiment is termed a *nonparametric study*. In contrast, a **parametric analysis** seeks to discover the differential effects of a range of values of the independent variable. Lerman, Kelley, Vorndran, Kuhn, and LaRue (2002) conducted a parametric analysis when they assessed the effects of different reinforcer magnitudes (20, 60, or 300 sec of access to toys or escape from demands) on the duration of postreinforcement pause and resistance to extinction. Examples of different values of independent variables in other parametric studies: short (2 sec), progressive (2 sec to 20 sec), and long (20 sec) intertrial-interval durations during language training (Cariveau, Kodak, & Campbell, 2016); and teacher praise rates of 1, 2, or 8 per minute during small-group instruction (Kranak, Alber-Morgan, & Sawyer, 2017).

When an investigator is interested in comparing the effects of two or more treatment alternatives, multiple independent variables become part of the experiment. For example, perhaps two separate treatments are evaluated as well as the effects of a third treatment, which is a combination of both variables. However, even in studies with multiple independent variables, the researcher must heed a simple but fundamental rule of experimentation: *Change only one variable at a time*. Failure to heed this rule eliminates the possibility of attributing any measured behavior change to a specific independent variable.

If two or more variables are altered simultaneously and changes in the dependent variable are noted, no conclusions can be made with regard to the contribution of any one of the altered variables to the behavior change. If two variables changed together, both could have contributed equally to the resultant behavior change; one variable could have been solely, or mostly, responsible for the change; or one variable may have had a negative or counterproductive effect, but the other independent variable was sufficiently strong to overcome this effect, resulting in a net gain. Any of these explanations or combinations may have accounted for the change.

As stated previously, applied behavior analysts often conduct their experiments in "noisy" environments where effective treatments are required for reasons related to personal safety or exigent circumstances. In such cases, applied behavior analysts sometimes "package" multiple and well-documented and effective treatments, knowing that multiple independent variables are being introduced. As implied earlier, a package intervention is one in which multiple independent variables are being combined or bundled into one program (e.g., token reinforncement + praise + self-recording + time-out). However, from the perspective of experimental analysis, the rule to change only one variable at a time still holds. When manipulating a treatment package, the experimenter must ensure that the entire package is presented or withdrawn each time a manipulation occurs. In this situation, it is important to understand that the entire package is being evaluated, not the discrete components that make up the package. If, at a later time, the analyst wishes to determine the relative contributions of each part of the package, she would need to carry out a component analysis. Chapters 8 and 9 describe experimental tactics for component analyses.

No off-the-shelf experimental designs are available for a given research problem. Investigators must avoid following textbook "designs" that (a) require a priori assumptions about the nature of the functional relation one seeks to investigate and (b) may be insensitive to unanticipated changes in behavior. Researchers should select and combine experimental tactics that best fit their research questions, while standing ever ready to "explore relevant variables by manipulating them in an improvised and rapidly changing design" (Skinner, 1966, p. 21).

Simultaneous with, and to a large degree responsible for, the growth and success of applied behavior analysis have been the development and refinement of a powerful group of extremely flexible experimental tactics for analyzing behavior–environment relations. We describe the most widely used of these tactics in Chapters 8 and 9. However, to effectively select, modify, and combine these tactics into convincing experiments, behavior analysts must fully understand the experimental reasoning, or logic, that provides the foundation for within-subject experimental comparisons.

STEADY STATE STRATEGY AND BASELINE LOGIC

Steady state responding—"a pattern of responding that exhibits relatively little variation in its measured dimensional quantities over a period of time" (Johnston & Pennypacker, 1993a, p. 199)—provides the basis for a powerful form of experimental reasoning called baseline logic. **Baseline logic** entails three elements—prediction, verification, and replication—each of which depends on an overall experimental approach called steady state strategy. **Steady state strategy** entails exposing a subject to a given condition while trying to eliminate or control any extraneous influences on the behavior and obtaining a stable pattern of responding before introducing the next condition.

Nature and Function of Baseline Data

Behavior analysts discover behavior–environment relations by comparing data from repeated measures of a subject's behavior under the different conditions of the experiment. The most

common method of evaluating the effects of a given variable is to impose it on an ongoing measure of behavior obtained in its absence. These original data serve as the **baseline** against which any observed changes in behavior when the independent variable is introduced can be compared. A baseline serves as a control condition; baseline does not necessarily mean the absence of instruction or treatment, only the absence of the independent variable of experimental interest.

Why Establish a Baseline?

From a purely scientific or analytic perspective, the primary purpose for establishing a baseline level of responding is to use the subject's performance in the absence of the independent variable as an objective basis for detecting the effects of the independent variable. Obtaining baseline data can yield several applied benefits. For one, systematic observation of the target behavior before a treatment variable is introduced provides the opportunity to look for and note environmental events that occur just before and just after the target behavior. Such empirically obtained descriptions of antecedent-behavior-consequent correlations are often invaluable in planning an effective intervention (see Chapter 25). For example, baseline observations revealing that a child's disruptive outbursts are consistently followed by parent or teacher attention can be used in designing an intervention of ignoring outbursts and contingent attention following desired behavior.

Second, baseline data can provide valuable guidance in setting initial criteria for reinforcement, a particularly important step when a contingency is first put into effect (see Chapter 11). If the criteria are too high, the subject never comes into contact with the contingency; if they are too low, little or no improvement can be expected.

From a practical perspective, a third reason for collecting baseline data concerns the merits of objective measurement versus subjective opinion. The results of systematic baseline measurement may convince the behavior analyst or significant others to reconsider the necessity and value of attempting to change the behavior. For example, a behavior targeted for intervention because of several recent and extreme instances is no longer targeted because baseline data show it is decreasing. Or, perhaps a behavior's topography attracted undue attention from teachers or parents, but objective baseline measurement over several days reveals the behavior is not occurring at a rate or level that warrants intervention.

Baseline Data Patterns

Figure 7.1 shows examples of four data patterns sometimes generated by baseline measurement. These hypothetical baselines represent only four examples of the wide variety of baseline data patterns experimenters and practitioners encounter. The potential combinations of different levels, trends, and degrees of variability are infinite. Nevertheless, in an effort to provide guidance to the beginning behavior analyst, some general statements will be given about the experimental decisions that might be warranted by the data patterns shown in Figure 7.1.

Graph A shows a relatively **stable baseline**. The data present no evidence of an upward or downward trend, and all of the measures fall within a small range of values. A stable baseline provides the most desirable basis, or context, against which to look for effects of an independent variable. If changes in level, trend, and/or variability coincide with the introduction of an independent variable on a baseline as stable as that shown in Graph A, one can reasonably suspect that those changes may be related to the independent variable.

The data in Graphs B and C represent an **ascending baseline** and a **descending baseline**, respectively. The data path in Graph B shows an increasing trend in the behavior over

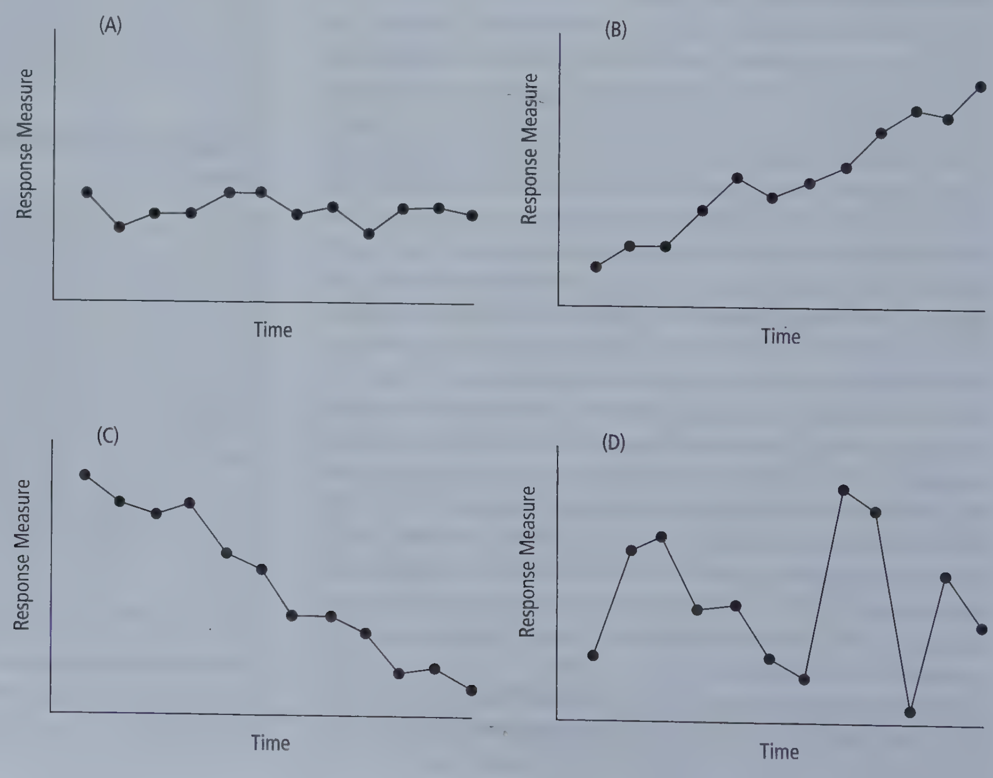

Figure 7.1 Data patterns illustrating stable (A), ascending (B), descending (C), and variable (D) baselines.

time, whereas the data path in Graph C presents a decreasing trend. The applied behavior analyst must treat ascending and descending baseline data cautiously. Applied behavior analysts select dependent variables because they represent target behaviors that need to be changed. But ascending and descending baselines reveal behaviors in the process of changing. The effects of an independent variable introduced at this point are likely to be obscured or confounded by the variables responsible for the already-occurring change. But what if the applied investigator needs to change the behavior immediately? The applied perspective can help solve the dilemma.

Whether a treatment variable should be introduced depends on whether the trending baseline data represent improving or deteriorating performance. When an ascending or a descending baseline represents behavior change in the therapeutically desired direction, the investigator should withhold treatment and continue to monitor the dependent variable under baseline conditions. When the behavior ceases to improve (as evidenced by stable responding) or begins to deteriorate, the independent variable can be applied. If the trend does not level off and the behavior continues to improve, the original problem may no longer be present, leaving no reason for introducing the treatment as planned (although the investigator might be motivated to isolate and analyze the variables responsible for the "spontaneous" improvement). Introducing an independent variable to an already-improving behavior makes it difficult, and often impossible, to claim any continued improvement as a function of the independent variable.

An ascending or descending baseline that represents significantly deteriorating performance signals an immediate application of the independent variable. From an applied perspective, the decision to intervene is obvious: The subject's behavior is worsening, and a treatment designed to improve it should be introduced. An independent variable capable of effecting desired behavior change in spite of other variables "pushing" the behavior in the opposite direction is most likely a robust variable, one that will be a welcome addition to the behavior analyst's list of effective treatments. The decision to introduce a treatment variable on a descending baseline is also a sound one from an analytic perspective, which will be discussed in the next section.

Graph D in Figure 7.1 shows a highly unstable or **variable baseline.** The data in Graph D show just one of many possible patterns of unstable responding. The data points do not consistently fall within a narrow range of values, nor do they suggest any clear trend. Introducing the independent variable in the presence of such variability is unwise from an experimental standpoint. Variability is assumed to be the result of environmental variables, which in the case shown by Graph D seem to be operating in an uncontrolled fashion. Before the researcher can analyze the effects of an independent variable effectively, these uncontrolled sources of variability must be isolated and controlled.

Stable baseline responding provides an index of the degree of experimental control the researcher has established. "If sufficiently stable responding cannot be obtained, the experimenter is in no position to add an independent variable of suspected but unknown influence. To do so would be to compound confusion and lead to further ignorance" (Johnston & Pennypacker, 1980, p. 229).

Again, however, applied considerations must be balanced against purely scientific pursuits. The applied problem may be one that cannot wait to be solved (e.g., severe self-injurious behavior). Or, confounding variables in the subject's environment and the setting(s) of the investigation may simply be beyond the experimenter's control.[10] In such situations, the independent variable is introduced with the hope of producing stable responding in its presence. Sidman (1960) agreed that "the behavioral engineer must ordinarily take variability as he finds it, and deal with it as an unavoidable fact of life" (p. 192).

Prediction

Prediction can be defined as "the anticipated outcome of a presently unknown or future measurement. It is the most elegant use of quantification upon which validation of all scientific and technological activity rests" (Johnston & Pennypacker, 1980, p. 120). Figure 7.2 shows a series of hypothetical measures representing a stable pattern of baseline responding. The consistency of the first five data points in the series encourages the prediction that—if no changes occur in the subject's environment—subsequent measures will fall within the range of values obtained thus far. Indeed, a sixth measure is taken that gives credence to this prediction. The same prediction is made again, this time with more confidence, and another measure of behavior shows it to be correct. Throughout a baseline (or any other experimental condition), predictions are made and confirmed until the investigator has every reason to believe that the response measure will not change appreciably under the present conditions. Open data points in Figure 7.2 represent predicted measures of future responding. Given the stability of the obtained measures, few experienced scientists would quarrel with the prediction.

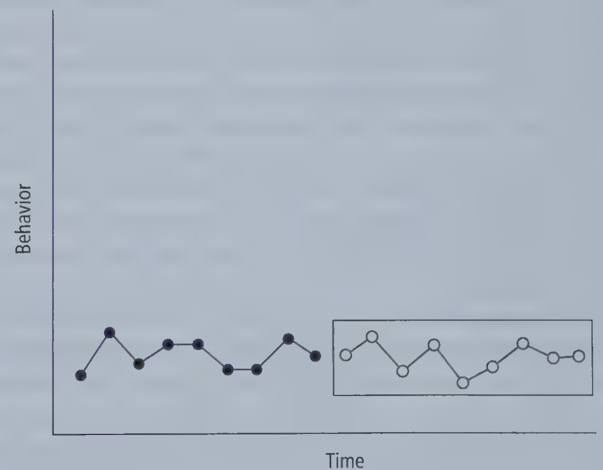

Figure 7.2 Solid data points represent actual measures of behavior that might be generated in a stable baseline; open data points within the box represent the level of responding predicted on the basis of the obtained measures, should the environmental conditions remain unchanged.

How many measures must be taken before an experimenter or practitioner can predict future behavior with confidence? There are no criteria or pre-determined number of data points that ensure confident prediction. However, the following statements can serve as guidelines.

- Baer and colleagues (1968) recommended continuing measurement until "stability is clear."
- All things being equal, many measures are better than a few; and the longer the period of time in which stable responding is obtained, the better the predictive power of those measures.
- If the experimenter is not sure whether measurement has revealed stable responding, in all likelihood it has not, and more data should be collected before the independent variable is introduced.
- The investigator's knowledge of the characteristics of the behavior being studied under constant conditions is invaluable in deciding when to terminate baseline measurement and introduce the independent variable. That knowledge can be drawn from personal experience in obtaining stable baselines on similar response classes and from familiarity with patterns of baseline responding found in the published literature.

Statements such as "collect baseline data for at least five sessions" or "obtain baseline measures for 2 consecutive weeks" are misguided or naive. Depending on the situation, five baseline data points or 2 weeks of baseline data may or may not provide a convincing picture of steady state responding. The question that must be addressed is this: Are the data sufficiently stable to provide a basis for comparison to measures collected from other conditions? This question can be answered only by ongoing prediction and confirmation with repeated measures obtained in an environment where all relevant conditions are held constant.

Behavior analysts are often interested in analyzing functional relations between an instructional variable and the acquisition of new skills. In such situations it is sometimes assumed that baseline measures are zero. For example, one would expect repeated observations of a child who has never tied her shoes to yield a perfectly stable baseline of zero correct responses. However, casual observations that have never shown a child to use a particular skill do not constitute a scientifically valid baseline and should not be used to justify any claims about the effects of instruction. It could be that, if given repeated opportunities to respond, the child would begin to emit the target behavior at a nonzero level.

Practice effects refer to improvements in performance resulting from repeated opportunities to emit the behavior so that baseline measurements can be obtained. For example, attempting to obtain stable baseline data for students answering arithmetic problems may result in improved performance simply because of the repeated practice inherent in the measurement process. Practice effects can confound a study, making it impossible to separate and account for the effects of practice and instruction on the student's final performance. Repeated baseline measures should be used either to reveal the existence or to demonstrate the nonexistence of practice effects. When practice effects are suspected or found, baseline data collection should be continued until steady state responding is attained.

The necessity to demonstrate a stable baseline and to control for practice effects empirically does not require applied behavior analysts to withhold needed treatment or intervention. Nothing is gained by collecting unduly long baselines of behaviors that cannot reasonably be expected to be in the subject's repertoire. Many behaviors cannot be emitted unless the subject is competent in certain prerequisite behaviors. For example, there is no legitimate possibility of a child's tying his shoes if he currently does not pick up the laces, or of a student's solving division problems if she cannot subtract and multiply. Obtaining extended baseline data in such cases is unnecessary pro forma measurement. Such measures do "not so much represent zero behavior as zero opportunity for behavior to occur, and there is no need to document at the level of well-measured data that behavior does not occur when it cannot" (Horner & Baer, 1978, p. 190).

Fortunately, applied behavior analysts need neither abandon the use of steady state strategy nor repeatedly measure nonexistent behavior at the expense of a treatment condition. The multiple probe design, described in Chapter 9, embodies steady state logic to analyze functional relations between instruction and the acquisition of behaviors shown to be nonexistent in the subject's repertoire prior to the introduction of the independent variable.

Affirmation of the Consequent

The predictive power of steady state responding enables the behavior analyst to employ a form of inductive logic known as **affirmation of the consequent** (Johnston & Pennypacker, 1980). The reasoning behind affirmation of the consequent begins with a true antecedent–consequent (if-A-then-B) statement and proceeds as follows:

1. If A is true, then B is true.
2. B is found to be true.
3. Therefore, A is true.

The behavior analyst's version goes like this:

1. If the independent variable is a controlling factor for the behavior (A), then the data obtained in the presence of the independent variable will show that the behavior has changed (B).
2. When the independent variable is present, the data show that the behavior has changed (B is true).
3. Therefore, the independent variable is a controlling variable for the behavior (therefore, A is true).

Although the logic is flawed—other factors could be responsible for the truthfulness of A—a successful (i.e., convincing) experiment affirms several if-A-then-B possibilities, each one reducing the likelihood that factors other than the independent variable are responsible for the observed changes in behavior.

Figures 7.3 to 7.5 illustrate how prediction, verification, and replication are employed in a hypothetical experiment using a reversal design, one of the more powerful analytic tactics used by behavior analysts (see Chapter 8). The data in Figure 7.3

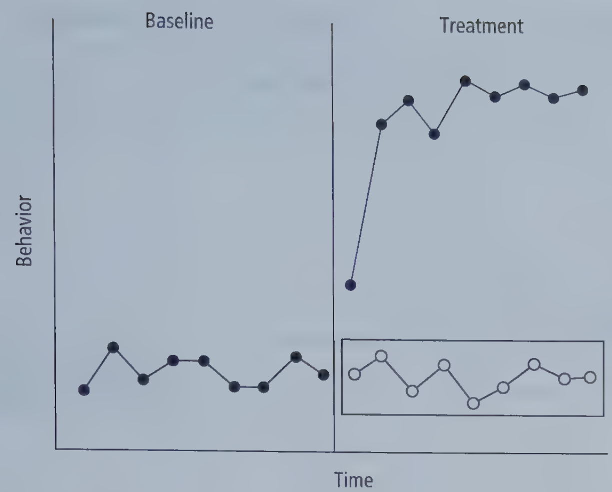

Figure 7.3 Affirmation of the consequent supporting the possibility of a functional relation between the behavior and treatment variable. The measures obtained in the presence of the treatment variable differ from the predicted level of responding in the absence of the treatment variable (open data points within the boxed area). Solid data points represent an A-B design.

show a successful affirmation of the consequent. Steady state responding during Baseline enabled a prediction that, if no changes were made in the environment, continued measurement would yield data similar to those represented by the open-circle data points within the boxed area. The experimenter also predicted that (more precisely, questioned whether) the treatment condition would produce a change in the behavior. The independent variable was introduced, and repeated measures of the dependent variable showed that the behavior did indeed change (solid data points in Treatment condition).

These data enable two comparisons, one real and one hypothetical. First, the difference between the obtained measures in the presence of the independent variable and those obtained during baseline supports the prediction that treatment would change the behavior and represents the extent of a possible effect of the independent variable. The second comparison is between the data obtained in the treatment condition and the predicted measures had the treatment variable not been introduced (i.e., the open data points within the boxed area of Figure 7.3). This comparison represents the behavior analyst's hypothetical approximation of the ideal, but impossible-to-achieve, experimental design: the simultaneous measurement and comparison of the behavior of an individual subject in both the presence and absence of the treatment variable (Risley, 1969).

Although the data in Figure 7.3 affirm the initial antecedent–consequent statement—a change in the behavior was observed in the presence of the independent variable—asserting a functional relation between the treatment variable and behavior change is unwarranted. The experimenter has not yet ruled out the possibility of other variables being responsible for the behavior change. Perhaps some factor within or outside the experimental setting occurred at the same time the independent variable was introduced, and that factor is responsible for the change in behavior.

Although two-phase experiments consisting of a pretreatment baseline condition followed by a treatment condition (i.e., an **A-B design**) enable neither verification of the prediction of continued responding at baseline levels nor replication of the effects of the independent variable, studies using A-B designs can nevertheless contribute important and useful findings to research and practice (e.g., Azrin & Wesolowski, 1974; Ghaemmaghami, Hanley, & Jessel, 2016; Krueger, Rapp, Ott, Lood, & Novotny, 2013; Reid, Parsons, Phillips, & Green, 1993).

A firmer statement about the relation between the treatment and the behavior can be made at this point, however, if changes in the dependent variable are *not* observed in the presence of the independent variable. If accurate measures of the dependent variable were obtained with a measurement system sensitive to changes in the behavior and the treatment condition was implemented as planned, then no behavior change in the presence of the independent variable constitutes disconfirmation of the consequent (B was shown not to be true), and the independent variable may be eliminated as a controlling variable. However, eliminating a treatment from the ranks of controlling variables on the basis of no observed effects presupposes experimental control of the highest order (Johnston & Pennypacker, 1993a).

However, the data set in Figure 7.3 shows that behavior changed in the presence of the independent variable, revealing a correlation between the independent variable and the behavior change. To what extent was the behavior change a function of the independent variable? To pursue this question, the behavior analyst employs the next component of baseline logic: verification.

Verification

The experimenter can increase the probability that an observed change in behavior was functionally related to the introduction of the independent variable by verifying the original prediction of unchanging baseline measures. **Verification** can be accomplished by demonstrating that the prior level of baseline responding would have remained unchanged had the independent variable not been introduced. If that can be demonstrated, this operation verifies the accuracy of the original prediction of continued stable baseline responding and reduces the probability that some uncontrolled (confounding) variable was responsible for the observed change in behavior. Again, the reasoning behind affirmation of the consequent is the logic that underlies the experimental strategy.

Figure 7.4 illustrates the verification of effect in our hypothetical experiment. When steady state responding was established in the presence of the independent variable, the investigator removed the treatment variable, thereby returning to the previous baseline conditions. This tactic allows the possibility of affirming two different antecedent–consequent statements. The first statement and its affirmation follow this pattern:

1. If the independent variable is a controlling factor for the behavior (A), then its removal will coincide with changes in the response measure (B).
2. Removal of the independent variable is accompanied by changes in the behavior (B is true).
3. Therefore, the independent variable controls responding (therefore, A is true).

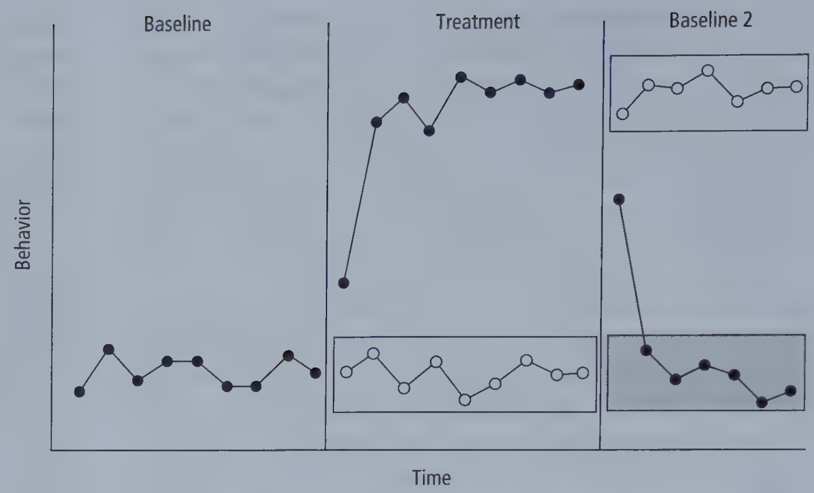

Figure 7.4 Verification of a previously predicted level of baseline responding by withdrawal of the treatment variable. The measures obtained during Baseline 2 (solid data points within the shaded box) show a successful verification and a second affirmation of the consequent based on a comparison with the predicted level of responding (open dots in Baseline 2) in the continued presence of the treatment variable.

The second statement and affirmation follows this pattern:

1. If the original baseline condition controlled the behavior (A), then a return to baseline conditions will result in similar levels of responding (B).
2. The baseline condition is reinstated, and levels of responding similar to those obtained during the original baseline phase are observed (B is true).
3. Therefore, the baseline condition controlled the behavior both then and now (therefore, A is true).

The six measures within the shaded area obtained during Baseline 2 of our hypothetical experiment verify the prediction made for Baseline 1. The open data points in Baseline 2 represent the predicted level of responding if the independent variable had not been removed. (The prediction component of baseline logic applies to steady state responding obtained during any phase of an experiment, baseline and treatment conditions alike.) The difference between the data actually obtained during Treatment (solid data points) and the data obtained during Baseline 2 (solid data points) affirms the first if-A-then-B statement: If the treatment is a controlling variable, then its removal will result in changes in behavior. The similarity between measures obtained during Baseline 2 and those obtained during Baseline 1 confirms the second if-A-then-B statement: If baseline conditions controlled the behavior before, reinstating baseline conditions will result in similar levels of responding.

As before, the observed changes in behavior associated with the introduction and withdrawal of the independent variable are subject to interpretations other than the existence of a functional relation between the two events. However, the case for a functional relation is becoming stronger. When the independent variable was applied, behavior change was observed; when the independent variable was withdrawn, behavior again changed and responding returned to baseline levels. To the extent that the experimenter has effectively controlled the presence and absence of the independent variable and held constant all other variables in the experimental setting that may have influenced the behavior, a functional relation appears likely. An important behavior change has been produced and reversed by the introduction and withdrawal of the independent variable. The process of verification reduces the likelihood that a variable other than the independent variable was responsible for the observed behavior changes.

Does this two-step strategy of prediction and verification constitute sufficient demonstration of a functional relation? What if some uncontrolled variable covaried with the independent variable as it was presented and withdrawn and that uncontrolled variable was responsible for the observed changes in behavior? If such were the case, claiming a functional relation between the target behavior and the independent variable would at best be wrong and at the worst perhaps end the search for the actual controlling variables whose identification and control would contribute to an effective and reliable technology of behavior change.

The appropriately skeptical investigator (and practitioner/research consumer) will also question the reliability of the obtained effect. Was the apparent functional relation a fleeting, one-time-only phenomenon, or will repeated applications of the independent variable reliably (i.e., consistently) produce a similar pattern of behavior change? An effective (i.e., convincing) experimental design yields data responsive to these important questions. To investigate uncertain reliability, the behavior analyst employs the final, and perhaps the most important, component of baseline logic and experimental design: replication.

Replication

> Replication is the essence of believability.
>
> —Baer, Wolf, and Risley (1968, p. 95)

Within the context of any given experiment, **replication** means repeating independent variable manipulations conducted previously in the study and obtaining similar outcomes.[11] Replication within an experiment has two important purposes. First, replicating a previously observed behavior change reduces the probability that some factor other than the independent variable was responsible for the now twice-observed behavior change. Second, replication demonstrates the reliability of the

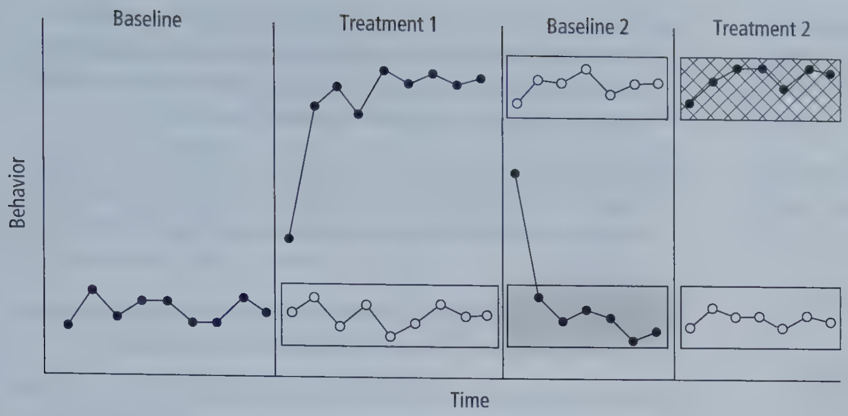

Figure 7.5 Replication of experimental effect accomplished by reintroducing the treatment variable. The measures obtained during Treatment 2 (solid data points within the cross hatched box) enhance the case for a functional relation between the treatment variable and the target behavior.

behavior change; it can be made to happen again. Together, these joint outcomes make replication the basis for inferences that the independent variable is responsible for the observed behavior change.

Figure 7.5 adds the component of replication to our hypothetical experiment. After steady state responding was obtained during Baseline 2, the independent variable is reintroduced. To the extent the data obtained during the Treatment 2 phase (data points within the box shaded with cross-hatched lines) resemble the measures obtained during Treatment 1, replication has occurred. Our hypothetical experiment has now produced powerful evidence of a functional relation between the independent and dependent variables. Confidence in the assertion of a functional relation rests on numerous factors, some of the most important of which are the accuracy and sensitivity of the measurement system; the degree of control the experimenter maintained over all relevant variables; the duration of experimental phases; the stability of responding within each phase; and the speed, magnitude, and consistency of behavior change between conditions. If each of these considerations is satisfied, then replication of effect becomes perhaps the most critical factor in claiming a functional relation.

An independent variable can be manipulated in an effort to replicate an effect many times within an experiment. The number of replications required to demonstrate a functional relation convincingly is related to many considerations, including all of those just enumerated, and to the existence of other similar experiments that have produced the same effects.

SUMMARY

Introduction

1. Measurement can show whether, when, and how much behavior changes, but measurement alone cannot reveal why the behavior changes occurred.
2. A useful technology of behavior change depends upon knowing that specific arrangements of environmental variables will reliably produce desired forms of behavior change.
3. An experimental analysis must be performed to determine how a given behavior functions in relation to specific environmental events.

Concepts and Assumptions Underlying the Analysis of Behavior

4. The overall goal of science is to achieve an understanding of the phenomena under study—socially important behavior, in the case of applied behavior analysis.
5. Science produces understanding at three levels: description, prediction, and control.
6. Descriptive research yields a collection of facts about the observed events—facts that can be quantified and classified.
7. A correlation exists when two events systematically covary with one another. Predictions can be made about the probability that one event will occur based on the occurrence of the other event.

Experimental Control: The Path to and Goal of Behavior Analysis

8. The greatest potential benefits of science are derived from the third, and highest, level of scientific understanding, which comes from establishing experimental control.
9. Experimental control is achieved when a predictable change in behavior (the dependent variable) is reliably produced by the systematic manipulation of some aspect of the environment (the independent variable).
10. An analysis of a behavior has been achieved when a reliable functional relation between the behavior and some specified aspect of the environment has been demonstrated convincingly.
11. A functional analysis does not eliminate the possibility that the behavior under investigation is also a function of other variables.

12. An experiment that shows convincingly that changes in behavior are a function of the independent variable and not the result of uncontrolled or unknown variables has internal validity.

13. External validity refers to the degree to which a study's results are generalizable to other subjects, settings, and/or behaviors.

Behavior: Defining Features and Assumptions that Guide Its Analysis

14. Confounding variables exert unknown or uncontrolled influences on the dependent variable.

15. Because behavior is an individual phenomenon, the experimental strategy of behavior analysis features within-subject (or single-case) methods of analysis.

16. Because behavior is a dynamic and continuous phenomenon that occurs in and changes through time, measuring behavior as it changes over time is a fundamental feature of applied behavior analysis.

17. The assumption of determinism guides experimental method in behavior analysis.

18. Experimental methods in behavior analysis also derive from the assumption that behavioral variability is extrinsic to the organism, not an inherent trait; that is, variability is imposed by environmental variables.

19. Behavior analysts strive to isolate and experimentally manipulate the environmental factors responsible for variability.

Components of Applied Behavior Analysis Experiments

20. A research question specifies what the investigator wants to learn from conducting the experiment; all aspects of an experiment's design and conduct should follow from it.

21. Experiments in applied behavior analysis are referred to as *single-case* research designs because the experimental logic for detecting and analyzing behavior change employs each subject as his or her own control.

22. The dependent variable in an applied behavior analysis experiment is a measurable dimensional quantity of the target behavior.

23. Some studies include multiple dependent variables for three major reasons: (a) To provide additional data paths that serve as controls for evaluating and replicating the effects of an independent variable as it is applied sequentially to each behavior, (b) to assess the presence and extent of the independent variable's effects on behaviors other than the response class to which it was applied directly, and (c) to determine whether changes in the behavior of a person other than the subject occur during the course of an experiment and whether such changes might in turn explain observed changes in the subject's behavior.

24. In addition to precise manipulation of the independent variable, the behavior analyst must hold constant all other aspects of the experimental setting—extraneous variables—to prevent unplanned environmental variation.

25. When unplanned events or variations occur in the experimental setting, the behavior analyst must either wait out their effects or incorporate them into the design of the experiment.

26. Observation and measurement procedures must be conducted in a standardized manner throughout an experiment.

27. Because behavior is a continuous and dynamic phenomenon, ongoing visual inspection of the data is necessary to identify changes in level, trend, and/or variability as they develop during the course of an experiment.

28. Changes in the independent variable are made to maximize its effect on the target behavior.

29. The term *experimental design* refers to the sequence and form of independent variable manipulations in a study.

30. Although an infinite number of experimental designs are possible as a result of the many ways independent variables can be manipulated and combined, an experimenter can make only two basic kinds of independent variable changes: introduce a new condition, or reinstate an old condition.

31. A parametric study compares the differential effects of different values of the independent variable.

32. The fundamental rule of experimentation: change only one variable at a time.

33. Rather than follow rigid, pro forma experimental designs, behavior analysts should select experimental tactics suited to the original research questions, while standing ready to "explore relevant variables by manipulating them in an improvised and rapidly changing design" (Skinner, 1966, p. 21).

Steady State Strategy and Baseline Logic

34. Steady state responding enables a form of inductive reasoning called baseline logic. Baseline logic entails three elements: prediction, verification, and replication.

35. The most common method for evaluating the effects of a given variable is to impose it on an ongoing measure of behavior obtained in its absence. These preintervention data serve as the baseline against which any observed changes in behavior when the independent variable is introduced can be compared.

36. A baseline condition does not necessarily mean the absence of instruction or treatment per se, only the absence of a specific independent variable of experimental interest.

37. In addition to the primary purpose of establishing a baseline as an objective basis for evaluating the effects of the independent variable, three other reasons for baseline data collection are: (a) Systematic observation of the target

behavior prior to intervention sometimes yields information about antecedent-behavior-consequent correlations that may be useful in planning an effective intervention; (b) baseline data can provide valuable guidance in setting initial criteria for reinforcement; and (c) baseline data may reveal that the behavior targeted for change does not warrant intervention.

38. Four types of baseline data patterns are stable, ascending, descending, and variable.
39. The independent variable should be introduced when stable baseline responding has been achieved.
40. The independent variable should not be introduced when an ascending or descending baseline indicates improving performance.
41. The independent variable should be introduced when an ascending or a descending baseline indicates deteriorating performance.
42. An independent variable should not be imposed on a highly variable, unstable baseline.

Affirmation of the Consequent

43. Prediction of future behavior can be made when repeated measures of behavior under relatively constant environmental conditions show little or no variation.
44. Practice effects refer to improvements in performance resulting from opportunities to emit the behavior that must be provided to obtain repeated measures.
45. Extended baseline measurement is not necessary for behaviors that have no logical opportunity to occur.
46. The predictive power of steady state responding enables a form of inductive reasoning known as affirmation of the consequent.
47. Although the logic of affirmation of the consequent is flawed (some other event may have caused the change in behavior), an effective experimental design confirms several if-A-then-B possibilities, each one reducing the likelihood that factors other than the independent variable are responsible for the observed changes in behavior.
48. Verification is accomplished by demonstrating that the prior level of baseline responding would have remained unchanged had the independent variable not been introduced.
49. Replication within an experiment means reproducing a previously observed behavior change by reintroducing the independent variable. Replication demonstrates the reliability of the behavior change and reduces the probability that some factor other than the independent variable was responsible for the now twice-observed behavior change.

MULTIPLE-CHOICE QUESTIONS

1. Which of the following is not an assumption underlying the analysis of behavior?
   a. Determinism
   b. Empiricism
   c. Philosophic doubt
   d. Pseudoscience
   Hint: (See "Concepts and Assumptions Underlying the Analysis of Behavior")

2. The assumption that the universe is a lawful and orderly place and that natural phenomena occur in relation to other events describes which assumption underlying the analysis of behavior?
   a. Empiricism
   b. Determinism
   c. Parsimony
   d. Philosophic doubt
   Hint: (See "Concepts and Assumptions Underlying the Analysis of Behavior")

3. The three levels of scientific understanding include:
   a. Empiricism, determinism, and philosophic doubt
   b. Verification, prediction, and replication
   c. Group designs, single-subject designs, and correlations
   d. Description, prediction, control

   Hint: (See "Concepts and Assumptions Underlying the Analysis of Behavior")

4. ____ science yields a collection of facts about the observed events—facts that can be quantified and classified.
   a. Replicated
   b. Experimental
   c. Predictive
   d. Descriptive

   Hint: (See "Concepts and Assumptions Underlying the Analysis of Behavior")

5. The highest level of scientific understanding results from establishing:
   a. Experimental control
   b. Prediction
   c. Replication
   d. Analysis

   Hint: (See "Experimental Control: The Path to and Goal of Behavior Analysis")

6. An ________ of behavior has been achieved when a reliable functional relation between the behavior and the independent variable has been demonstrated convincingly.
   a. Application
   b. Investigation
   c. Analysis
   d. Experimental design

   Hint: (See "Experimental Control: The Path to and Goal of Behavior Analysis")

7. ________ refers to the degree to which a study's results are generalizable to other subjects, settings, and/or behaviors.
   a. Internal validity
   b. External validity
   c. Experimental control
   d. Prediction

   Hint: (See "Experimental Control: The Path to and Goal of Behavior Analysis")

8. An experiment has a high degree of _______ when the experiment shows convincingly that changes in behavior are a function of the independent variable and not the result of uncontrolled or unknown variables.
   a. Internal validity
   b. External validity
   c. Replication
   d. Prediction

   Hint: (See "Experimental Control: The Path to and Goal of Behavior Analysis")

9. ________ are variables known or suspected to exert an uncontrolled influence on the dependent variable.
   a. Independent variables
   b. Investigated variables
   c. Confounding variables
   d. Specified variables

   Hint: (See "Experimental Control: The Path to and Goal of Behavior Analysis")

10. Behavior analysts believe behavioral variability is ________ to the organism.
    a. Internal
    b. External
    c. Inevitable
    d. Confined

    Hint: (See "Behavior: Defining Features and Assumptions that Guide Its Analysis")

11. _________ is the "hallmark of applied behavior analysis."
    a. Internal and external validity
    b. Replication, prediction, and control
    c. Single-measurement
    d. Systematic repeated measurement of behavior

    Hint: (See "Behavior: Defining Features and Assumptions that Guide Its Analysis")

12. _________ is the interaction between an organism and its environment.
    a. Measurement
    b. Independent variable
    c. Behavior
    d. Science

    Hint: (See "Behavior: Defining Features and Assumptions that Guide Its Analysis")

13. Which of the following is not considered to be an essential component of experiments in applied behavior analysis?
    a. At least one subject
    b. At least one setting
    c. At least one large group for statistical comparisons
    d. At least one independent variable
    Hint: (See "Components of Applied Behavior Analysis Experiments")

14. A well-planned experiment begins with
    a. A research question
    b. Selection of participants
    c. Selection of a setting
    d. Selection of an experimental design
    Hint: (See "Components of Applied Behavior Analysis Experiments")

15. As a general rule, the independent variable should be introduced when ________ baseline responding has been achieved.
    a. Variable
    b. Replicable
    c. Stable
    d. Complete
    Hint: (See "Steady State Strategy and Baseline Logic")

16. When the data show no evidence of an upward or downward trend and all the measures fall within a small range of values, the data pattern is referred to as
    a. Ascending
    b. Descending
    c. Level
    d. Stable
    Hint: (See "Steady State Strategy and Baseline Logic")

17. The three elements of baseline logic include the following:
    a. Prediction, verification, and replication
    b. Ascending, descending, and stable
    c. Internal validity, external validity, and reliability
    d. Dependent variable, independent variable, baseline
    Hint: (See "Steady State Strategy and Baseline Logic")

ESSAY-TYPE QUESTIONS

1. Discuss the basic assumption scientists hold about the universe.
   Hint: (See "Behavior: Defining Features and Assumptions That Guide Its Analysis")
2. Discuss how experimental control, the highest level of scientific understanding, is achieved in a single-subject research design.
   Hint: (See "Experimental Control: The Path to and Goal of Behavior Analysis")
3. Discuss how behavior analysts approach variability in their data.
   Hint: (See "Behavior: Defining Features and Assumptions That Guide Its Analysis")
4. List the essential components of experiments in behavior analysis.
   Hint: (See "Components of Applied Behavior Analysis Experiments")
5. What provides the basis for comparison in single-subject experimental designs?
   Hint: (See "Components of Applied Behavior Analysis Experiments")
6. Discuss two reasons an experimenter might measure multiple behaviors within one single-subject study.
   Hint: (See "Components of Applied Behavior Analysis Experiments")
7. Discuss the importance of the following "fundamental rule of experimentation" as it relates to the demonstration of a functional relationship between a dependent and an independent variable: "Change only one variable at a time."
   Hint: (See "Intervention or Treatment: Independent Variable")
8. Discuss one scientific benefit and one applied benefit of establishing a baseline level of responding.
   Hint: (See "Steady State Strategy and Baseline Logic")

9. Draw the following from the written description provided:

a. Baseline: High level, stable, no trend

b. Baseline: Low level, stable, no trend

c. Baseline: Slightly increasing, high variability

d. Baseline: Decreasing variable trend

Hint: (See "Steady State Strategy and Baseline Logic")

10. List and describe the three components of baseline logic (also known as "experimental reasoning") used in single-subject research designs.

Hint: (See "Steady State Strategy and Baseline Logic")

NOTES

1. Behavior analysis has benefited immensely from two particularly noteworthy contributions to the literature on experimental method: Sidman's *Tactics of Scientific Research* (1960) and Johnston and Pennypacker's *Strategies and Tactics of Behavioral Research* (1980). Both books are essential reading and working references for any serious student or practitioner of behavior analysis.
2. The researcher's audience (journal editors, reviewers, readers, and practitioners) ultimately determines whether a claimed functional relation is believable or convincing. We examine the believability of research findings further in Chapter 10.
3. Some investigators also use between-group designs to produce results they believe will have more external validity. Group comparison and within-subject experimental methods are compared in Chapter 10.
4. It has become commonplace to refer to the person(s) whose behavior is the dependent variable in an experiment as a *participant*, instead of the more traditional term, *subject*. We use both terms in this text and urge readers to consider Sidman's (2002) perspective on the issue: "[W]e are no longer permitted to call our subjects 'subjects.' The term is supposed to be dehumanizing, and so we are supposed to call them 'participants.' I think this is completely misguided. Experimenters, too, are participants in their experiments. What does making them non-participants do to our perception of science and of scientists? Are experimenters merely robots who follow prescribed and unbreakable scientific rules? Are they supposed just to manipulate variables and coldly record the results of their manipulations? Separating them as nonparticipating manipulators and recorders of the behavior of participants really dehumanizes not only experimenters but, along with them, the whole scientific process." (p. 9)
5. A study by Rindfuss, Al-Attrash, Morrison, and Heward (1998) provides a good example of the extent to which the term *single-subject* research can be a misnomer. A reversal design was used to evaluate the effects of response cards on the quiz and exam scores of 85 students in 5 eighth-grade American history classes. Although a large group of students participated, the study actually consisted of 85 individual experiments; or 1 experiment and 84 replications!
6. Iverson (2013) points out two good reasons why $N = 1$ design should be avoided as a synonym for single-case design: (a) $N = 1$ clearly means the use of only one subject; and (b) in statistics, N denotes the number of measures or data points collected, not the number of subjects. Additionally, *single-case designs* should not be confused with *case studies*, which do involve just one participant and may or may not entail an experimental design.
7. This is the distinguishing feature of the *multiple baseline across behaviors design*, an experimental tactic used widely in applied behavior analysis. Multiple baseline designs are described in Chapter 9.
8. This analytic tactic is known as a *multiple baseline across settings design*. Multiple baseline designs are presented in Chapter 9.
9. How many different experimental designs are there? Because an experiment's design includes careful selection and consideration of each component discussed here (i.e., subject, setting, behavior, etc.), not counting the direct replication of experiments, one could say that there are as many experimental designs as there are experiments.
10. The applied researcher must guard very carefully against assuming automatically that unwanted variability is a function of variables beyond his capability or resources to isolate and control, and thus fail to pursue the investigation of potentially important functional relations.
11. Replication also refers to the repeating of experiments to determine the reliability of functional relations found in previous studies and the extent to which those findings can be extended to other subjects, settings, and/or behaviors (i.e., generality or external validity). The replication of experiments is examined in Chapter 10.

CHAPTER 8

Reversal and Multielement Designs

LEARNING OBJECTIVES

- Analyze the effects of a variety of independent variables using two types of experimental tactics widely used by applied behavior analysts: the reversal design and the alternating treatments design.
- Select the appropriate experimental tactic based on the research question of interest and the appropriateness of the design.
- Discuss how the reversal design and the alternating treatments design and their variations incorporate the elements of baseline logic (prediction, verification, and replication).
- State and describe advantages and disadvantages in using the reversal design and alternating treatments design.
- Identify practical and ethical considerations in using the reversal design and alternating treatments design.

This chapter describes the reversal and multielement designs, two single-case research tactics used widely by applied behavior analysts. In a reversal design, the effects of introducing, withdrawing (or "reversing" the focus of), and reintroducing an independent variable are observed on the target behavior. In a multielement design, two or more experimental treatments are rapidly alternated (or presented simultaneously and the participant is able to select the treatment), and the differential effects on the target behavior noted. We explain how each design incorporates the three elements of steady state strategy—prediction, verification, and replication—and present examples illustrating the major variations of each. Considerations for selecting and using reversal and multielement designs are also presented.

REVERSAL DESIGN

A **reversal design** entails repeated measures of behavior in a given setting that requires at least three consecutive phases: (a) an initial baseline phase in which the independent variable is absent, (b) an intervention phase during which the independent variable is introduced and remains in contact with the behavior, and (c) a return to baseline conditions accomplished by withdrawal of the independent variable. In the widely used notation system for describing experimental designs in applied behavior analysis, the capital letters *A* and *B* denote the first and second conditions, respectively, in a study. Baseline (A) data are collected until steady state responding is achieved. Next, an intervention (B) condition is applied that signifies the presence of a treatment—the independent variable. An experiment entailing one reversal is described as an **A-B-A design**. Although studies using an A-B-A design are reported in the literature (e.g., Armendariz & Umbriet, 1999; Christle & Schuster, 2003; Geller, Paterson, & Talbott, 1982; Jacobson, Bushell, & Risley, 1969; Raiff & Dallery, 2010), the **A-B-A-B design** is preferred because reintroducing the B condition enables replication of treatment effects, which strengthens the demonstration of experimental control (see Figure 8.1).

The A-B-A-B reversal is the most straightforward and generally most powerful within-subject design for demonstrating a functional relation between an environmental manipulation and a behavior. When a reversal design[1] reveals a functional relation, the data show how the behavior works.

> As explanations go, the one offered by the reversal design was not at all a bad one. In answer to the question, "How does this response work?" we could point out demonstrably that it worked like so [e.g., see Figure 8.1]. Of course, it might also work in other ways; but, we would wait until we had seen the appropriate graphs before agreeing to any other way. (Baer, 1975, p. 19, words in brackets added)

Baer's point must not be overlooked: Showing that a behavior "works" in a predictable and reliable way in the presence and absence of a given variable provides only one answer to the question, How does this behavior work? There may be (and quite likely are) other controlling variables for the targeted response class. Whether additional experimentation exploring those other possibilities is necessary or desirable depends on the social and scientific importance of obtaining a more complete analysis.

Operation and Logic of the Reversal Design

Risley (2005) described the rationale and operation of the reversal design as follows:

> The reversal or ABAB design that Wolf reinvented from Claude Bernard's early examples in experimental medicine entailed establishing a baseline of repeated quantified observations sufficient to see a trend and forecast that trend into the near future (A); to then alter conditions and see

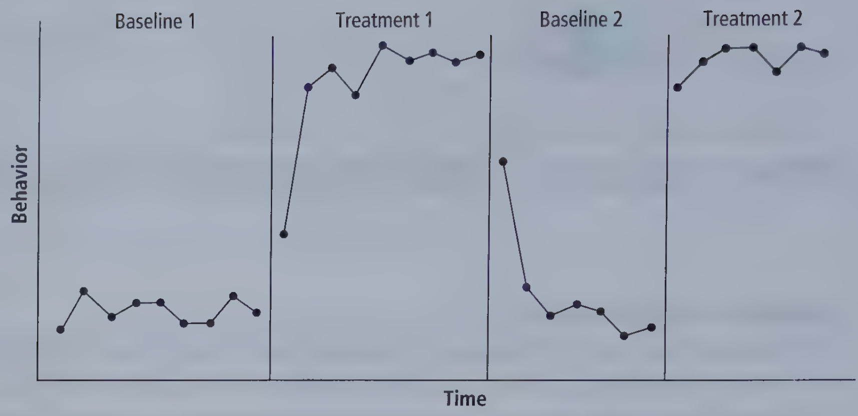

Figure 8.1 Graphic prototype of an A-B-A-B reversal design (hypothetical data).

> if the repeated observations become different than they were forecast to be (B); to then change back and see if the repeated observations return to confirm the original forecast (A); and, finally, to reintroduce the altered conditions and see if the repeated observations again become different than forecast (B). (pp. 280–281)[2]

Because the reversal design was used in Chapter 7 to illustrate baseline logic, a brief review of the roles of prediction, verification, and replication in the reversal design will suffice here. Figure 8.2 shows the same data from Figure 8.1 with the addition of open data points representing predicted measures of behavior if conditions in the previous phase had remained unchanged. After a stable pattern of responding, or counter-therapeutic trend, is obtained in Baseline 1, the independent variable is introduced. In our hypothetical experiment, the measures obtained during Treatment 1, when compared with those from Baseline 1 and with the measures *predicted* by Baseline 1, show that behavior change occurred and that the change in behavior coincided with the intervention. After steady state responding is attained in Treatment 1, the independent variable is withdrawn and baseline conditions re-established. If the level of responding in Baseline 2 parallels or closely approximates the measures obtained during Baseline 1, *verification* of the prediction made from Baseline 1 data is obtained. Stated otherwise, had the intervention not been introduced and had the initial baseline conditions remained in effect, the predicted data path would have appeared as shown in Baseline 2. When withdrawal of the independent variable results in a reversal of the behavior change associated with its introduction, a case builds that the intervention is responsible for the observed behavior change. If reintroduction of the independent variable in Treatment 2 reproduces the behavior change observed during Treatment 1, *replication* of effect has been achieved, and a functional relation demonstrated. Stated in other terms, had the intervention continued and had the second baseline condition not been introduced, the predicted data path of the treatment would have appeared as shown in Treatment 2.

Lambert, Cartledge, Lo, and Heward (2006) used an A-B-A-B design to evaluate the effects of response cards on disruptive behavior and academic responding of students during math lessons in two fourth-grade classrooms. During the baseline (A) condition, single-student responding (SSR), the teacher called on one student who had raised a hand to answer the question. During the treatment (B) condition, response cards (RC), each student could respond to every teacher-posed question by writing an answer on a white laminated board. Figure 8.3 shows the results for disruptive behavior by four students targeted in one of the two classrooms. The data reveal a clear functional relation between the use of response cards and substantial reductions in disruptive behavior. The A-B-A-B design revealed an equally clear functional relation between response cards and increased academic responding.

In the 1960s and early 1970s, applied behavior analysts relied almost exclusively on the A-B-A-B reversal design. The straightforward A-B-A-B design played such a dominant role in the early years of applied behavior analysis that it came to symbolize the field (Baer, 1975). This was no doubt due, at least in part, to the reversal design's potential to expose variables

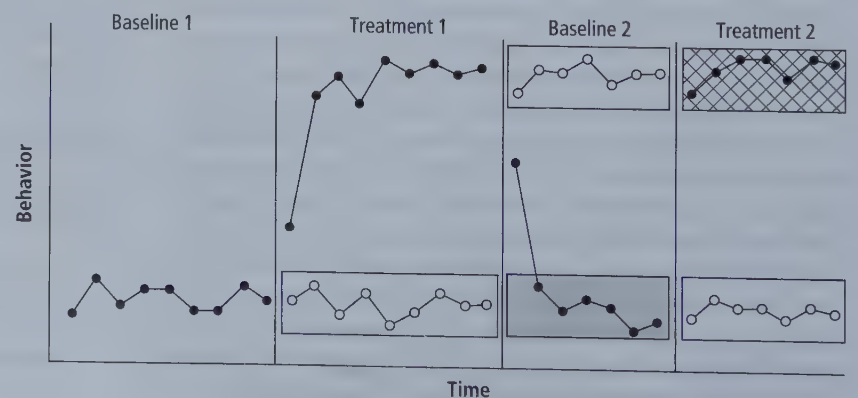

Figure 8.2 Illustration of baseline logic in an A-B-A-B reversal design (hypothetical data). *Prediction:* Open data points (in clear boxes) represent predicted measures if conditions from previous phases remained in effect. *Verification:* Baseline 2 data (lightly shaded box) verify the prediction from Baseline 1. *Replication:* Treatment 2 data (cross-hatch shaded box) replicate the experimental effect.

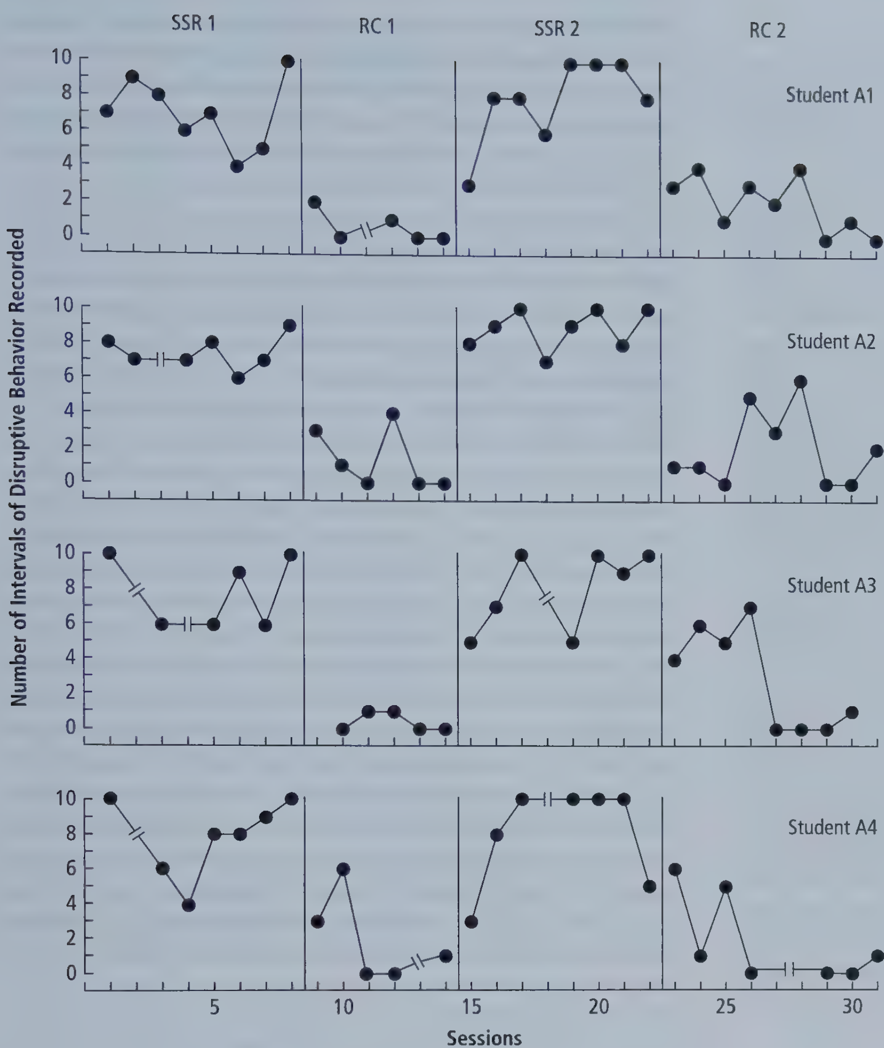

Figure 1. Number of disruptive behaviors during single-student responding (SSR) and response card (RC) conditions for the target students in Classroom A. Breaks in data points represent student absences.

Figure 8.3 Example of an A-B-A-B reversal design.

Based on "Effects of Response Cards on Disruptive Behavior and Academic Responding by Fourth-Grade Urban Students" by M. C. Lambert, G. Cartledge, Y. Lo, and W. L. Heward, 2006, *Journal of Positive Behavioral Interventions*, *8*, p. 93. Copyright 2006 by Sage Publishing.

for what they are—strong and reliable or weak and unstable. Another reason for the reversal design's early dominance may have been that few alternative analytic tactics were available that effectively combined the intrasubject experimental elements of prediction, verification, and replication.

Although the reversal design is just one of many experimental designs available to applied behavior analysts today, the simple, unadorned A-B-A-B design continues to play a major role in the behavior analysis literature (e.g., Beavers, Iwata, & Gregory, 2014; Bicard, Ervin, Bicard, & Baylot-Casey 2012; Hine, Ardoin, & Foster, 2015; Kamps, Conklin, & Wills, 2015; Krentz, Miltenberger, & Valbuena, 2016). Additional examples of the reversal design can be viewed in studies described in this text: Anderson and Long (2002, Figure 24.2); Austin and Bevan (2011, Figure 25.10); Cammilleri and Hanley (2005, Figure 30.14); Cowdery, Iwata, and Pace (1990, Figure 25.6); Deaver, Miltenberger, and Stricker (2001, Figure 24.3); Hall et al. (1971, Figure 14.1); Kuhn, Lerman, Vorndran, and Addison (2006, Figure 23.13); and Lindberg, Iwata, Kahng, and DeLeon (1999, Figure 25.9).

Variations of the A-B-A-B Design

Many applied behavior analysis studies use variations or extensions of the A-B-A-B design.

Repeated Reversals

Perhaps the most obvious variation of the A-B-A-B reversal design is a simple extension in which the independent variable is withdrawn and reintroduced once again (A-B-A-B-A-B). Each additional presentation and withdrawal that reproduces the previously observed effects on behavior increases the likelihood that the behavior changes result from manipulating the independent variable. All other things being equal, an experiment that incorporates multiple reversals presents a more convincing and compelling demonstration of a functional relation than does an experiment with one reversal (e.g., Krentz et al., 2016 [Figure 6.2]; Steege et al., 1990). That said, it is also possible to reach a point of redundancy beyond which the findings of a given analysis are no longer enhanced significantly by additional reversals.

B-A-B and B-A-B-A Designs

The **B-A-B design** begins with the application of the independent variable: the treatment. After stable responding has been achieved during the initial treatment phase (B), the independent variable is withdrawn. If the behavior worsens in the absence of the independent variable (the A condition), the treatment variable is reintroduced in an attempt to recapture the level of responding obtained during the first treatment phase, which would verify the prediction based on the data path obtained during the initial treatment phase.

Practitioners may prefer the B-A-B design to the A-B-A design in that the study ends with the treatment variable in effect. However, in terms of demonstrating a functional relation, the B-A-B design is the weaker of the two because it does not enable an assessment of the effects of the independent variable on the preintervention level of responding. The nonintervention (A) condition in a B-A-B design cannot verify a prediction of a previous nonexistent baseline. Practitioners can remedy this weakness by withdrawing and then reintroducing the independent variable, as in a B-A-B-A-B design (e.g., Dixon, Benedict, & Larson, 2001 [see Figure 25.1]).

Because the B-A-B design provides no data to determine whether the measures of behavior taken during the A condition represent preintervention performance, sequence effects cannot be ruled out: The level of behavior observed during the A condition may have been influenced by the fact that the treatment condition preceded it. Nevertheless, there are exigent situations in which initial baseline data cannot be collected. For instance, the B-A-B design may be appropriate with target behaviors that result in physical harm or danger to the participant or to others. In such instances, withholding a possibly effective treatment until a stable pattern of baseline responding can be obtained may present an ethical problem. For example, Murphey, Ruprecht, Baggio, and Nunes (1979) used a B-A-B design to evaluate the effectiveness of mild punishment combined with reinforcement on the number of self-choking responses by a 24-year-old man with profound intellectual disabilities. After treatment was in effect for 24 sessions, it was withdrawn for 3 sessions, during which an immediate and large increase in self-choking was recorded (see Figure 8.4). Reintroduction of the treatment package reproduced behavior levels observed during the first treatment phase. The mean number of self-chokes during each phase of the B-A-B study was 22, 265, and 24, respectively.

Despite the impressive reduction of behavior, the results of Murphey and colleagues' (1979) B-A-B design study may have been enhanced by gathering and reporting objectively measured data on the level of behavior prior to the first intervention. Presumably, they chose not to collect an initial baseline for ethical and practical reasons. Murphey and colleagues reported anecdotally that self-chokes averaged 434 per day immediately prior to their intervention when school staff had used a different procedure to reduce the self-injurious behavior. This anecdotal information increased the believability of the functional relation suggested by the experimental data from the B-A-B design.

Other situations in which a B-A-B or B-A-B-A design might be warranted include (a) when a treatment is already in place (e.g., Marholin, Touchette, & Stuart, 1979; Pace & Troyer, 2000), (b) when "baseline levels of performance are obvious because the behavior has never been performed (e.g., exercise for many of us, practicing a musical instrument, reading, eating

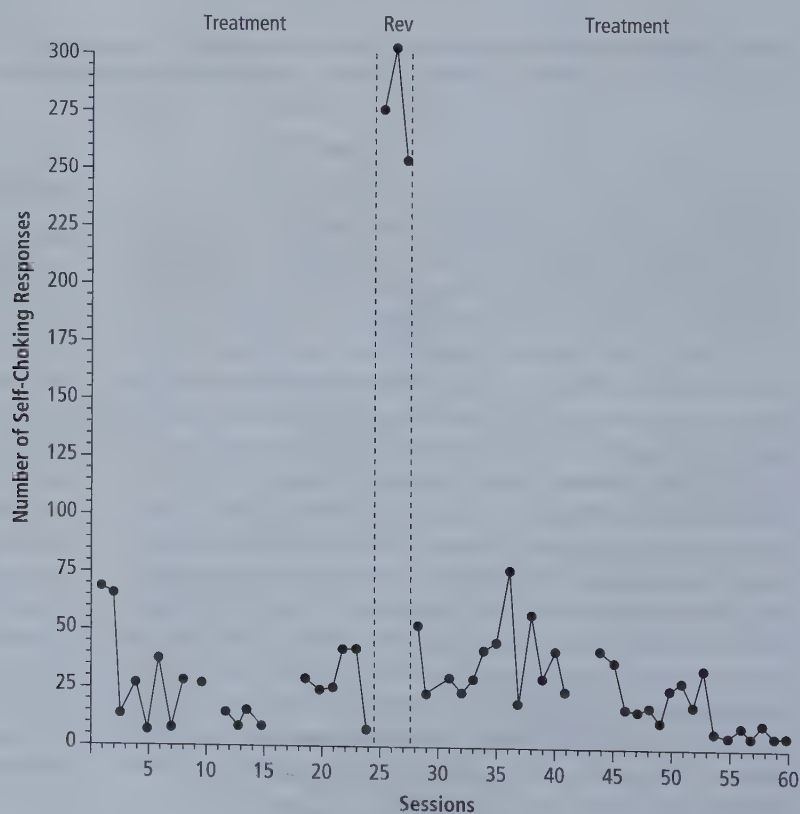

Figure 8.4 Example of a B-A-B reversal design.

Based on "The Use of Mild Punishment in Combination with Reinforcement of Alternate Behaviors to Reduce the Self-Injurious Behavior of a Profoundly Retarded Individual" by R. J. Murphy, M. J. Ruprecht, P. Baggio, and D. L. Nunes, 1979, *AAESPH Review, 4*, p. 191. Copyright 1979 by the *AAESPH Review*.

healthful foods)" (Kazdin, 2011, p. 134), (c) when the behavior analyst has limited time in which to demonstrate practical and socially significant results (e.g., Robinson et al., 1981), and (d) when the client or significant others want an intervention to begin immediately (e.g., Kazdin & Polster, 1973).

Multiple Treatment Reversal Designs

Experiments that use the reversal design to compare the effects of two or more experimental conditions to baseline and/or to one another are said to use a **multiple treatment reversal design**. The letters *C*, *D*, and so on, denote when additional conditions were in effect during the study, as in the following designs: A-B-A-C-B-C (Dickman, Bright, Montgomery, & Miguel, 2012); A-B-C-A-C (Kamps et al., 2015); A-B-C-A-C-B-C (Falcomata, Roane, Hovanetz, Kettering, & Keeney (2004); A-B-A-B-C-A-C-B (Hansen & Wills, 2014); and A-B-A-C-A-D-A-E-A-F (Wilson & Tunnard, 2014).

These designs are considered variations of the reversal design because they embody the experimental method and logic of the reversal tactic: Responding in each phase provides baseline (or control condition) data for the subsequent phase (prediction), independent variables are withdrawn in an attempt to reproduce levels of behavior observed in a previous condition (verification), and each independent variable that contributes fully to the analysis is introduced at least twice (replication). Independent variables can be introduced, withdrawn, changed in value, combined, and otherwise manipulated to produce an endless variety of experimental designs.

For example, Kennedy and Souza (1995) used an A-B-C-B-C-A-C-A-C design to analyze and compare the effects of two kinds of competing sources of stimulation on eye poking by a 19-year-old student with profound disabilities. Geoff had a 12-year history of poking his forefinger into his eyes during periods of inactivity, such as after lunch or while waiting for the bus. The two treatment conditions were music (B) and a video game (C). During the music condition, Geoff was given a Sony Walkman radio with headphones. The radio was tuned to a station that his teacher and family thought he preferred. Geoff had continuous access to the music during this condition, and he could remove the headphones at any time. During the video game condition, Geoff was given a small handheld video game on which he could observe a variety of visual patterns and images on the screen with no sound. As with the music condition, Geoff had continuous access to the video game and could discontinue using it at any time.

Figure 8.5 shows the results of the study. Following an initial baseline phase (A) in which Geoff averaged 4 eye pokes per hour, the music condition (B) was introduced and eye pokes decreased to a mean of 2.8 per hour. The video game (C) was implemented next, and eye pokes decreased further to 1.1 per hour. Measures obtained during the next two phases—a reintroduction of music (B) followed by a second phase of the video game (C)—replicated previous levels of responding under each condition. This B-C-B-C portion of the experiment revealed a functional relation between video game condition and lower frequency of eye pokes compared to music. The final five phases of the experiment (C-A-C-A-C) provided an experimental comparison of the video game and baseline (no-treatment) condition.

In most instances, extended designs involving multiple independent variables are not preplanned. Instead of following a predetermined structure that dictates when and how experimental manipulations will be made, the behavior analyst makes design decisions based on ongoing assessment of the data. For example, Cummings and Carr (2005) used an A-B-C-A-D-BC-A-E-F-A-BF-BCDEF design to evaluate the effects of five interventions that resulted in a treatment package (the BCDEF condition) successful in eliminating the joint dislocation behavior of a child with autism.

> [A] single experiment may be viewed as a number of successive designs that are collectively necessary to clarify relations between independent and dependent variables. Thus, some design decisions might be made in response to the data unfolding as the investigation progresses. This sense of design encourages the experimenter to pursue in more dynamic fashion the solutions to problems of experimental control immediately upon their emergence. (Johnston & Pennypacker, 1980, pp. 250–251)

Students of applied behavior analysis should not interpret this description of experimental design as a recommendation for a free-form approach to the manipulation of independent variables. The researcher must always obey the rule of changing only one variable at a time and must understand the opportunities for

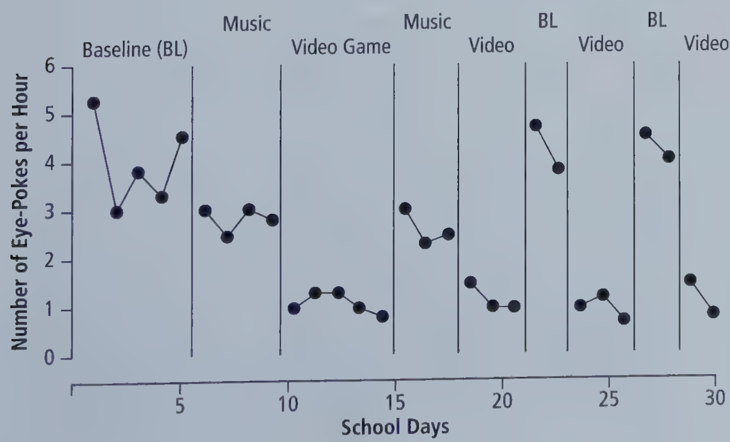

Figure 8.5 Example of a multiple treatment reversal design (A-B-C-B-C-A-C-A-C).

From "Functional Analysis and Treatment of Eye Poking," by C. H. Kennedy and G. Souza, 1995, *Journal of Applied Behavior Analysis*, *28*, p. 33. Copyright 1995 by the Society for the Experimental Analysis of Behavior, Inc. Reprinted by permission.

legitimate comparisons and the limitations that a given sequence of manipulations places on the conclusions that can be drawn from the results.

Experiments using a reversal design to compare two or more treatments are vulnerable to confounding by sequence effects. **Sequence effects** are the effects on a subject's behavior in a given condition that are influenced by the subject's experience with a prior condition. For example, the analyst must use caution in interpreting results from the A-B-C-B-C design that is produced by the following fairly common sequence of events in practice: After baseline (A), an initial treatment (B) is implemented and little or no behavioral improvements are noted. A second treatment (C) is next tried, and the behavior improves. A reversal is then conducted by reintroducing the first treatment (B), followed by reinstatement of the second treatment (C) (e.g., Foxx & Shapiro, 1978). In this case, we can only speak knowingly about the effects of C when it follows B. Recapturing the original baseline levels of responding before introducing the second treatment condition (i.e., an A-B-A-C-A-C sequence) reduces the threat of sequence effects (or helps to expose them for what they are).

An A-B-A-B-C-B-C design, for instance, enables direct comparisons of B to A and C to B, but not of C to A. An experimental design consisting of A-B-A-B-B+C-B-B+C (e.g., Jason & Liotta, 1982) permits an evaluation of the additive or interactive effects of B+C, but does not reveal the independent contribution of C. And in both of these examples, it is impossible to determine what effects, if any, C may have had on the behavior if it had been implemented prior to B. Manipulating each condition so that it precedes and follows every other condition in the experiment (e.g., A-B-A-B-C-B-C-A-C-A-C) is the only way to know for sure. However, manipulating multiple conditions requires significant time and resources, and such extended designs become more susceptible to confounding by maturation and other historical variables not controlled by the experimenter.

Noncontingent Reinforcement (NCR) Reversal Technique

With interventions based on positive reinforcement, it can be hypothesized that observed improvements in behavior result from the participant's feeling better about himself because of the enriched environment created by the reinforcement, not because specific instances of the target behavior have been immediately followed by contingent reinforcement. This hypothesis is most often advanced when interventions consisting of social reinforcement are involved. For example, a person may claim that it doesn't matter *how* the teacher's praise and attention were given; the student's behavior improved because the praise and attention created a warm and supporting environment. If, however, the behavioral improvements observed during a contingent reinforcement condition are lost during a condition in which equal amounts of the same consequence are delivered independent of the occurrence of the target behavior, a functional relation between the reinforcement contingency and behavior change may be demonstrated.

This experimental control tactic, called **noncontingent reinforcement (NCR) reversal technique**, can show that behavior change is the result of *contingent* reinforcement, not simply the presentation of or contact with the stimulus event (Thompson & Iwata, 2005). A study by Baer and Wolf (1970a) on the effects of teachers' social reinforcement on the cooperative play of a preschool child provides an excellent example of the NCR reversal technique (Figure 8.6). The authors described the use and purpose of the design as follows:

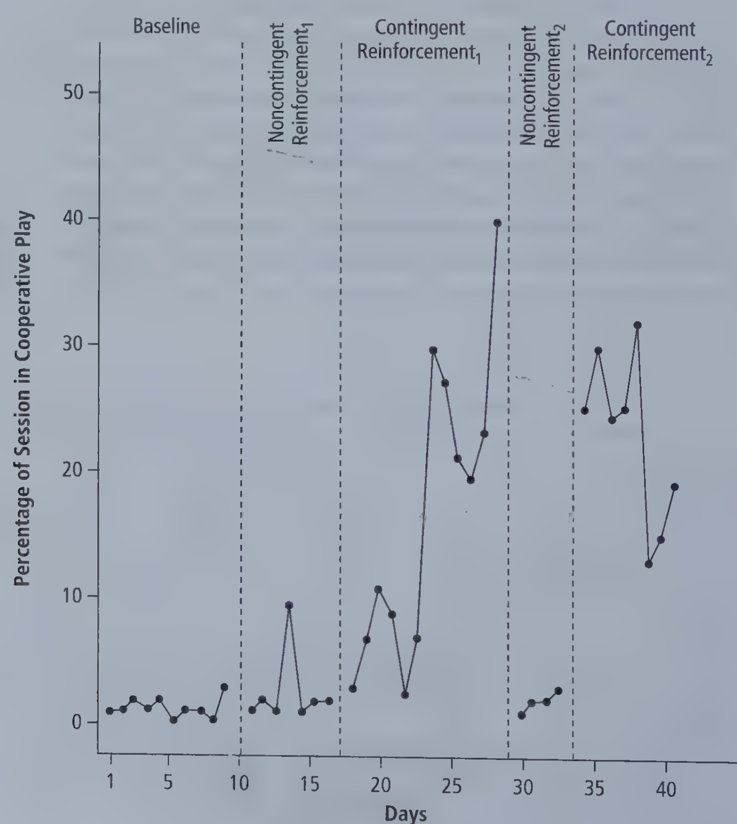

Figure 8.6 Reversal design using noncontingent reinforcement (NCR) as a control technique.

From "Recent Examples of Behavior Modification in Pre-school Settings," by D. M. Baer and M. M. Wolf, in *Behavior Modification in Clinical Psychology*, pp. 14–15, edited by C. Neuringer and J. L. Michael, 1970, Upper Saddle River, NJ: Prentice Hall. Copyright 1970 by Prentice Hall. Adapted by permission.

> [The teachers first collected] baselines of cooperative and other related behaviors of the child, and of their own interaction with the child. Ten days of observation indicated that the child spent about 50% of each day in proximity with other children (meaning within 3 feet of them indoors, or 6 feet outdoors). Despite this frequent proximity, however, the child spent only about 2% of her day in cooperative play with these children. The teachers, it was found, interacted with this girl about 20% of the day, not all of it pleasant. The teachers, therefore, set up a period of intense social reinforcement, offered not for cooperative play but free of any response requirement at all: the teachers took turns standing near the girl, attending closely to her activities, offering her materials, and smiling and laughing with her in a happy and admiring manner. The results of 7 days of this noncontingent extravagance of social reinforcement were straightforward: the child's cooperative play changed not at all, despite the fact that the other children of the group were greatly attracted to the scene, offering the child nearly double the chance to interact with them cooperatively. These 7 days having produced no useful change, the teachers then began their planned reinforcement of cooperative behavior. . . . Contingent social reinforcement, used in amounts less than half that given during the noncontingent period, increased the child's cooperative play from its usual 2% to a high of 40% in the course of 12 days of reinforcement. At that point, in the interests of certainty, the teachers discontinued contingent reinforcement in favor of noncontingent. In the course of 4 days, they lost virtually all of the cooperative behavior they had gained during the reinforcement period of the study, the child showing about a 5% average of cooperative play over that period of time. Naturally, the study concluded with a return to the contingent use of social reinforcement, a recovery of desirable levels of cooperative play, and a gradual reduction of the teacher's role in maintaining that behavior. (pp. 14–15)

Using NCR as a control condition to demonstrate a functional relation is advantageous when it is not possible or appropriate to eliminate completely the event or activity used as a contingent reinforcement. For example, Lattal (1969) employed NCR as a control condition to "reverse" the effects of swimming as reinforcement for tooth brushing by children in a summer camp. In the contingent reinforcement condition, the campers could go swimming only if they had brushed their teeth; in the NCR condition, swimming was available whether or not tooth brushing occurred. The campers brushed their teeth more often in the contingent reinforcement condition.

The usual procedure is to deliver NCR on a fixed or variable time schedule independent of the subject's behavior. A potential weakness of the NCR control procedure becomes apparent when high rate of the desired behavior has been produced during the preceding contingent reinforcement phase. It is probable in such situations that at least some instances of NCR, delivered according to a predetermined time schedule, will follow occurrences of the target behavior closely in time, and thereby function as adventitious, or accidental, reinforcement (Thompson & Iwata, 2005). In fact, an intermittent schedule of reinforcement might be created inadvertently that results in even higher levels of performance than those obtained under contingent reinforcement. (Intermittent schedules of reinforcement and their effects are described in Chapter 13). In such cases the investigator might consider using one of the two control techniques described next, both of which involve "reversing" the behavioral focus of the contingency.[3]

DRO Reversal Technique

One way to ensure that reinforcement will not immediately follow the target behavior is to deliver reinforcement immediately following the subject's performance of *any behavior other than the target behavior.* With a **DRO reversal technique**, the control condition consists of delivering the event suspected of functioning as reinforcement following the emission of any behavior other than the target behavior (e.g., Baer, Peterson, & Sherman, 1967 Osborne, 1969; Poulson, 1983). For example, Reynolds and Risley (1968) used contingent teacher attention to increase the frequency of talking in a 4-year-old girl enrolled in a preschool program for disadvantaged children. After a period of teacher attention contingent on verbalization, in which the girl's talking increased from a baseline average of 11% of the intervals observed to 75%, a DRO condition was implemented during which the teachers attended to the girl for any behavior except talking. During the 6 days of DRO, the girl's verbalization dropped to 6%. Teacher attention was then delivered contingent on talking, and the girl's verbalization "immediately increased to an average of 51%" (p. 259).

DRI/DRA Reversal Technique

During the control condition in a **DRI/DRA reversal technique**, occurrences of a specified behavior that is either incompatible with the target behavior (i.e., the two behaviors cannot possibly be emitted at the same time) or an alternative to the target behavior are immediately followed by the same consequence previously delivered as contingent reinforcement for the target behavior. Goetz and Baer's (1973) investigation of the effects of teacher praise on preschool children's creative play with building blocks illustrates the use of a DRI control condition. Figure 8.7 shows the number of different block forms (e.g., arch, tower, roof, ramp) constructed by the three children who participated in the study. During baseline (data points indicated by the letter *N*), "the teacher sat by the child as she built with the blocks, watching closely but quietly, displaying neither criticism nor enthusiasm about any particular use of the blocks" (p. 212). During the next phase (the *D* data points), "the teacher remarked with interest, enthusiasm, and delight every time that the child placed and/or rearranged the blocks so as to create a form that had not appeared previously in that session's construction(s). . . . 'Oh, that's very nice—that's different!'" (p. 212). Then, after increasing form diversity was clearly established, instead of merely withdrawing verbal praise and returning to the initial baseline condition, the teacher provided descriptive praise only when the children had constructed the same forms (the *S* data points). "Thus, for the next two to four sessions, the teacher continued to display interest, enthusiasm, and delight, but only at those times when the

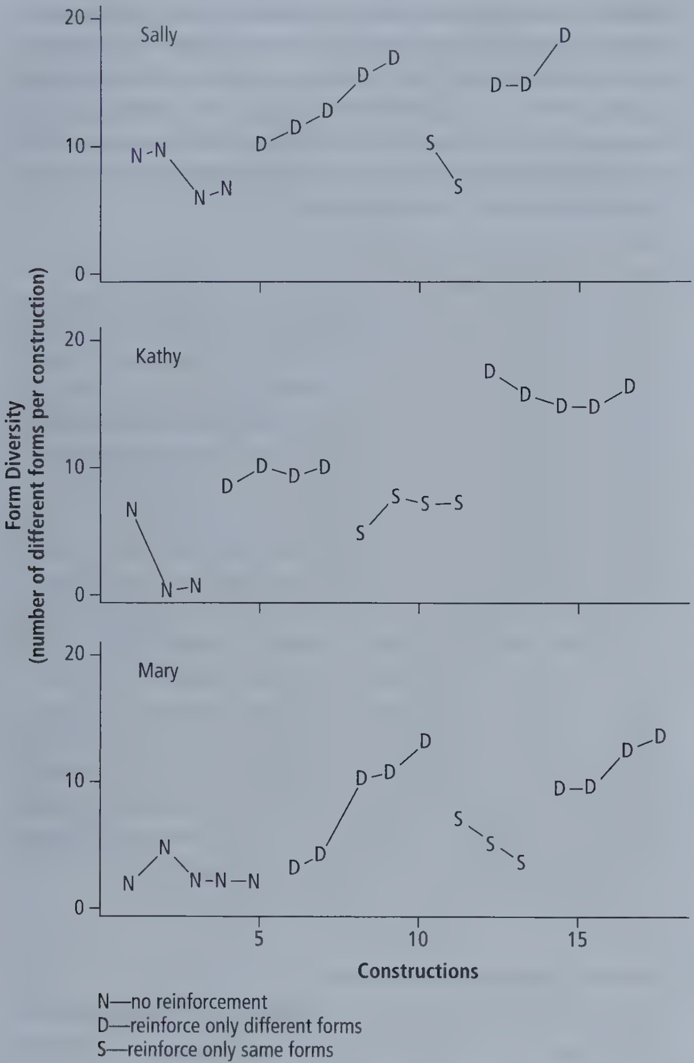

Figure 8.7 Reversal design using a DRI control technique.

Based on "Social Control of Form Diversity and the Emergence of New Forms in Children's Blockbuilding" by E. M. Goetz and D. M. Baer, 1973, *Journal of Applied Behavior Analysis*, 6, p. 213. Copyright 1973 by the Society for the Experimental Analysis of Behavior, Inc.

child placed and/or rearranged a block so as to create a repetition of a form already apparent in that session's construction(s). . . . Thus, no first usage of a form in a session was reinforced, but every second usage of that form and every usage thereafter within the session was. . . . 'How nice—another arch!'" (p. 212). The final phase of the experiment entailed a return to descriptive praise for different forms. Results show that the form diversity of children's block building was a function of teacher praise and comments. The DRI reversal tactic allowed Goetz and Baer to determine that it was not just the delivery of teacher praise and comment that resulted in more creative block building by the children; the praise and attention had to be contingent on different forms to produce increasing form diversity.[4]

Considering the Appropriateness of the Reversal Design

The primary advantage of the reversal design is its ability to provide a clear demonstration of the existence (or absence) of a functional relation between the independent and dependent variables. An investigator who reliably turns the target behavior on and off by presenting and withdrawing a specific variable makes a clear and convincing demonstration of experimental control. In addition, the reversal design enables quantification of the amount of behavior change over the preintervention level of responding. And the return to baseline provides information on the need to program for maintenance. Furthermore, a complete A-B-A-B design ends with the treatment condition in place.[5]

In spite of its strengths as a tool for analysis, the reversal design entails some potential scientific and social disadvantages that should be considered prior to its use. The considerations are of two types: irreversibility, which affects the scientific utility of the design; and the social, educational, and ethical concerns related to withdrawing a seemingly effective intervention.

Irreversibility: A Scientific Consideration

A reversal design is not appropriate in evaluating the effects of a treatment variable that, by its very nature, cannot be withdrawn once it has been presented. Although independent variables involving reinforcement and punishment contingencies can be manipulated with some certainty—the experimenter either presents or withholds the contingency—an independent variable such as providing information or modeling, once presented, cannot simply be removed. For example, a reversal design would not be an effective element of an experiment investigating the effects of attending an in-service training workshop for teachers during which participants observed a master teacher use contingent praise and attention with students. After the participants have listened to the rationale for using contingent praise and attention and observed the master teacher model it, the exposure provided by that experience could not be withdrawn. Such interventions are said to be irreversible.

Irreversibility of the dependent variable must also be considered in determining whether a reversal would be an effective analytic tactic. Behavioral **irreversibility** means that a level of behavior observed in an earlier phase cannot be reproduced even though the experimental conditions are the same as they were during the earlier phase (Sidman, 1960). Once improved, many target behaviors of interest to the applied behavior analyst remain at their newly enhanced level even when the intervention responsible for the behavior change is removed. From a clinical or educational standpoint, such a state of affairs is desirable: The behavior change is shown to be durable, persisting even in the absence of continued treatment. For example, Kuoch and Mirenda (2003) reported irreversibility as a positive outcome of their study evaluating the effects of social stories on problem behavior. Problem behavior by three children with autism decreased from initial baseline levels during a social stories intervention and remained low when the intervention was withdrawn, a pattern of results the authors described as "short-term maintenance of behavioral reduction once the social stories were discontinued" (p. 224). However, irreversibility is a problem if demonstration of the independent variable's role in the behavior change depends on verification by recapturing baseline levels of responding.

For example, baseline observations might reveal very low, almost nonexistent, rates of talking and social interaction for a young child. An intervention consisting of teacher-delivered

social reinforcement for talking and interacting could be implemented, and after some time the girl might talk to and interact with her peers at a frequency and in a manner similar to that of her classmates. The independent variable, teacher-delivered reinforcement, could be terminated in an effort to recapture baseline rates of talking and interacting. But the girl might continue to talk to and interact with her classmates even though the intervention, which may have been responsible for the initial change in her behavior, is withdrawn. In this case a source of reinforcement uncontrolled by the experimenter—the girl's classmates talking to and playing with her as a consequence of her increased talking and interacting with them—could maintain high rates of behavior after the teacher-delivered reinforcement is no longer provided. In such instances of irreversibility, an A-B-A-B design would fail to reveal a functional relation between the independent variable and the target behavior.

Nonetheless, one of the major objectives of applied behavior analysis is establishing socially important behavior through experimental treatments so that the behavior will contact natural "communities of reinforcement" to maintain behavioral improvements in the absence of treatment (Baer & Wolf, 1970b). When irreversibility is suspected or apparent, in addition to considering DRO or DRI/DRA conditions as control techniques, investigators can consider other experimental tactics, most notably the multiple baseline designs described in Chapter 9. A multiple treatment reversal design requires a reversible dependent variable. If the initial treatment condition in a multiple treatment reversal design changes an irreversible behavior, the opportunity to assess and compare the effects of any other treatment conditions is lost.

Withdrawing an Effective Intervention: A Social, Educational, and Ethical Consideration

Although it can yield an unambiguous demonstration of experimental control, withdrawing a seemingly effective intervention to evaluate its role in behavior change presents a legitimate cause for concern. One must question the appropriateness of any procedure that allows (indeed, seeks) an improved behavior to deteriorate to baseline levels of responding. Various concerns have been voiced over this fundamental feature of the reversal design. Although considerable overlap exists among the concerns, they can be classified as having primarily a social, educational, or ethical basis.

Social Concerns. Applied behavior analysis is, by definition, a social enterprise. Behaviors are selected, defined, observed, measured, and modified by and for people. Sometimes the people involved in an applied behavior analysis—administrators, teachers, parents, and participants—object to the withdrawal of an intervention they associate with desirable behavior change. Even though a reversal may provide the most unqualified picture of the behavior–environment relation under study, it may not be the analytic tactic of choice because key participants do not want the intervention to be withdrawn. When a reversal design offers the best experimental approach scientifically and poses no ethical problems, the behavior analyst may choose to explain the operation and purpose of the tactic to those who do not favor it. But it is unwise to attempt a reversal without the full support of the people involved, especially those who will be responsible for withdrawing the intervention. Without their cooperation the procedural integrity of the experiment could easily be compromised. For example, people who are against the withdrawal of treatment might sabotage the return to baseline conditions by implementing the intervention, or at least those parts of it they consider the most important.

Educational and Clinical Issues. Educational or clinical issues concerning the reversal design are often raised in terms of instructional time lost during the reversal phases, as well as the possibility that the behavioral improvements observed during intervention may not be recaptured when treatment is resumed after a return to baseline conditions. Prolonged reversals are neither justifiable nor necessary (Stolz, 1978). If preintervention levels of responding are reached quickly, reversal phases can be quite short in duration. Sometimes only three or four sessions are needed to show that initial baseline rates have been reproduced (e.g., Ashbaugh & Peck, 1998; Cowdery et al., 1990 [Figure 25.6]; Hall et al., 1971, Figure 14.1). Two or three brief reversals can provide an extremely convincing demonstration of experimental control. Concern that the improved levels of behavior will not return when the treatment variable is reintroduced, while understandable, has not been supported by empirical evidence. Hundreds of published studies have shown that behavior acquired under a given set of environmental conditions can be reacquired rapidly during subsequent reapplication of those conditions.

Ethical Concerns. A serious ethical concern must be addressed when the use of a reversal design is considered for evaluating a treatment for self-injurious or dangerous behaviors. With mild self-injurious or aggressive behaviors, short reversal phases consisting of one or two baseline probes can sometimes provide the empirical evidence needed to reveal a functional relation (e.g., Akers, Higbee, Pollard, Pellegrino, & Gerencser, 2016; Kelley, Jarvie, Middlebrook, McNeer, & Drabman, 1984; Luce, Delquadri, & Hall, 1980; Murphey et al., 1979 [Figure 8.4]). For example, in their study evaluating a treatment for elopement (i.e., running away from supervision) by a child with attention-deficit hyperactivity disorder (ADHD), Kodak, Grow, and Northup (2004) returned to baseline conditions for a single session (see Figure 8.8).

Nonetheless, with some behaviors it may be determined that withdrawing an intervention associated with improvement for even a few one-session probes would be unethical. In such cases experimental designs that do not rely on the reversal tactic must be used.

MULTIELEMENT DESIGN

An important and frequently asked question by teachers, therapists, and others who are responsible for changing behavior is this: Which of these treatments will be most effective with this student or client? In many situations, the research literature, the analyst's experience, and/or logical extensions of the principles of behavior point to several possible interventions. Determining which of several possible treatments or combination of treatments will produce the greatest improvement in behavior is a

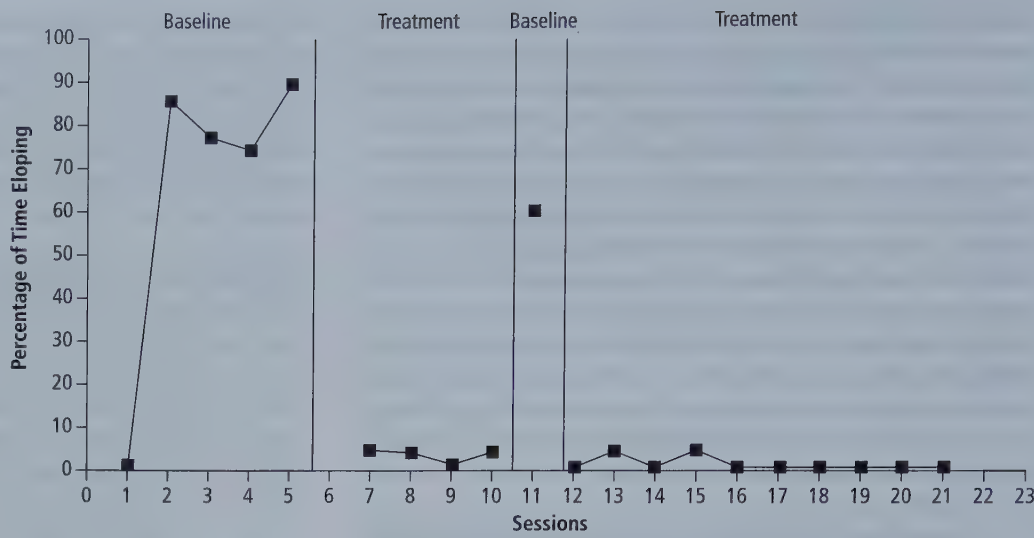

Figure 8.8 Reversal design with a single-session return-to-baseline probe to evaluate and verify effects of treatment for a potentially dangerous behavior.

Based on "Functional Analysis and Treatment of Elopement for a Child with Attention Deficit Hyperactivity Disorder" by T. Kodak, L. Grow, and J. Northrup, 2004, *Journal of Applied Behavior Analysis, 37*, p. 231. Copyright 2004 by the Society for the Experimental Analysis of Behavior, Inc.

primary task for applied behavior analysts. As described earlier, although a multiple treatment reversal design (e.g., A-B-C-B-C) can be used to compare the effects of two or more treatments, such designs have some inherent limitations. Because the different treatments in a multiple treatment reversal design are implemented during separate phases that occur in a particular order, the design is particularly vulnerable to confounding by sequence effects (e.g., Treatment C may have produced its effect only because it followed Treatment B). A second disadvantage of using the reversal tactic to compare multiple treatments is the extended time required to demonstrate differential effects. Most behaviors targeted for change by teachers and therapists are selected because those behaviors need immediate improvement. An experimental design that will quickly reveal the most effective treatment among several possible approaches is important for the applied behavior analyst. The **multielement design** (also called **alternating treatments design**) is an experimentally sound and efficient method for comparing the effects of two or more treatments.

Operation and Logic of the Multielement Design

The multielement design is characterized by the rapid alternation of two or more distinct treatments (i.e., independent variables) while their effects on the target behavior (i.e., dependent variable) are measured. In contrast to the reversal design, in which experimental manipulations are made after steady state responding is achieved in a given phase of an experiment, the different interventions in a multielement design are manipulated independent of the level of responding. To aid the subject's discriminating which treatment condition is in effect at any given time, a distinct stimulus (e.g., a sign, verbal instructions, different-colored worksheets) is often associated with each treatment. Barlow and Hayes (1979) introduced the term *alternating treatments design* and described it this way:

> The data are plotted separately for each intervention to provide a ready visual representation of the effects of each treatment. Because confounding factors such as time of administration have been neutralized (presumably) by counterbalancing, and because the two treatments are readily discriminable by subjects through instructions or other discriminative stimuli, differences in the individual plots of behavior change corresponding with each treatment should be attributable to the treatment itself, allowing a direct comparison between two (or more) treatments. (p. 200)

Figure 8.9 shows a graphic prototype of an alternating treatments design comparing the effects of two treatments, A and B, on some response measure. In an alternating treatments design, the different treatments can be alternated in a variety of ways. For example, the treatments might be (a) alternated across daily sessions, one treatment in effect each day; (b) administered in separate sessions occurring within the same day; or (c) implemented each during a portion of the same session. Counterbalancing the days of the week, times of day, sequence in which the different treatments occur (e.g., first or second each day), persons delivering the different treatments, and so forth, reduces the probability that any observed differences in behavior are the result of variables other than the treatments themselves. For example, assume that Treatments A and B in Figure 8.9 were each administered for a single

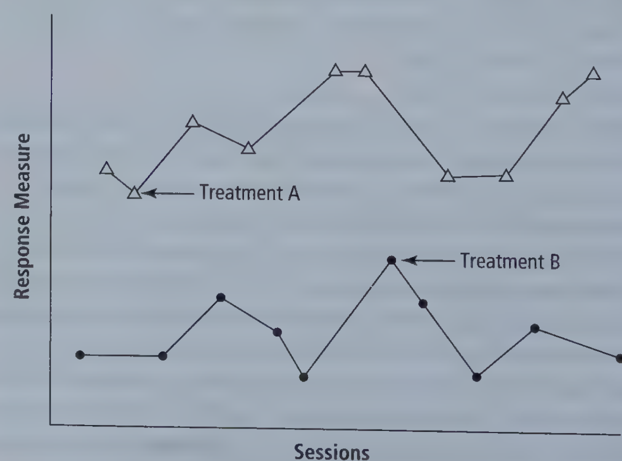

Figure 8.9 Graphic prototype of a multielement design comparing the differential effects of two treatments (A and B).

30-minute session each day, with the daily sequence of the two treatments determined by a coin flip.

The data points in Figure 8.9 are plotted on the horizontal axis to reflect the actual sequence of treatments each day. Thus, the horizontal axis is labeled *Sessions*, and each consecutive pair of sessions occurred on a single day. Some published reports of experiments using an alternating treatments design in which two or more treatments were presented each day (or session) plot the measures obtained during each treatment above the same point on the horizontal axis, thus implying that the treatments were administered simultaneously. This practice masks the temporal order of events and has the unfortunate consequence of making it difficult for the researcher or reader to discover potential sequence effects.

The three components of steady state strategy—prediction, verification, and replication—are found in the alternating treatments design. However, each component is not readily identified with a separate phase of the design. In an alternating treatments design, each successive data point for a specific treatment plays all three roles: It provides (a) a basis for the *prediction* of future levels of responding under that treatment, (b) potential *verification* of the previous prediction of performance under that treatment, and (c) the opportunity for *replication* of previous effects produced by that treatment.

To see this logic unfold, the reader should place a piece of paper over all the data points in Figure 8.9 except those for the first five sessions of each treatment. The visible portions of the data paths provide the basis for predicting future performance under each respective treatment. Moving the paper to the right reveals the two data points for the next day, each of which provides a degree of verification of the previous predictions. As more data are recorded, the predictions of given levels of responding within each treatment are further strengthened by continued verification (if those additional data conform to the same level and/or trend as their predecessors). Replication occurs each time Treatment A is reinstated and measurement reveals responding similar to previous Treatment A measures and different from those obtained when Treatment B is in effect. Likewise, another mini-replication is achieved each time a reintroduction of Treatment B results in measures similar to previous Treatment B measures and different from Treatment A levels of responding. A consistent sequence of verification and replication is evidence of experimental control and strengthens the investigator's confidence of a functional relation between the two treatments and different levels of responding.

The presence and degree of experimental control in a multielement design is determined by visual inspection of the differences between (or among) the data paths representing the different treatments. Inspecting multielement design data should include visual analysis of mean shift in level, trend, and variability throughout the comparison phase(s) of the experiment (Diller, Barry, & Gelino, 2016). Experimental control is defined in this instance as objective, believable evidence that different levels of responding (and perhaps degrees of trends and variability) are predictably and reliably produced by the presence of the different treatments. When the data paths for two treatments show no overlap with each other and either stable levels or opposing trends, a clear demonstration of experimental control has been made. Such is the case in Figure 8.9, in which there is no overlap of data paths and the picture of differential effects is clear. When some overlap of data paths occurs, a degree of experimental control over the target behavior can still be demonstrated if the majority of data points for a given treatment fall outside the range of values of the majority of data points for the contrasting treatment.

The extent of any differential effects produced by two treatments is determined by the vertical distance—or fractionation—between their respective data paths and quantified by the vertical axis scale. The greater the vertical distance, the greater the differential effects of the two treatments on the response measure. It is possible for experimental control to be shown between two treatments but for the amount of behavior change to be socially insignificant. For instance, experimental control may be demonstrated for a treatment that reduces a person's severe self-injurious behavior from 10 occurrences per hour to 2 per hour, but the participant is still engaged in self-mutilation. However, if the vertical axis is scaled meaningfully, the greater the separation of data paths on the vertical axis, the higher the likelihood that the difference represents a socially significant effect.

Data from an experiment that compared the effects of two types of group-contingent rewards on the spelling accuracy of fourth-grade underachievers (Morgan, 1978) illustrate how the alternating treatments design reveals experimental control and the quantification of differential effects. The six children in the study were divided into two equally skilled teams of three on the basis of pretest scores. Each day during the study the students took a five-word spelling test. The students received a list of the words the day before, and a 5-minute study period was provided just prior to the test. Three different conditions were used in the alternating treatments design: (a) *no game*, in which the spelling tests were graded immediately and returned to the students, and the next scheduled activity in the school day began; (b) *game*, in which test papers were graded immediately, and each member of the team who had attained the highest total score received a Certificate of Achievement and was allowed to stand up and cheer; and (c) *game plus*, consisting of the same procedure as the game condition, plus each student on the winning team also received a small trinket (e.g., a sticker or pencil).

The results for Student 3 (see Figure 8.10) show that experimental control over spelling accuracy was obtained between the no-game condition and both the game and the game-plus conditions. Only the first two no-game data points overlap the lower range of scores obtained during the game or the game-plus conditions. However, the data paths for the game and game-plus conditions overlap completely and continuously throughout the study, revealing no difference in spelling accuracy between the two treatments. The vertical distance between the data paths represents the amount of improvement in spelling accuracy between the no-game condition and the game and the game-plus conditions. The mean difference between the two game conditions and the no-game condition was two words per test. Whether such a difference represents a significant improvement is an educational question, not a mathematical or statistical one, but most educators and parents would agree

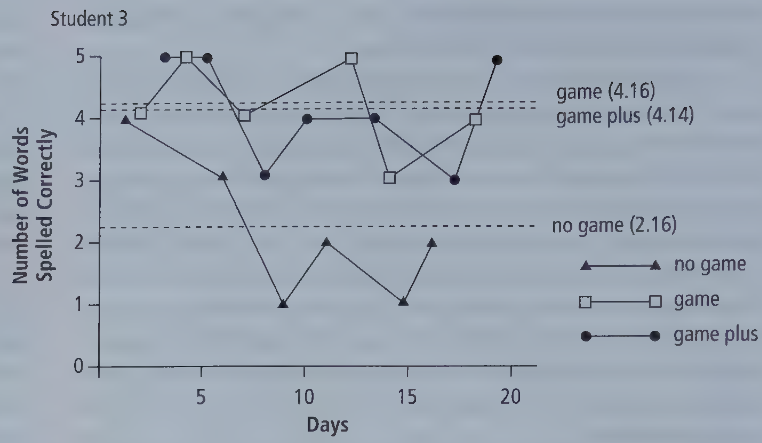

Figure 8.10 A multielement design comparing the effects of three different treatments on the spelling accuracy of a fourth-grade student.

Based on *Comparison of Two "Good Behavior Game" Group Contingencies on the Spelling Accuracy of Fourth-Grade Students* by Q. E. Morgan, 1978, unpublished master's thesis, The Ohio State University.

that an increase of two words spelled correctly out of five is socially significant, especially if that gain can be sustained from week to week. The cumulative effect over a 180-day school year would be impressive. There was virtually no difference in Student 3's spelling performance between the game and game-plus conditions. However, even a larger mean difference would not have contributed to the conclusions of the study because of the lack of experimental control between the game and the game-plus treatments.

Student 6 earned consistently higher spelling scores in the game-plus condition than he did in the game or no-game conditions (see Figure 8.11). Experimental control was demonstrated between the game-plus and the other two treatments for Student 6, but not between the no-game and game conditions. Again, the difference in responding between treatments is quantified by the vertical distance between the data paths. In this case there was a mean difference of 1.55 correctly spelled words per test between the game-plus and no-game conditions.

Figures 8.10 and 8.11 illustrate two other important points about the multielement design. First, the two graphs show how the multielement design enables a quick comparison of interventions. After 20 sessions the teacher had sufficient empirical evidence for selecting the most effective consequences for each student. If only two conditions had been compared, even fewer sessions may have been required to identify the most effective intervention. Second, these data underscore the importance of evaluating treatment effects at the level of the individual subject. All six children spelled more words correctly under one or both of the game conditions than they did under the no-game condition. However, Student 3's spelling accuracy was equally enhanced by either the game or the game-plus contingency, whereas Student 6's spelling scores improved only when a tangible reward was available.

Variations of the Multielement Design

The multielement design can be used to compare one or more treatments to a no-treatment or baseline condition, assess the relative contributions of individual components of a package intervention, and perform parametric investigations in which different values of an independent variable are alternated to determine differential effects on behavior change. The following sections describe the most common variations of the multielement design.

Single-phase Multielement Design

A single-phase experiment in which the effects of two or more treatment conditions are compared is the most basic application of the multielement design (e.g., Barbetta, Heron, & Heward, 1993; McNeish, Heron, & Okyere, 1992; Morton, Heward, & Alber, 1998). For example, Brady and Kubina (2010) compared the multiplication fact fluency of three elementary-age students with attention-deficit hyperactivity disorder (ADHD) under two practice procedures: whole time practice trials and endurance building

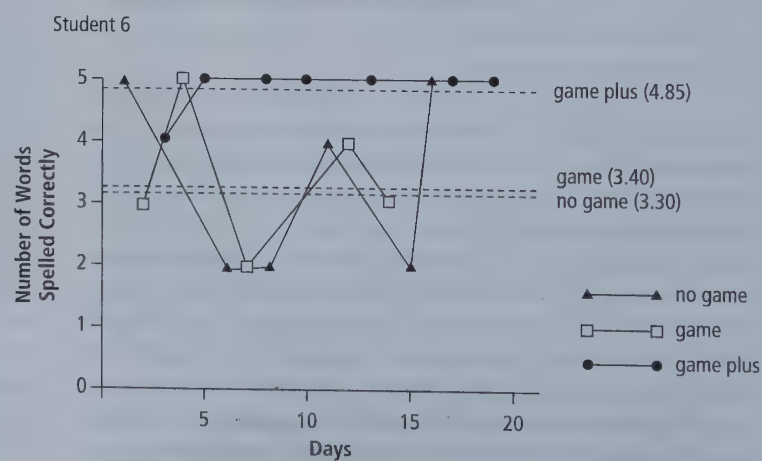

Figure 8.11 A multielement design comparing the effects of three different treatments on the spelling accuracy of a fourth-grade student.

Based on *Comparison of Two "Good Behavior Game" Group Contingencies on the Spelling Accuracy of Fourth-Grade Students* by Q. E. Morgan, 1978, unpublished master's thesis, The Ohio State University.

practice trials. Each procedure lasted 2.5 minutes and consisted of students writing as many answers to single-digit multiplication math fact sheet assessments as they could for a combined total of 2 minutes and receiving corrective feedback from the experimenter for a combined total of 30 seconds. The procedures differed in how time for writing answers and corrective feedback was distributed. The whole time practice condition consisted of one 1-minute practice trial, 30 seconds of corrective feedback, and a 1-minute multiplication math fact sheet assessment. The endurance building practice condition consisted of three 20-second practice trials interspersed with 10-second corrective feedback, and a 1-minute multiplication math fact sheet assessment. The two practice conditions were alternated daily.

Figure 8.12 shows the results on the daily multiplication math fact sheet assessments for one of the three participants. Brady and Kubina (2010) reported that as participants' "performance levels for the three 20 second intervals improved so too did their ability to perform over the longer time interval of 1 minute" (p. 90). Although practice time equaled 1 minute in both conditions, the students practiced 30% more problems during the endurance building practice trials condition than they did in the whole time practice trial condition.

A no-treatment condition is often incorporated into the design as one of the treatments to be compared. For example, the no-game condition in the Morgan (1978) study served as a no-treatment control condition against which the students' spelling scores in the game and game-plus conditions were compared (see Figures 8.10 and 8.11). Including a no-treatment control condition as one of the conditions in a multielement design provides valuable information on any differences in responding under the intervention treatment(s) and no treatment. However, the measures obtained during the no-treatment control condition should not be considered representative of an unknown baseline level of responding. It may be that the measures obtained in the no-treatment condition represent only the level of behavior under a no-treatment condition when it is interspersed within an ongoing series of treatment condition(s), and do not represent the level of behavior that existed before the alternating treatments design was begun.

The single-phase multielement design is the primary experimental tool for conducting functional analyses of problem behavior (Chapter 27). Figure 6.5 and Figures 27.7, 27.8, 25.10, and 27.11 in this text show examples of functional analyses using multielement designs.

Two-phase Design: Baseline and Comparison

Investigators often use a two-phase experimental design in which baseline measures are collected until a stable level of responding or counter-therapeutic trend is obtained prior to the alternating treatments phase (e.g., Kranak, Alber-Morgan, & Sawyer, 2017; Martens, Lochner, & Kelly, 1992 [see Figure 13.6]; Neef, Iwata, & Page, 1980 [see Figure 6.12]). The baseline condition may be continued during the treatments comparison phase as a no-treatment control condition.

Wilder, Atwell, and Wine (2006) used a multielement design with an initial baseline phase to evaluate the relative effectiveness of three levels of treatment integrity on compliance by typically developing preschool children with instructions not usually complied with by the children: "Give me the [snack item]," "Put the toy away," and "Come here." Each session the therapist presented one of the three instructions 10 times at a rate of once per minute. Compliance, defined as doing what the therapist instructed within 10 seconds, resulted in brief praise from the therapist throughout the study. During baseline, noncompliance produced no response from the therapist. During the alternating treatments phase, the therapist responded to noncompliance by implementing a three-step prompting procedure for 100% of trials for one instruction (e.g. "Give me the [snack item]"), 50% of trials for another instruction (e.g., "Put

the toy away"), and 0% of trials for the third instruction (e.g., "Come here"). The 0% integrity condition was identical to baseline and served as a no-treatment control condition.

Figure 8.13 shows the results for the two children who participated in the study. Each child complied most often with the instruction for which the therapist implemented the prompting intervention with 100% integrity, complied at a higher than baseline level with the instruction associated with 50% treatment integrity, and seldom or never complied with the instruction associated with 0% integrity (i.e., baseline conditions). By associating the 100% integrity condition with a different instruction for each child, the experimenters strengthened the replication of the functional relation between the 100% integrity condition and the highest level of compliance.

Sindelar, Rosenberg, and Wilson (1985) described a variation of the multielement design for comparing the efficiency of instructional procedures they called the **adapted alternating treatments design**. The comparison phase of the design features the alternating application of two (usually) or more different teaching methods, each method applied to different but equivalent sets of instructional items. All items are topographically different members of the same response or skill class, such as reading printed words, defining vocabulary terms, spelling words, answering math problems, and stating history facts. Sindelar and colleagues described the design's operation and purpose as follows:

> A baseline in which the equivalence of performance on the two sets is demonstrated is followed by an experimental condition in which acquisition of one set taught by one method is compared to the acquisition of the second set taught by the second method. Differences are demonstrated when acquisition of one set is more rapid than acquisition of the other, and the effect is consistent across subjects, settings, or behaviors. (p. 70)

Wine, 2006, Journal of *Applied Behavior Analysis*, *39*, p. 372. Copyright 2006 by the Society for the Experimental Analysis of Behavior, Inc.

Vladescu and Kodak (2013) used an adapted alternating treatments design to analyze the extent and speed with which preschool children with autism would acquire secondary learning targets as a function of presenting information on secondary learning targets during the antecedent or consequence portion of learning trials for primary targets. Pretests determined an individualized pool of unknown targets—naming items on picture cards or responding to fill-in-the-blank statements ("The opposite of hot is ____ ?")—for each participant. The targets were assigned to different sets, each set representing an experimental condition (i.e., teaching method) distinguished by whether and when information on secondary targets was presented. The experimenters equated the sets by considering the number of syllables contained in responses to the targets and putting targets that sounded similar in different sets. In the *antecedent condition*, the experimenter presented information on a secondary target (e.g., held up a picture and said, "This is a seal."), waited 3 seconds, and then presented the primary target (e.g., held up a picture of a lion and asked, "What is it?"). In the *consequence condition*, the experimenter presented information on a secondary target in the same way immediately after delivering reinforcement for the participant's response to the primary target. An error correction procedure ensured that primary target trials ended with a correct response by the participant. In the *secondary-targets-only condition*, the experimenter presented information on secondary targets in the absence of teaching primary targets. In the *primary-targets-only condition*, no secondary target information was provided. Participants' acquisition of secondary-target information was measured by probes, conducted every one to three training sessions in other conditions. Participants received no feedback or reinforcement for responses to secondary target presentations in any condition.

Figure 8.14 shows the results for one of the four participants. Rick acquired the primary targets in the antecedent, consequence, and primary-targets-only conditions (top panel) in five, six, and five sessions, respectively. He correctly echoed the secondary targets on 100% of opportunities during the antecedent, consequence, and secondary-targets-only conditions. Probes showed that Rick mastered the secondary targets during the training of primary targets, and he did so in a similar number of

sessions as the primary targets (bottom panel). Like Rick, two of the three other children in the study mastered secondary targets without explicit instruction. That is, when information on secondary targets was presented in the antecedent or consequence condition, the children learned double the number of targets in a similar amount of training time compared to the condition in which only the primary targets were presented.

Three-phase Design: Baseline, Comparison, and Best Treatment

Another widely used variation of the alternating treatments design consists of three sequential phases: an initial baseline phase, a second phase comparing two or more alternating treatments (one of which may be the baseline control condition), and a final phase in which only the most effective treatment is administered (e.g., Heckaman, Alber, Hooper, & Heward, 1998; Mechling, 2006; Ollendick, Matson, Esvelt-Dawson, & Shapiro, 1980).

Tincani (2004) used such a design to investigate the relative effectiveness of sign language and picture exchange training on the acquisition of mands (requests for preferred items) by two children with autism.[6] A related research question was whether a relation existed between students' pre-existing motor imitation skills and their abilities to learn mands through sign language or by picture exchange. Two assessments were conducted for each student prior to baseline. A stimulus preference assessment was conducted to identify a list of 10 to 12 preferred items (e.g., drinks, edibles, toys), and each student's ability to imitate 27 hand, arm, and finger movements similar to those required for sign language was assessed.[7]

The purpose of baseline was to ensure that the participants were not able to request preferred items with picture exchange, sign language, or speech prior to training. Baseline trials consisted of giving the student 10 to 20 seconds of noncontingent access to a preferred item, removing the item briefly, and then placing it out of the student's reach. A laminated 2-inch-by-2-inch picture of the item was placed in front of the student. If the student placed the picture symbol in the experimenter's hand, signed the name of the item, or spoke the name of the item within 10 seconds, the experimenter provided access to the item. If not, the item was removed and the next item on the list was presented. Following a three-session baseline, during which neither participant emitted an independent mand in any modality, the alternating treatments phase was begun.

The sign language training procedures were adapted from Sundberg and Partington's (1998) *Teaching Language to Children with Autism or Other Developmental Disabilities.* The simplest sign from American Sign Language for each item was taught. Procedures used in the Picture Exchange Communication System (PECS) training condition were adapted from Bondy and Frost's (2002) *The Picture Exchange Communication System Training Manual.* In both conditions, training on each preferred item continued for five to seven trials per session, or until the participant showed no interest in the item. At that time, training then began on the next item and continued until all 10 or 12 items on the participant's list of preferred items had been presented. During the study's final phase, each participant received either sign language or PECS training only, depending on which method had been most successful during the alternating treatments phase.

The percentage of independent mands by the two students throughout the study is shown in Figures 8.15 (Jennifer) and 8.16 (Carl). Picture exchange training was clearly more effective than sign language for Jennifer. Jennifer demonstrated weak motor imitation skills in the pre-baseline assessment, correctly imitating 20% of the motor movements attempted in the pre-baseline imitation assessment. After a slight modification in sign language training procedures was implemented to eliminate Carl's prompt dependency, he emitted independent mands more often during sign language training than with picture exchange training. Carl's pre-existing motor imitation skills were better than Jennifer's. He imitated correctly 43% of the attempted motor movements in the pre-baseline imitation assessment.

This study highlights the importance of individual analyses and exploring the possible influence of variables not manipulated during the study. In discussing the study's results, Tincani (2004) noted that

> For learners without hand-motor imitation skills, including many children with autism, PECS training may be more appropriate, at least in terms of initial mand acquisition. Jennifer had weak hand-motor imitation skills prior to intervention and learned picture exchange more rapidly than sign language. For learners who have moderate hand-motor imitation skills, sign language training may be equally, if not more, appropriate. Carl had moderate hand-motor imitation skills prior to intervention and learned sign language more rapidly than picture exchange. (p. 160)

Three-phase Design: Baseline, Comparison, and Participant's Choice

Another three-phase variation of the multielement design entails an initial baseline, a comparison phase in which two or more treatment conditions (one of which may be the baseline control condition) are alternated, and a final "choice" phase in which only the treatment selected by each participant is implemented.

Jowett Hirst, Dozier, and Payne (2016) used this sequence of phases in two experiments assessing (a) the relative effects of the differential reinforcement of alternative behavior (DRA) and response cost (RC) procedures on the on-task behavior of typically developing preschool children and (b) the children's preferences for the procedures.[8] In Experiment I, conducted in the context of small-group activities, both DRA and RC increased on-task behavior for the majority of children and five of six children chose RC more often than DRA. Prior to each session in Experiment II, conducted in the context of individual work tasks (e.g., worksheets with printed letters and shapes for tracing), the experimenter explained the rules and contingencies that would be in effect:

> *Baseline.* "Today you get the white board, and there are no tokens. When we start, you can either work on tracing or play with toys. If you are working (i.e., tracing), nothing will happen. If you are not working, nothing will happen." (p. 338)
>
> *Differential reinforcement of alternative behavior.* "Today you get the green board, and it doesn't have any tokens on it. When we start, you can either work on tracing or play with toys. If you are working, you will get a token; if you are not working, you will not get a token. At the end, you can trade your tokens for prizes and snacks. If you don't have any tokens, you don't get anything." (pp. 338)
>
> *Response cost.* "Today you get the red board, and it has 10 tokens on it. When we start, you can either work on

tracing or play with toys. If you are working, you will keep your tokens; if you are not working, you will lose tokens. At the end,. . . " [same as DRA instructions] (p. 338)

Choice. The experimenter placed the stimuli (i.e., poster and token boards) associated with each type of condition (i.e., baseline, RC, and DRA) near the participant and reminded him or her of the contingencies associated with each set of materials . . . . [T]he experimenter asked the participant to pick (by pointing to or touching a set of materials) which session he or she wanted to do. (pp. 338–339)

On 10 occasions (at intervals ranging from 15 to 45 seconds) during each 5-minute session, except for baseline sessions, the experimenter delivered (DRA) or removed (RC) a token per the condition in effect. Figure 8.17 shows the results for 6 of the 10 children who participated in the multielement comparison of DRA and RC in Experiment II. All children displayed moderate and variable or extremely low levels of on-task behavior in baseline. As in Experiment I, both DRA and RC resulted in roughly equal levels of increased on-task behavior during the comparison phase (Adam was the lone exception), and those levels were maintained during the choice phase. Two participants selected DRA for each session of the choice phase, two selected RC exclusively, and six switched their selections.

Concurrent Chains (or Schedule) Design

A design in which participants choose between two or more concurrently available treatments is termed a **concurrent schedule** or **concurrent chains design**.[9] Participants are presented with two or more response options; each option is associated with a distinctive discriminative stimulus and leads to a different set of treatment procedures. Hanley, Piazza, Fisher, and Maglieri (2005) used a concurrent chains design to assess clients' preference for problem behavior treatments. Participants were two children who had been admitted to an inpatient unit that specialized in treating severe problem behavior. A functional analysis demonstrated that both children engaged in problem behavior (hitting, biting, head butting, throwing objects at people) most often in the attention condition (the therapist provided brief reprimand following each occurrence of problem behavior). The researchers then evaluated (with reversal and multielement designs) the effects of several function-based treatments for each participant. Functional communication training (FCT) was moderately effective in reducing problem behavior for both children, and FCT plus punishment was more effective in reducing problem behavior for both children than FCT alone.

With FCT, each child was trained to emit an alternative response (saying "attention please" or "excuse me" for Betty; handing the therapist a card on which the word "play" was printed for Jay). Emitting the alternative behavior resulted in 20 seconds of attention from the therapist. Occurrences of problem behavior were followed by no differential consequence (i.e., extinction). Procedures for FCT plus punishment were identical to FCT except that each occurrence of problem behavior involved "a 30-s hands-down procedure for Jay (the therapist stood behind Jay and held his hands to his sides) and a 30-s hands-down and visual-screen procedure for Betty (the therapist stood behind the child and placed one arm around the child's arms while placing the other hand over the child's eyes)." (Hanley et al., 2005, p. 56).

The researchers then used a concurrent-chains strategy to evaluate each child's relative preference for various treatments. Prior to entering the therapy room during each session of this analysis, each child was presented with three different-colored microswitches, each switch corresponding to one of

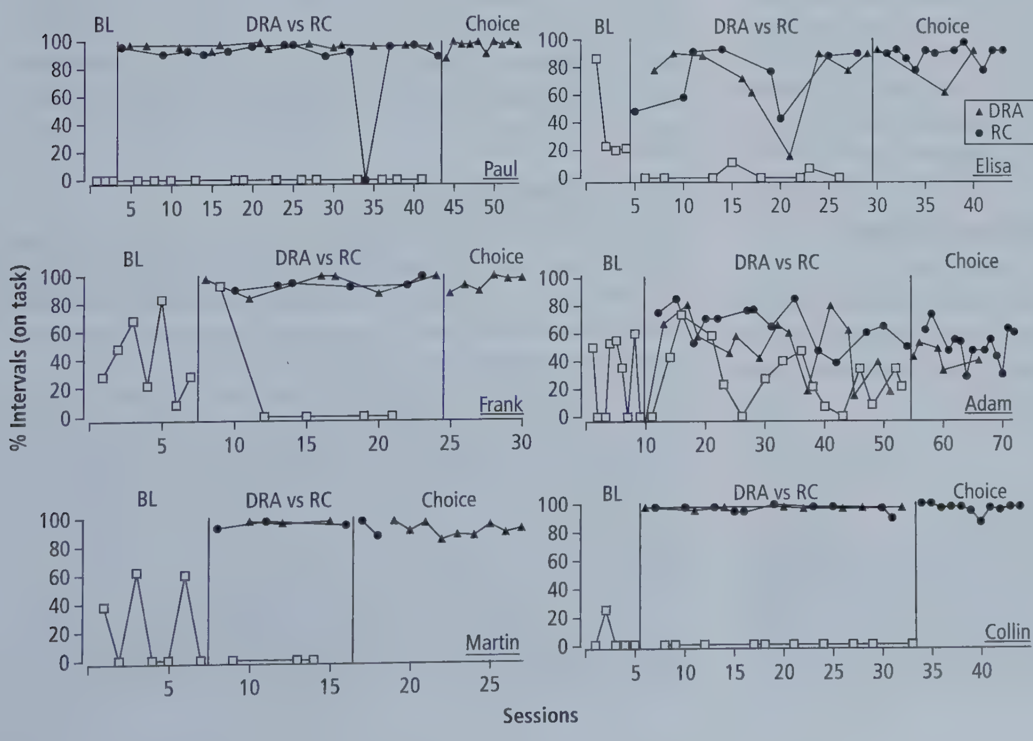

Figure 8.17 Multielement design with an initial baseline and a final participant's choice phase.

"Efficacy of and preference for reinforcement and response cost in token economies" by E. S. Jowett Hirst, C. L. Dozier, and S. W. Payne, 2016, *Journal of Applied Behavior Analysis*, *49*, p. 340. Reproduced with permission of John Wiley & Sons Inc.

three treatment procedures: FCT, FCT with punishment, and punishment only. Pressing one of the switches (the initial links in the chained schedule) resulted in a 2-minute period inside the therapy room (terminal links in the chain) during which the child experienced the contingencies corresponding to the switch he or she had selected. The FCT and FCT plus punishment conditions were carried out in the same manner as the treatment evaluation. When the punishment-only condition was selected, problem behavior resulted in a 30-seconds hands-down procedure for Jay or a 30-seconds hands-down and visual-screen procedure for Betty. Prior to using switch pressing to evaluate treatment preference, each child was prompted to push the different switches and was exposed to the different contingencies associated with each switch (four exposure sessions with Jay, two with Betty).

During treatment preference sessions, after each two-link chain (switch-press followed by 2 minutes of the selected contingencies for problem behavior), the child then exited the therapy room and was repositioned in front of the switches. The procedure was repeated until 20 minutes had elapsed for Jay; or until 10 initial-link responses were recorded for Betty. Hanley and colleagues (2005) described the results of the treatment preference evaluation (see Figure 8.18):

> Jay allocated the majority (79.3%) of his switch presses to the FCT plus punishment intervention. A preference for FCT plus punishment emerged during Betty's evaluation, in that all switch presses were allocated to FCT plus punishment in the final five sessions. These data provide direct evidence that the function-based treatments involving punishment contingencies were more preferred (reinforcing) than similar function-based treatments involving extinction or interventions consisting of punishment alone. (p. 61)

Readers should not view the variations of the multielement design described here as a catalog of possible and appropriate applications of this experimental tactic. In countless other ways, a multielement/alternating treatments tactic can be incorporated within an experimental design employing one or more reversal to baseline phases, multiple baselines, and changing criterion designs (e.g., Cariveau, Kodak, & Campbell, 2016; Coon & Miguel, 2012; Saini, Gregory, Uran, & Fantetti, 2015).

Advantages of the Multielement Design

The multielement design offers numerous advantages for evaluating and comparing two or more independent variables. Most of the benefits cited here were described by Ulman and Sulzer-Azaroff (1975), who first brought the rationale and possibilities of the multielement design to the attention of the applied behavior analysis community.

Treatment Withdrawal Not Required

A major advantage of the alternating treatments design is that it does not require the investigator to withdraw a seemingly effective treatment to demonstrate a functional relation. Reversing behavioral improvements raises ethical issues that can be avoided with the alternating treatments design. Regardless of ethical concerns, however, administrators and teachers may be more likely to accept a multielement design over a reversal design even when one of the alternating treatments is a no-treatment control condition. "It would appear that a return to baseline conditions every other day or every third day is not as disagreeable to a teacher as is first establishing a high level of desirable behavior for a prolonged period, and then reinstating the baseline behaviors" (Ulman & Sulzer-Azaroff, 1975, p. 385).

Allows Rapid Comparison

The experimental comparison of two or more treatments can often be made quickly with the multielement design. The ability of this design to rapidly demonstrate differential effects is a major reason it is the basic experimental tactic used in functional analysis of problem behavior (see Chapter 27).

When the effects of different treatments become apparent early in a multielement design, the investigator can then switch to programming only the most effective treatment. The efficiency of the multielement design can leave a researcher with meaningful data even when an experiment must be terminated early. A reversal or multiple baseline design, in contrast, must be carried through to completion to show a functional relation.

Researchers and practitioners must guard against judging that a functional relation exists between outcomes associated with two or more conditions in a multielement design when no

such relation exists. Such false positives are highly likely when only one or two measures are taken per condition. For example, Kahng and Iwata (1999) found that false positives were obtained more often in brief multielement designs than in multielement designs with three or more sessions in each condition.

Equally important is discovering ineffective treatments. For example, multielement designs enabled researchers to demonstrate that colored overlays did not improve reading fluency of children diagnosed with dyslexia (Freeze Denton & Meindle, 2016); and that weighted vests did not increase appropriate in-seat behaviors of elementary-age students with autism and severe to profound intellectual disabilities (Cox, Gast, Luscre, & Ayers, 2009).

Minimizes Irreversibility Problem

Some behaviors, even though they have been brought about or modified by an intervention, do not return to baseline levels when the intervention is withdrawn and thereby resist analysis with an A-B-A-B design. However, rapidly alternating treatment and no-treatment (baseline) conditions may reveal differences in responding between the two conditions, especially early in an experiment before responding in the no-treatment condition begins to approximate the level of responding in the treatment condition.

Minimizes Sequence Effects

A properly conducted multielement design minimizes the extent to which sequence effects confound the experiment's results. Sequence effects pose a threat to the internal validity of any experiment, but especially to studies involving multiple treatments. The concern over sequence effects can be summed up by this simple question: Would the results have been the same had the sequence of treatments been different? Sequence effects can be extremely difficult to control in experiments using reversal or multiple baseline tactics (see Chapter 9) to compare two or more independent variables because each experimental condition must remain in effect for a fairly long period, thereby producing a specific sequence of events. However, in a multielement design, independent variables can be rapidly alternated in a random fashion that produces no particular sequence. Also, each treatment is in effect for short periods, reducing the likelihood of carryover effects (O'Brien, 1968). The multielement design's ability to minimize sequence makes it a powerful tool for achieving complex behavior analyses.

Accommodates Unstable Data

Determining functional behavior–environment relations in the presence of unstable data presents a serious problem for the applied behavior analyst. Using steady state responding to predict, verify, and replicate behavioral changes is the foundation of experimental reasoning in behavior analysis (Sidman, 1960). However, obtaining stable baseline responding with many socially important behaviors of interest to applied behavior analysts is extremely difficult. Merely providing a subject with repeated opportunities to emit a target response can result in gradually improved performance. Although practice effects are worthy of empirical investigation because of their applied and scientific importance, the unstable baselines they create pose problems for the analysis of intervention variables. The changing levels of task difficulty inherent in moving through a curriculum of progressively more complex material also make obtaining steady state responding for many academic behaviors difficult.

Because the different treatment conditions are alternated rapidly in a multielement design, because each condition is presented many times throughout each time period encompassed by the study, and because no single condition is present for any considerable length of time, it can be presumed that any effects of practice, change in task difficulty, maturation, or other historical variables are equally represented in each treatment condition and therefore will not differentially affect any one condition more or less than the others. For example, even though each of two data paths representing a student's reading performance under two different teaching procedures shows variable and ascending trends that might be due to practice effects and uneven curriculum materials, any consistent separation and vertical distance between the data paths can be attributed to differences in the teaching procedures.

Reveals Generalization of Effects

By alternating various conditions of interest, an experimenter can continually assess the degree of generalization of behavior change from an effective treatment to other conditions of interest. For example, by alternating different therapists in the final phase of their study of pica behavior, Singh and Winton (1985) demonstrated the extent to which the overcorrection treatment was effective when presented by different persons.

Intervention Can Begin Immediately

Although determining the preintervention level of responding is generally preferred, the clinical necessity of immediately attempting to change some behaviors precludes repeated measurement in the absence of intervention. When necessary, a multielement design can begin without an initial baseline phase.

Considering the Appropriateness of the Multielement Design

The advantages of the multielement design are significant. As with any experimental tactic, however, the multielement design presents certain disadvantages and leaves unanswered certain questions that can be addressed only by additional experimentation.

Multiple Treatment Interference

The fundamental feature of the multielement design is the rapid alternation of two or more independent variables irrespective of the behavioral measures obtained under each treatment. Although the rapid alternation minimizes sequence effects and reduces the time required to compare treatments, it raises the important question of whether the effects observed under any of the alternated treatments would be the same if each treatment

were implemented alone. **Multiple treatment interference** refers to the confounding effects of one treatment on a subject's behavior being influenced by the effects of another treatment administered in the same study.

Multiple treatment interference must always be suspected in the multielement design. However, by following the alternating treatments phase with a phase in which only one treatment is in effect, the experimenter can assess the effects of that treatment when administered in isolation.

Unnatural Nature of Rapidly Alternating Treatments

The rapid back-and-forth switching of treatments does not reflect the typical manner in which clinical and educational interventions are applied. From an instructional perspective, rapid switching of treatments can be viewed as artificial and undesirable. In most instances, however, the quick comparison of treatments offered by the multielement design compensates for its contrived nature. The concern of whether participants might suffer detrimental effects from the rapid alternation of conditions is an empirical question that can be determined only by experimentation. Also, it is helpful for practitioners to remember that one purpose of the multielement design is to identify an effective intervention as quickly as possible so that the participant does not have to endure ineffective instructional approaches or treatments that would delay progress toward educational or clinical goals. On balance, the advantages of rapidly switching treatments to identify efficacious interventions will usually outweigh any undesirable effects that such manipulation may cause.

Limited Capacity

Although the multielement design enables an elegant, scientifically sound method for comparing the differential effects of two or more treatments, it is not an open-ended design with which an unlimited number of treatments can be compared. Although multielement designs with up to five conditions have been reported (e.g., Didden, Prinsen, & Sigafoos, 2000), in most situations a maximum of four different conditions (one of which may be a no-treatment control condition) can be compared effectively within a given phase of an alternating treatments design, and in many instances only two different treatments can be accommodated. To separate the effects of each treatment condition from effects that may be caused by aspects of the alternating treatments design, each treatment must be carefully counterbalanced across all potentially relevant aspects of its administration (e.g., time of day, order of presentation, settings, therapists). In many applied settings, the logistics of counterbalancing more than two or three treatments would be overly cumbersome and require too many sessions to complete the experiment. Also, too many competing treatments might hamper the subject's ability to discriminate between treatments, thereby reducing the design's effectiveness.

Selection of Treatments

Theoretically, although a multielement design can be used to compare the effects of any two discrete treatments, in reality the design is more limited. To enhance the probability of discrimination between conditions, and thereby the possibility of obtaining reliable, measurable differences in behavior, the treatments should embody significant differences from one to the other. For example, an investigator using a multielement design to study the effects of group size on students' academic performance during instruction might include conditions of 4-student, 10-student, and 20-student groups. Alternating conditions of 6-, 7-, and 8-student groups is less likely to reveal differences between group size and performance. However, a treatment condition should not be selected for inclusion in a multielement design only because it might yield a data path easily differentiated from that of another condition.

The *applied* in applied behavior analysis encompasses the nature of treatment conditions as well as the nature of behaviors investigated (Wolf, 1978). An important consideration in selecting treatment conditions should be the extent to which they represent current practices or practices that could conceivably be implemented. Although an experiment comparing the effects of 5, 10, and 20 minutes of math homework per school night on math achievement might be useful, a study comparing the effects of 5 minutes, 10 minutes, and 3 hours of math homework per night would not be. Even if such a study found 3 hours of nightly math homework effective in raising students' achievement in math, few teachers, parents, administrators, or students would carry out a program of 3 hours of nightly homework for a single content area.

Another consideration is that some interventions may not produce socially significant behavior change unless and until they have been implemented consistently for a continuous period of time.

> When a multielement baseline design is employed, overlapping data do not necessarily rule out the possible efficacy of an experimental procedure. The session-by-session alternation of conditions might obscure effects that could be observed if the same condition was presented during several consecutive sessions. It is therefore possible that a given treatment may prove to be effective with a reversal or multiple baseline design, but not with a multielement baseline design. (Ulman & Sulzer-Azaroff, 1975, p. 382)

The suspicion that a given treatment may be effective if presented in isolation for an extended period is an empirical question that can be explored through experimentation. At one level, if extended application of a single treatment results in behavioral improvement, the practitioner might be satisfied, and no further action would be needed. However, the practitioner-researcher who is interested in determining experimental control might return to a multielement design and compare the performance of the single treatment with that of another intervention.

SUMMARY

Reversal Design

1. The reversal tactic (A-B-A) entails repeated measures of behavior in a given setting during three consecutive phases: (a) baseline (independent variable absent), (b) treatment (independent variable present), and (c) return to baseline (independent variable absent).
2. Reintroducing the independent variable in the form of an A-B-A-B design strengthens the reversal design tremendously. The A-B-A-B design is the most straightforward and generally most powerful intrasubject design for demonstrating functional relations.

Variations of the A-B-A-B Design

3. Extending the A-B-A-B design with repeated reversals may provide a more convincing demonstration of a functional relation than a design with one reversal.
4. The B-A-B reversal design can be used with target behaviors for which an initial baseline phase is inappropriate or not possible for ethical or practical reasons.
5. Multiple treatment reversal designs (e.g., A-B-A-B-C-B-C, A-B-C-A-C-B-C) use the reversal tactic to compare the effects of two or more experimental conditions to baseline and/or to one another.
6. Multiple treatment reversal designs are particularly susceptible to confounding by sequence effects.
7. The noncontingent reinforcement (NCR) reversal technique enables the isolation and analysis of the contingent aspect of reinforcement.
8. Reversal techniques incorporating differential reinforcement control conditions (DRO and DRI/DRA) can also be used to analyze the effects of contingent reinforcement.

Considering the Appropriateness of the Reversal Design

9. Experimental designs featuring the reversal tactic are ineffective in evaluating the effects of treatment variables that, by their very nature, cannot be withdrawn once presented (e.g., instruction, modeling).
10. Once changed during treatment, some behaviors will not reverse to baseline levels when the independent variable has been withdrawn. Such behavioral irreversibility precludes effective use of the reversal design.
11. Withdrawing a seemingly effective treatment variable to provide scientific verification of its function in changing behavior may raise legitimate social, educational, and ethical concerns.
12. Brief reversal phases, sometimes even one-session baseline probes, may be sufficient to demonstrate believable experimental control.

Multielement Design

13. The multielement design (also called alternating treatments design) compares two or more treatments (i.e., independent variables) while their effects on the target behavior (i.e., dependent variable) are measured.
14. In a multielement design, each successive data point for a specific treatment plays three roles: (a) a basis for the *prediction* of future levels of responding under that treatment, (b) potential *verification* of the previous prediction of performance under that treatment, and (c) the opportunity for *replication* of previous effects produced by that treatment.
15. Experimental control is demonstrated in a multielement design when the data paths for two different treatments show little or no overlap.
16. The extent of differential effects produced by two treatments is determined by the vertical distance between their respective data paths and quantified by the vertical axis scale.

Variations of the Multielement Design

17. Common variations of the multielement (alternating treatments) design include the following:
    - Single-phase design alternating two or more conditions (one of which may be a no-treatment control condition)
    - Two-phase design: initial baseline and comparison phase
    - Three-phase design: initial baseline, alternating treatments, and best treatment only
    - Three-phase design: initial baseline, alternating treatments, and participant's choice
    - Concurrent chains (or schedule) design

Advantages of the Multielement Design

18. Advantages of the multielement (alternating treatments) design include the following:
    - Does not require treatment withdrawal.
    - Rapidly compares the relative effectiveness of treatments.

- Minimizes the irreversibility problem.
- Minimizes sequence effects.
- Can be used with unstable data patterns.
- Can assess generalization of effects.
- Intervention can begin immediately.

Considering the Appropriateness of the Multielement Design

19. Multielement designs are susceptible to multiple treatment interference. However, by following the alternating treatments phase with a phase in which only one treatment is administered, the experimenter can assess the effects of that treatment in isolation.
20. The rapid back-and-forth switching of treatment conditions does not typify clinical or education practice and may be viewed as artificial and undesirable.
21. An alternating treatments phase is usually limited to a maximum of four different treatment conditions.
22. Multielement designs are most effective in revealing the differential effects of treatment conditions that differ significantly from one another.
23. Multielement designs are not effective for assessing the effects of independent variables that change behavior only when implemented over a continuous period of time.

KEY TERMS

A-B-A design
A-B-A-B design
adapted alternating treatments design
alternating treatments design
B-A-B design
concurrent chains (schedule) design
DRI/DRA reversal technique
DRO reversal technique
irreversibility
multielement design
multiple treatment interference
multiple treatment reversal design
noncontingent reinforcement (NCR) reversal technique
reversal design
sequence effects
withdrawal design

MULTIPLE-CHOICE QUESTIONS

1. All things being equal, an experiment that incorporates ________ reversal(s) presents a more convincing and compelling demonstration of experimental control than an experiment with _______ reversal(s).
   - **a.** Multiple, one
   - **b.** One, four
   - **c.** Several, multiple
   - **d.** Five, seven

   Hint: (See "Reversal Design")
2. Which of the following is considered to be a reason for using a B-A-B design instead of an A-B-A-B design?
   - **a.** Irreversibility
   - **b.** Unlimited time in which to demonstrate practical and social significance
   - **c.** Sequence effects
   - **d.** When treatment is already in place

   Hint: (See "Reversal Design")
3. This design is considered the most "straightforward" and generally the most powerful within-subject design for demonstrating a functional relationship.
   - **a.** Alternating treatments design
   - **b.** Multiple baseline design
   - **c.** AB design
   - **d.** A-B-A-B reversal design

   Hint: (See "Reversal Design")
4. For most investigations, it is suggested that you only change _______ variable(s) at a time.
   - **a.** One
   - **b.** Two
   - **c.** Three
   - **d.** Four

   Hint: (See "Reversal Design")
5. _________ control conditions might be used as a variation of the reversal design when it is not possible or when it is deemed inappropriate to completely eliminate an event or activity as a reinforcer.
   - **a.** Difference
   - **b.** Noncontingent reinforcement
   - **c.** Sequenced
   - **d.** Temporal

   Hint: (See "Reversal Design")

6. This experimental tactic entails repeated measures of behavior in a given setting that require at least three consecutive phases: baseline, introduction of the independent variable, and a return to baseline.
   - a. Alternating treatments design
   - b. Multiple baseline design
   - c. Repeated multiple measures design
   - d. ABA reversal design

   Hint: (See "Reversal Design")

7. ________ means that a level of behavior observed in an earlier phase cannot be reproduced even though experimental conditions return to preintervention conditions.
   - a. Sequence effects
   - b. Irreversibility
   - c. Order effects
   - d. Reliability

   Hint: (See "Reversal Design")

8. This design is predicated on the behavioral principle of stimulus discrimination and allows for the comparison of two or more different treatments.
   - a. Multiple baseline design
   - b. Alternating treatments design
   - c. A-B-A-B reversal design
   - d. Single-subject design

   Hint: (See "Multielement Design")

9. An investigator who ________ turns the target behavior on and off by presenting and withdrawing a specific variable makes a clear and convincing demonstration of experimental control.
   - a. Conditionally
   - b. Haphazardly
   - c. Covertly
   - d. Reliably

   Hint: (See "Reversal Design")

10. This term is used to describe the effects on a subject's behavior in a given condition that may be a result of the subject's experience with a prior condition.
    - a. Sequence
    - b. Irreversible
    - c. Temporal
    - d. Variable

    Hint: (See "Multielement Design")

ESSAY-TYPE QUESTIONS

1. Describe the experimental tactic shown in the figure. Discuss how the design allows for the detection of a functional relationship between the dependent and independent variables of interest.

   Hint: (See "Reversal Design")

2. You are interested in comparing the effects of two distinctly different schedules of reinforcement on students' academic engagement. Select an appropriate experimental tactic and describe its implementation.

   Hint: (See "Multielement Design")

3. State one disadvantage in the use of a reversal design and in the use of an alternating treatments design in applied settings.

   Hint: (See "Reversal Design" and "Multielement Design")

4. Summarize how the reversal design incorporates the elements of baseline logic (prediction, verification, and replication).

   Hint: (See "Multielement Design")

5. State one ethical consideration in the use of the reversal design as an experimental tactic in an applied school setting.

   Hint: (See "Multielement Design")

NOTES

1. Some authors use the term **withdrawal design** to describe experiments based on an A-B-A-B analysis and reserve the term *reversal design* for studies in which the behavioral focus of the treatment variable is reversed (or switched to another behavior), as in the DRO and DRI/DRA reversal techniques described later in this chapter. However, *reversal design*, as behavior analysts most often use the term, encompasses both withdrawals and reversals of the independent variable, signifying the investigator's attempt to demonstrate "behavioral reversibility" (Baer, Wolf, & Risley, 1968; Thompson & Iwata, 2005). Also, *withdrawal design* is sometimes used to describe an experiment in which the treatment variables are sequentially or partially withdrawn after their effects have been analyzed in an effort to promote maintenance of the target behavior (Rusch & Kazdin, 1981).
2. Risley (1997, 2005) credits Montrose Wolf with designing the first experiments using the reversal and multiple baseline designs. "The research methods that Wolf pioneered in these studies were groundbreaking. That methodology came to define applied behavior analysis" (pp. 280–281).
3. Strictly speaking, using NCR as an experimental control technique to demonstrate that the contingent application of reinforcement is requisite to its effectiveness is not a separate variation of the A-B-A reversal design. Technically, the NCR reversal technique, as well as the differential reinforcement of other behavior (DRO) and differential reinforcement of incompatible behavior (DRI)/differential reinforcement of alternative behavior (DRA) reversal techniques described next, is a multiple treatment design. For example, the Baer and Wolf (1970a) study of social reinforcement shown in Figure 8.6 used an A-B-C-B-C design, with B representing the NCR conditions and C representing the contingent reinforcement conditions.
4. The extent to which the increased diversity of the children's block building can be attributed to the attention and praise ("That's nice") or the descriptive feedback (". . . that's different") in the teacher's comments cannot be determined from this study because social attention and descriptive feedback were delivered as a package.
5. Additional manipulations in the form of the partial or sequential withdrawal of intervention components are made when it is necessary or desirable for the behavior to continue at its improved level in the absence of the complete intervention (cf., Rusch & Kazdin, 1981).
6. The mand is one of six types of elementary verbal operants identified by Skinner (1957). Chapter 18 describes Skinner's analysis of verbal behavior and its importance to applied behavior analysis.
7. Stimulus preference assessment procedures are described in Chapter 11.
8. DRA and response cost are described in Chapters 25 and 15, respectively.
9. Some published studies using a concurrent schedule design are described by their authors as using a *simultaneous treatment design*. Barlow and Hayes (1979), who introduced the term *simultaneous schedule design*, could find only one true example in the applied literature: a study by Browning (1967) in which three techniques for reducing the bragging of a 10-year-old boy were compared.

CHAPTER 9

Multiple Baseline and Changing Criterion Designs

LEARNING OBJECTIVES

- Describe the multiple baseline technique.
- Describe the differences between types of multiple baseline designs.
- Describe the changing criterion design technique.
- Explain how to systematically manipulate independent variables to analyze effects on treatment.
- Identify and explain the practical and ethical considerations in using various experimental designs.

This chapter describes two additional experimental tactics for analyzing behavior–environment relations: the multiple baseline design and the changing criterion design. In a multiple baseline design, after collecting initial baseline data simultaneously across two or more behaviors, settings, or people, the behavior analyst then applies the treatment variable sequentially across these behaviors, settings, or people and notes the effects. The changing criterion design is used to analyze improvements in behavior as a function of stepwise, incremental criterion changes in the level of responding required for reinforcement. In both designs, experimental control and a functional relation are demonstrated when the behaviors change from a steady state baseline to a new steady state after the introduction of the independent variable is applied, or a new criterion established.

MULTIPLE BASELINE DESIGN

The multiple baseline design is the most widely used experimental design for evaluating treatment effects in applied behavior analysis. It is a highly flexible tactic that enables researchers and practitioners to analyze the effects of an independent variable across multiple behaviors, settings, and/or subjects without having to withdraw the treatment variable to verify that the improvements in behavior were a direct result of the application of the treatment. As you recall from Chapter 8, the reversal design by its very nature requires that the independent variable be withdrawn to verify the prediction established in baseline. This is not so with the multiple baseline design.

Operation and Logic of the Multiple Baseline Design

Baer, Wolf, and Risley (1968) first described the **multiple baseline design** in the applied behavior analysis literature. They presented the multiple baseline design as an alternative to the reversal design for two situations: (a) when the target behavior is likely to be irreversible (e.g., once changed by the treatment variable, the behavior comes into contact with naturally existing contingencies of reinforcement or other sources of control that maintain the new level of performance) or (b) when it is undesirable, impractical, or unethical to withdraw a seemingly effective treatment condition. Additionally, some interventions, such as training or instructions, cannot be withdrawn. Terminating an ongoing instructional program does not re-establish conditions that existed prior to training; the participant "has been taught."

Figure 9.1 illustrates Baer and colleagues' explanation of the basic operation of the multiple baseline design.

> In the multiple baseline technique, a number of responses are identified and measured over time to provide baselines against which changes can be evaluated. With these baselines established, the experimenter then applies an experimental variable to one of the behaviors, produces a change in it, and perhaps notes little or no change in the other baselines. If so, rather than reversing the just-produced change, he instead applies the experimental variable to one of the other, as yet unchanged, responses. If it changes at that point, evidence is accruing that the experimental variable is indeed effective, and that the prior change was not simply a matter of coincidence. The variable then may be applied to still another response, and so on. The experimenter is attempting to show that he has a reliable experimental variable, in that each behavior changes maximally only when the experimental variable is applied to it. (p. 94)

The multiple baseline design takes three primary forms:

- The multiple baseline across behaviors design, consisting of two or more different behaviors of the same subject.
- The multiple baseline across settings design, consisting of the same behavior of the same subject in two or more different settings, situations, or time periods.
- The multiple baseline across subjects design, consisting of the same behavior of two or more different participants (or groups).

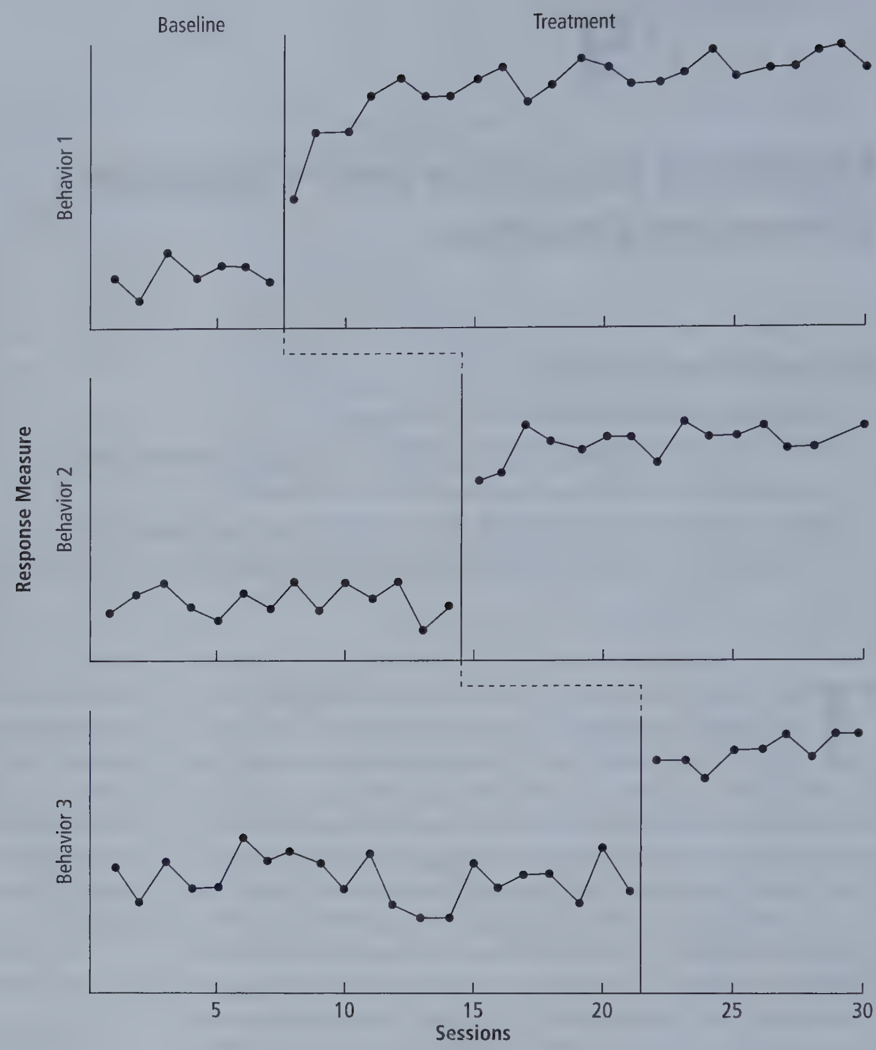

Figure 9.1 Graphic prototype of a multiple baseline design.

Although only one of the multiple baseline design's basic forms is called an "across behaviors" design, all multiple baseline designs involve the time-lagged application of a treatment variable across technically different (meaning independent) behaviors. That is, in the multiple baseline across settings design, even though the subject's performance of the same target behavior is measured in two or more settings, each behavior–setting combination is conceptualized and treated as a different behavior for analysis. Similarly, in a multiple baseline across subjects design, each subject–behavior combination functions as a different behavior in the operation of the design.

Figure 9.2 shows the same data set displayed in Figure 9.1, with the addition of data points representing predicted measures if baseline conditions were not changed and shaded areas illustrating how the three elements of baseline logic—prediction, verification, and replication—are operationalized in the multiple baseline design.[1] When stable baseline responding has been achieved for Behavior 1, a *prediction* is made that if the environment were held constant, continued measurement would reveal similar levels of responding. When the researcher's confidence in such a prediction is justifiably high, the independent variable is applied to Behavior 1. The open data points in the treatment phase for Behavior 1 represent the predicted level of responding. The solid data points show the actual measures obtained for Behavior 1 during the treatment condition. These data show a discrepancy with the predicted level of responding if no changes had been made in the environment, thereby suggesting that the treatment may be responsible for the change in behavior. The data collected for Behavior 1 in a multiple baseline design serve the same functions as the data collected during the first two phases of an A-B-A-B reversal design.

Continued baseline measures of the other behaviors in the experiment offer the possibility of verifying the prediction made for Behavior 1. In a multiple baseline design, *verification* of a predicted level of responding for one behavior (or tier) is obtained if little or no change is observed in the data paths of the behaviors (tiers) that are still exposed to the conditions under which the prediction was made. In Figure 9.2 those portions of the baseline condition data paths for Behaviors 2 and 3 within the shaded boxes verify the prediction for Behavior 1. At this point in the experiment, two inferences can be made: (a) The prediction that Behavior 1 would not change in a constant environment is valid because the environment was held constant for Behaviors 2 and 3 and their levels of responding remained unchanged; and (b) the observed changes in Behavior 1 were brought about by the independent variable because only Behavior 1 was exposed to the independent variable and only Behavior 1 changed.

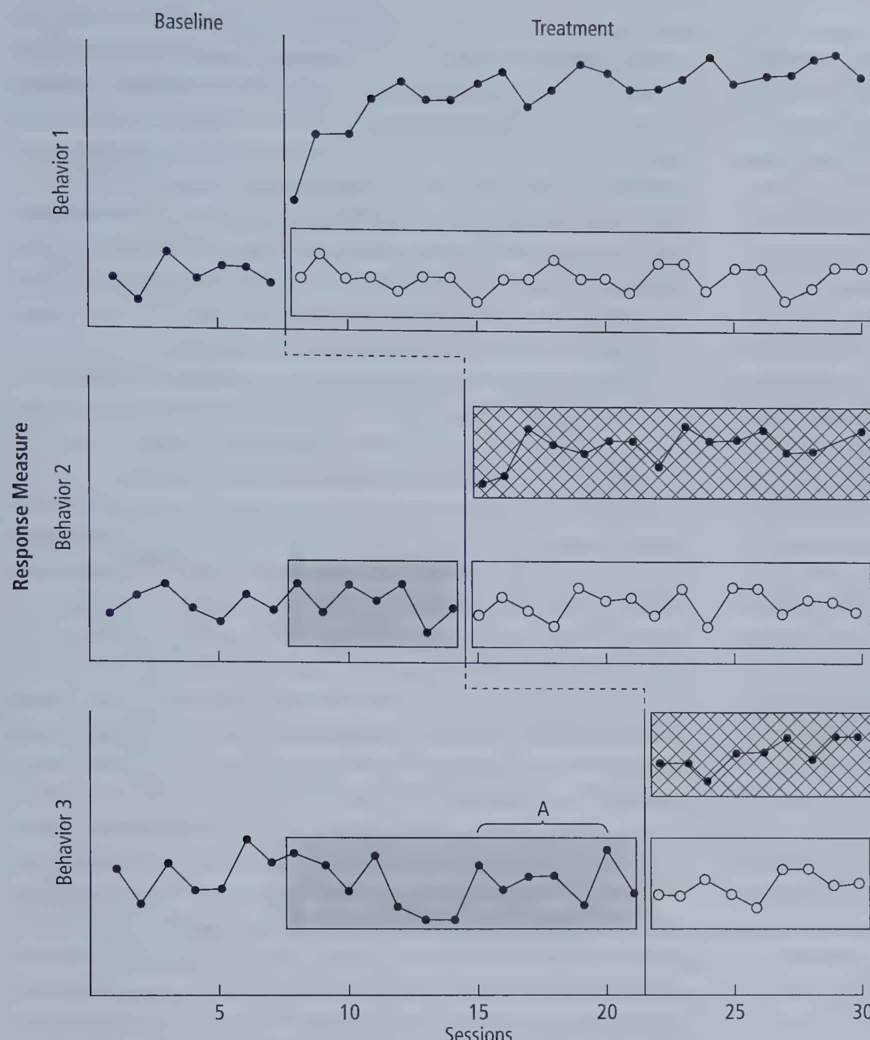

Figure 9.2 Graphic prototype of a multiple baseline design with shading added to show elements of baseline logic. Open data points represent predicted measures if baseline conditions were unchanged. Baseline data points for Behaviors 2 and 3 within shaded areas verify the prediction made for Behavior 1. Behavior 3 baseline data within Bracket A verify the prediction made for Behavior 2. Data obtained during the treatment condition for Behaviors 2 and 3 (cross-hatched shading) provide replications of the experimental effect.

In a multiple baseline design, the independent variable's function in changing a given behavior is inferred by the lack of change in untreated behaviors. However, verification of function is not demonstrated directly as it is with the reversal design, thereby making the multiple baseline design an inherently weaker tactic (i.e., less convincing from the perspective of experimental control) for revealing a functional relation between the independent variable and a target behavior. However, the multiple baseline design compensates somewhat for this weakness by providing the opportunity to verify or refute a series of similar predictions. Not only is the prediction for Behavior 1 in Figure 9.2 verified by continued stable baselines for Behaviors 2 and 3, but the bracketed portion of the baseline data for Behavior 3 also serves as verification of the prediction made for Behavior 2.

When the level of responding for Behavior 1 under the treatment condition has stabilized or reached a predetermined performance criterion, the independent variable is then applied to Behavior 2. If Behavior 2 changes in a manner similar to the changes observed for Behavior 1, *replication* of the independent variable's effect has been achieved (shown by the data path shaded with cross-hatching). After Behavior 2 has stabilized or reached a predetermined performance criterion, the independent variable is applied to Behavior 3 to see whether the effect will be replicated. The independent variable may be applied to additional behaviors in a similar manner until a convincing demonstration of the functional relation has been established (or rejected) and all of the behaviors targeted for improvement have received treatment.

As with verification, replication of the independent variable's specific effect on each behavior in a multiple baseline design is not manipulated directly. Instead, the generality of the independent variable's effect across the behaviors constituting the experiment is demonstrated by applying it to a series of behaviors. Assuming accurate measurement and proper experimental control of relevant variables (i.e., the only environmental factor that changes during the course of the experiment should be the presence—or absence—of the independent variable), each time a behavior changes when, and only when, the independent variable is introduced, confidence in the existence of a functional relation increases.

How many different behaviors, settings, or subjects must a multiple baseline design include to provide a believable demonstration of a functional relation? Baer, Wolf, and Risley (1968) suggested that the number of replications needed in any design is ultimately a matter to be decided by the consumers of the research. In this sense, an experiment using a multiple baseline design must contain the minimum number of replications necessary to convince those who will be asked to respond to the experiment and to the researcher's claims (e.g., teachers, administrators, parents, funding sources, journal editors). A two-tier

multiple baseline design is a complete experiment and can provide strong support for the effectiveness of the independent variable (e.g., Grossi & Heward, 1998 [see Figure 29.3]; Harding, Wacker, Berg, Rick, & Lee, 2004; Lindberg, Iwata, Roscoe, Worsdell, & Hanley, 2003 [see Figure 26.2]; McCord, Iwata, Galensky, Ellingson, & Thomson, 2001 [see Figure 6.6]; May, Downs, Marchant, & Dymond, 2016; Newstrom, McLaughlin, & Sweeney, 1999 [see Figure 28.13]; Pennington & McComas, 2017; Test, Spooner, Keul, & Grossi, 1990 [see Figure 23.10]). McClannahan, McGee, MacDuff, and Krantz (1990) conducted a multiple baseline design study in which the independent variable was sequentially implemented in an eight-tier design across 12 participants. Multiple baseline designs of three to five tiers are most common. When the effects of the independent variable are substantial and reliably replicated, a three- or four-tier multiple baseline design provides a convincing demonstration of experimental effect. Suffice it to say that the more replications one conducts, the more convincing the demonstration will be.

Some of the earliest examples of the multiple baseline design in the applied behavior analysis literature were studies by Risley and Hart (1968); Barrish, Saunders, and Wolf (1969); Barton, Guess, Garcia, and Baer (1970); Panyan, Boozer, and Morris (1970); and Schwarz and Hawkins (1970). Some of the pioneering applications of the multiple baseline technique are not readily apparent with casual examination: The authors may not have identified the experimental design as a multiple baseline design (e.g., Schwarz & Hawkins, 1970), and/or the now-common practice of stacking the tiers of a multiple baseline design one on the other so that all of the data can be displayed graphically in the same figure was not always used (e.g., Maloney & Hopkins, 1973; McAllister, Stachowiak, Baer, & Conderman, 1969; Schwarz & Hawkins, 1970).

In 1970, Vance Hall, Connie Cristler, Sharon Cranston, and Bonnie Tucker published a paper that described three experiments, each an example of one of the three basic forms of the multiple baseline design: across behaviors, across settings, and across subjects. Hall and colleagues' paper was important not only because it provided excellent illustrations that today still serve as models of the multiple baseline design, but also because the studies were carried out by teachers and parents, indicating that practitioners "can carry out important and significant studies in natural settings using resources available to them" (p. 255).

Multiple Baseline Across Behaviors Design

The **multiple baseline across behaviors design** begins with the concurrent measurement of two or more behaviors of each participant in the study. After steady state responding has been obtained under baseline conditions, the investigator applies the independent variable to one of the behaviors and maintains baseline conditions for the other behavior(s). When steady state or criterion-level performance has been reached for the first behavior, the independent variable is applied to the next behavior, and so on (e.g., Davenport, Alber-Morgan, Clancy, & Kranak, 2017; Downs, Miltenberger, Biedronski, & Witherspoon 2015; Gena, Krantz, McClannahan, & Poulson, 1996; Harding et al., 2004; Higgins, Williams, & McLaughlin, 2001 [see Figure 28.1]).

Ward and Carnes (2002) used a multiple baseline across behaviors design to evaluate the effects of self-set goals and public posting on the execution of three skills by five linebackers on a college football team: (a) *reads*, in which the linebacker positions himself to cover a specified area on the field on a pass play or from the line of scrimmage on a run; (b) *drops*, in which the linebacker moves to the correct position depending on the offensive team's alignment; and (c) *tackles*. A video camera recorded the players' movements during all practice sessions and games. Data were collected for the first 10 opportunities each player had with each skill. Reads and drops were recorded as correct if the player moved to the zone identified in the coaches' playbook; tackles were scored as correct if the offensive ball carrier was stopped.

Following baseline, each player met with one of the researchers, who described the player's mean baseline performance for a given skill. Players were asked to set a goal for their performances during practice sessions; no goals were set for games. The correct performances during baseline for all five players ranged from 60 to 80%, and all players set goals of 90% correct performance. The players were informed that their performance in each day's practice would be posted on a chart prior to the next practice session. A *Y* (yes) or an *N* (no) was placed next to each player's name to indicate whether he had met his goal. A player's performance was posted on the chart only for the skill(s) in intervention. The chart was mounted on a wall in the locker room where all players on the team could see it. The head coach explained the purpose of the chart to other players on the team. Players' performances during games were not posted on the chart.

The results for one of the players, John, are shown in Figure 9.3. John met or exceeded his goal of 90% correct performance during all practices for each of the three skills. Additionally, his improved performance generalized to games. The same pattern of results was obtained for each of the other four players in the study, illustrating that the multiple baseline across behaviors design is a single-subject experimental strategy in which each subject serves as his own control. Each player constituted a complete experiment, replicated in this case with four other participants.

Multiple Baseline Across Settings Design

In the **multiple baseline across settings design**, a single behavior of a person (or group) is targeted in two or more different settings or conditions (e.g., locations, times of day). After stable responding has been demonstrated under baseline conditions, the independent variable is introduced in one of the settings while baseline conditions remain in effect in the other settings. When maximum behavior change or criterion-level performance has been achieved in the first setting, the independent variable is applied in the second setting, and so on.

Roane, Kelly, and Fisher (2003) employed a multiple baseline across settings design to evaluate the effects of a treatment designed to reduce the rate at which an 8-year-old boy put inedible objects in his mouth. Jason, who had been diagnosed with autism, cerebral palsy, and moderate intellectual disabilities, had a history of putting objects such as toys, cloth, paper, tree bark, plants, and dirt into his mouth. Data on Jason's mouthing were obtained concurrently in a classroom, a playroom, and outdoors—three settings that contained a variety of inedible objects and where caretakers had reported Jason's mouthing to be problematic. Observers in each setting unobtrusively tallied the number of times Jason inserted an inedible object past the

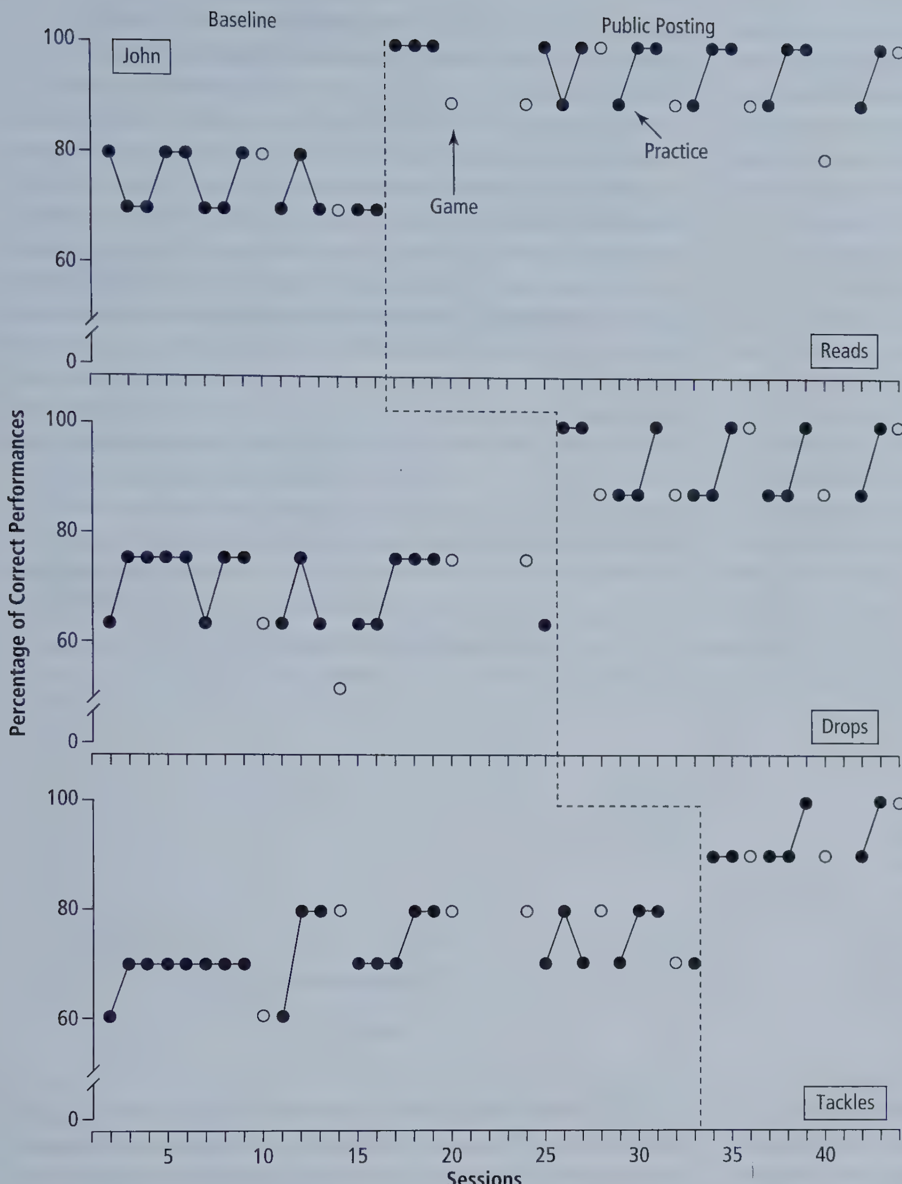

Figure 9.3 A multiple baseline across behaviors design showing percentage of correct reads, drops, and tackles by a college football player during practices and games.

Based on "Effects of Posting Self-Set Goals on Collegiate Football Players' Skill Execution During Practice and Games" by P. Ward and M. Carnes, 2002, *Journal of Applied Behavior Analysis, 35*, p. 5. Copyright 2002 by the Society for the Experimental Analysis of Behavior, Inc.

plane of his lips during 10-minute sessions. The researchers reported that Jason's object mouthing usually consisted of a series of discrete episodes, rather than an extended, continuous event, and that he often placed multiple objects (inedible objects and food) in his mouth simultaneously.

Roane and colleagues (2003) described the baseline and treatment conditions as follows:

> The baseline condition was developed based on the functional analysis results, which showed that mouthing was maintained by automatic reinforcement and occurred independent of social consequences. During baseline, a therapist was present (approximately 1.5 to 3 m from Jason), but all occurrences of mouthing were ignored (i.e., no social consequences were arranged for mouthing, and Jason was allowed to place items in his mouth). No food items were available during baseline. The treatment condition was identical to baseline except that Jason had continuous access to foods that had been previously identified to compete with the occurrence of object mouthing: chewing gum, marshmallows, and hard candy. Jason wore a fanny pack containing these items around his waist. (pp. 580–581)[2]

Figure 9.4 shows the staggered treatment sequence and results in each setting. During baseline, Jason mouthed objects at mean rates of 0.9, 1.1, and 1.2 responses per minute in the classroom, a playroom, and outdoor settings, respectively. Introduction of the fanny pack with food in each setting produced an immediate drop to a zero or near zero rate of mouthing. During treatment, Jason put items of food from the fanny pack into his mouth at mean rates of 0.01, 0.01, and 0.07 responses per minute in the classroom, a playroom, and outdoor settings, respectively. The multiple baseline across settings design revealed a functional relation between the treatment and a marked reduction in the frequency of Jason's object mouthing. No measures obtained during the treatment condition were as high as the lowest measures in baseline. During 22 of 27 treatment sessions across the three settings, Jason put no inedible objects in his mouth.

As was done in the Roane and colleagues' (2003) study, data for the different tiers in a multiple baseline across settings

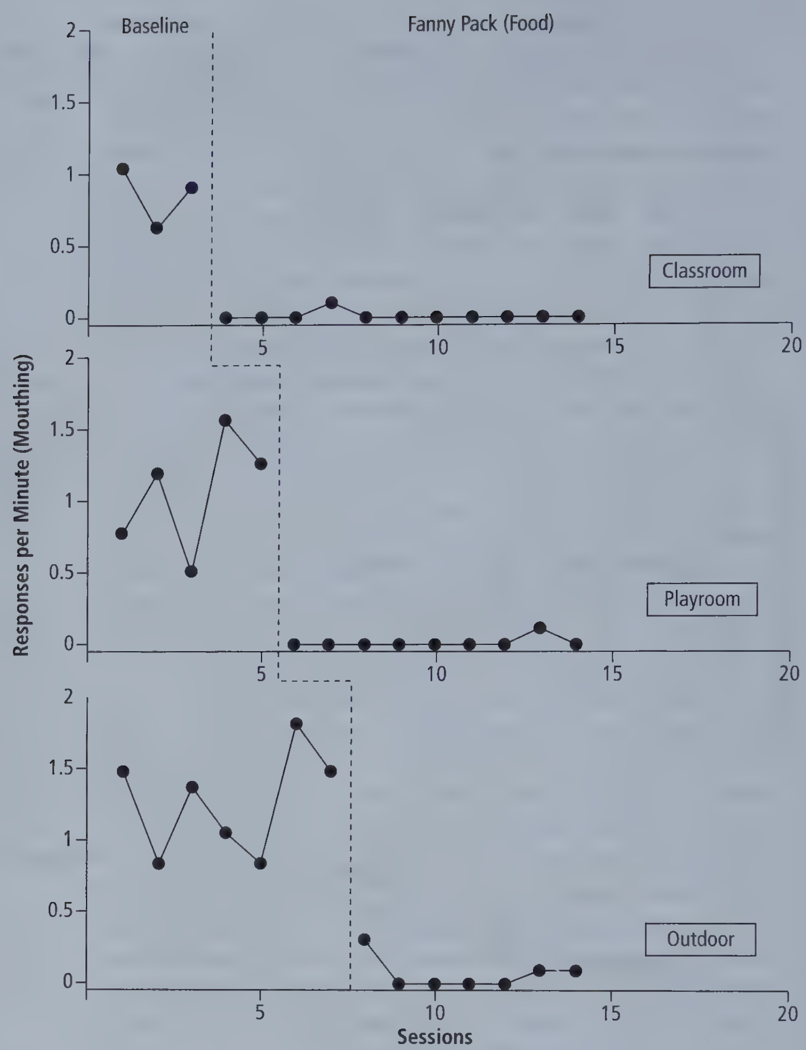

Figure 9.4 A multiple baseline across settings design showing the number of object mouthing responses per minute during baseline and treatment conditions.

Based on "The Effects of Noncontingent Access to Food on the Rate of Object Mouthing across Three Settings" by H. S. Roane, M. L. Kelly, and W. W. Fisher, 2003, *Journal of Applied Behavior Analysis, 36*, p. 581. Copyright 2003 by the Society for the Experimental Analysis of Behavior, Inc.

design are typically obtained in different physical environments (e.g., Cushing & Kennedy, 1997; Dalton, Martella, & Marchand-Martella, 1999). However, the different "settings" in a multiple baseline across settings design may exist in the same physical location and be differentiated from one another by different contingencies in effect, the presence or absence of certain people, and/or different times of the day. For example, in a study by Parker and colleagues (1984), the presence or absence of other people in the training room constituted the different settings (environments) in which the effects of the independent variable were evaluated. The attention, demand, and no-attention conditions (i.e., contingencies in effect) defined the different settings in a multiple baseline design study by Kennedy, Meyer, Knowles, and Shukla (2000; see Figure 6.4). The afternoon and the morning portions of the school day functioned as different settings in the multiple baseline across settings design used by Dunlap, Kern-Dunlap, Clarke, and Robbins (1991) to analyze the effects of curricular revisions on a student's disruptive and off-task behaviors.

In some studies using a multiple baseline across settings design, the participants are varied, changing, and perhaps even unknown to the researchers. For example, Van Houten and Malenfant (2004) used a multiple baseline design across two crosswalks on busy streets to evaluate the effects of an intensive driver enforcement program on the percentage of drivers yielding to pedestrians and the number of motor vehicle–pedestrian conflicts. Watson (1996) used a multiple baseline design across men's restrooms on a college campus to assess the effectiveness of posting signs in reducing bathroom graffiti.

Multiple Baseline Across Subjects Design

In the **multiple baseline across subjects design**, one target behavior is selected for two or more subjects in the same setting. After steady state responding has been achieved under baseline conditions, the independent variable is applied to one subject while baseline conditions remain in effect for the other subjects. When stable or criterion-level responding has been attained for the first subject, the independent variable is applied to another subject, and so on. The multiple baseline across subjects design is the most widely used of all three forms of the design, in part because practitioners are commonly confronted by multiple clients or students needing to learn the same skill or eliminate the same problem behavior (e.g., Craft, Alber, & Heward, 1998 [see Figure 30.10]; Kahng, Iwata, DeLeon, & Wallace, 2000 [see Figure 26.1]; Killu, Sainato, Davis, Ospelt, & Paul, 1998 [see Figure 26.3]; Kladopoulos & McComas, 2001 [see Figure 6.3]). Sometimes a multiple baseline design is conducted across "groups" of participants (e.g., Dixon & Holcomb, 2000 [see Figure 13.8]; Lewis, Powers, Kelk, & Newcomer, 2002 [see Figure 28.7]; White & Bailey, 1990 [see Figure 15.3]).

Scherrer and Wilder (2008) used a multiple baseline across subjects design to evaluate the effects of training of safe tray carrying by cocktail servers. Participants were three servers chosen randomly from the full-time staff of a bar, whose "managers reported that servers had complained of sore muscles and joints, particularly after a busy shift" (p. 132). The dependent variable was the percentage of eight safe tray-carrying behaviors (e.g., carrying position for amount of weight, finger and thumb positions, wrist position, tray distance from body) performed by each server when carrying trays to customers. During evening shifts, 3 to 4 days per week over the 8-week study, trained observers sitting at tables not assigned to the participants recorded safe tray-carrying behaviors on checklists they concealed. All three servers, when asked at the end of the study if they had been aware of data collectors recording their behavior, said they were unaware of the observers.

The independent variable was a single training session that began with a three-step procedure for each of the eight safe tray-carrying behaviors: (1) The trainer explained the correct position or technique, (2) the trainer modeled the correct position or technique, and (3) the participant described the correct position or technique and then demonstrated it. A series of trials were followed in which the server had to demonstrate each correct position or technique four times. All three participants met the mastery criteria in 30 to 50 minutes.

Figure 9.5 shows the results of the study. During baseline the three participants performed the safe carrying positions and techniques at means of 40% (Sara), 41% (Mike), and 49% (Tanya). Each participant's performance was variable, and no server attained as high as 70% safe performance on any baseline session. Although just three baseline measures were obtained for Sara, the sharp downward trend in the data indicated she should receive safety training first. Safe carrying behaviors by each participant increased immediately after training and remained at high and stable levels for the remainder of the study (means of 96% for Sara, 93% for Mike, and 96% for Tanya).

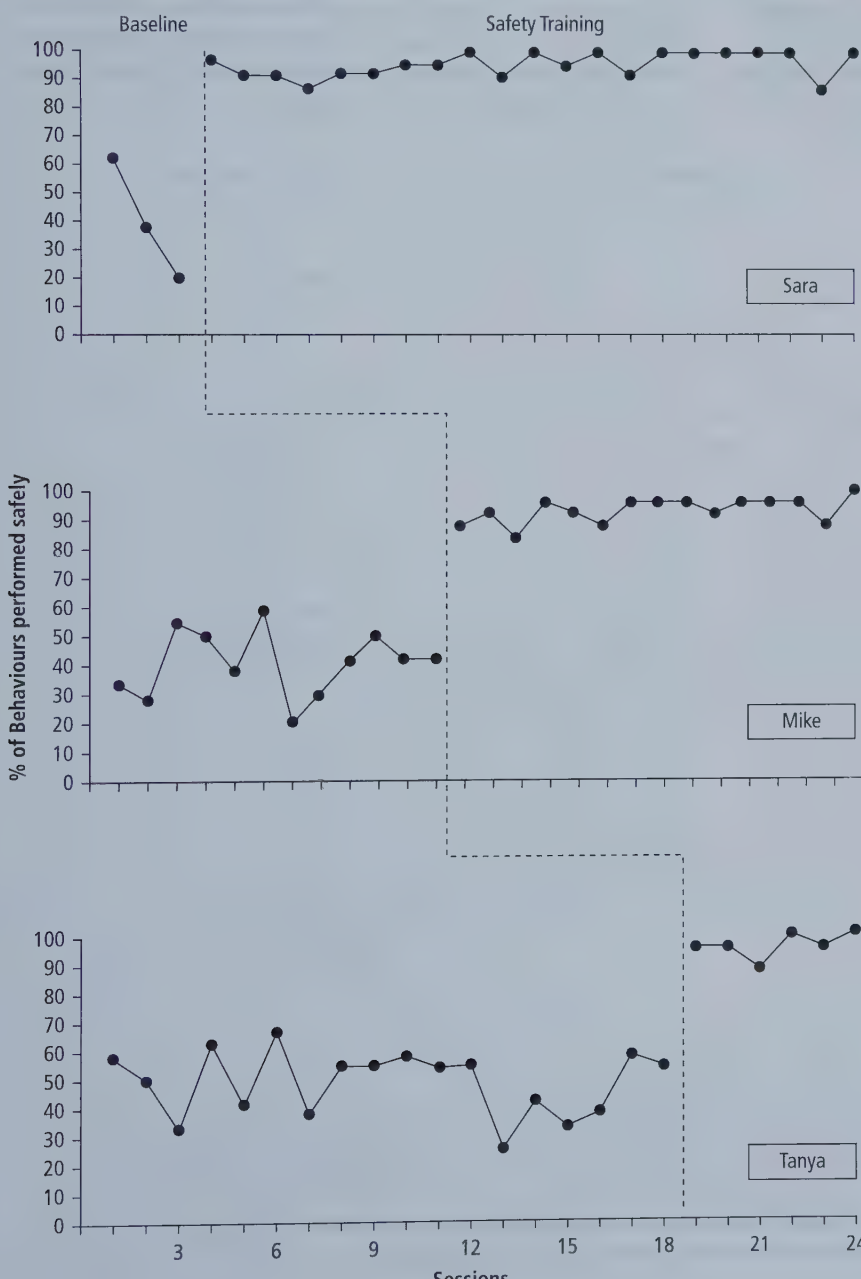

Figure 9.5 A multiple baseline across subjects design showing the percentage of safe tray-carrying positions and techniques by cocktail servers during baseline and post safety training conditions.

From "Training to Increase Safe Tray Carrying Among Cocktail Servers," by M. D. Scherrer and D. A. Wilder, 2008, *Journal of Applied Behavior Analysis, 41*, p. 134. Copyright 2008 by the Society for the Experimental Analysis of Behavior, Inc. Reprinted by permission.

The multiple baseline is not a true single-case design because each subject does not serve as his or her own control. Instead, verification of predictions based on the baseline data for each subject must be inferred from the relatively unchanging baseline measures of other subjects who are still in baseline, and replication of effects must be inferred from changes in the behavior of other subjects when they come into contact with the independent variable. This is both a weakness and a potential advantage of the multiple baseline across subjects design, and is discussed later in the chapter.

Variations of the Multiple Baseline Design

Three variations of the multiple baseline design are the multiple probe design, the delayed multiple baseline design, and the nonconcurrent multiple baseline across participants design.

Multiple Probe Design

The multiple probe design enables the behavior analyst to extend the operation and logic of the multiple baseline tactic to behaviors or situations in which concurrent measurement of all behaviors constituting the design is unnecessary, potentially reactive, impractical, or too costly. The **multiple probe design** was first described by Horner and Baer (1978) as a method for analyzing the relation between an independent variable and the acquisition of successive approximations or task sequence. In contrast to the standard multiple baseline design—in which data are collected simultaneously throughout the baseline phase for each behavior, setting, or subject in the experiment—in the multiple probe design, intermittent measures, or probes, provide the basis for determining whether behavior change has occurred prior to intervention. According to Horner and Baer, when applied to a chain or sequence of related behaviors to be learned, the multiple probe design provides answers to four questions: (a) What is the initial level of performance on each step (behavior) in the sequence? (b) What happens when sequential opportunities to perform each step in the sequence are provided prior to training on that step? (c) What happens to each step as training is applied? and (d) What happens to the performance of untrained steps in the sequence as criterion-level performance is reached on the preceding steps?

Figure 9.6 shows a graphic prototype of the multiple probe design. Although researchers have developed many variations of the multiple probe technique, the basic design has three key features: (a) An initial probe determines the subject's level of performance on each behavior in the sequence; (b) a series of baseline

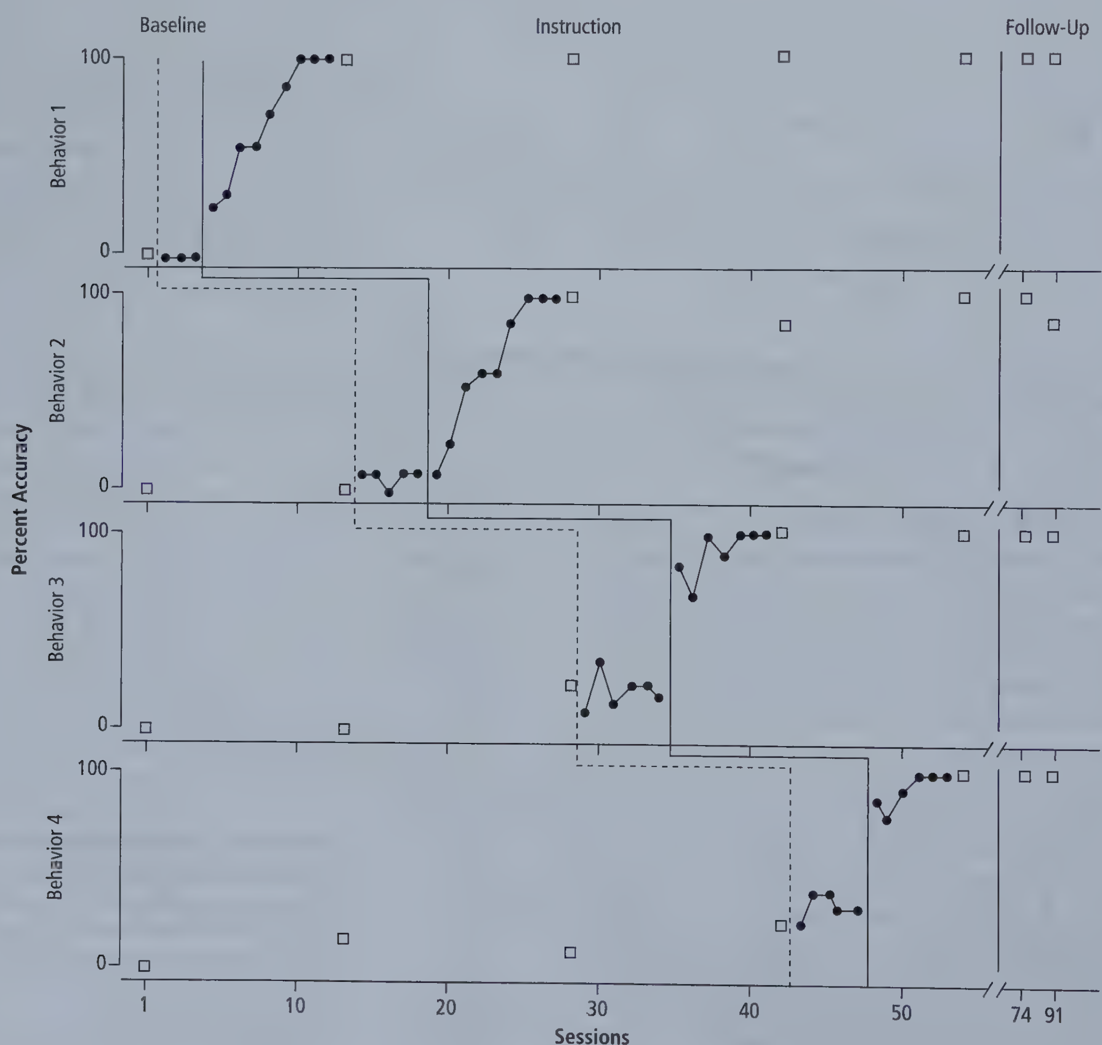

Figure 9.6 Graphic prototype of a multiple probe design. Square data points represent results of probe sessions in which the entire sequence or set of behaviors (1–4) is tested.

measures is obtained on each step prior to training on that step; and (c) after criterion-level performance is reached on any training step, a probe of each step in the sequence is obtained to determine whether performance has changed in any other steps.

Jimenez, Browder, Spooner, and Dibiase (2003) used a multiple probe design to analyze the effects of a peer-mediated instructional procedure on the acquisition of science knowledge by middle school students with moderate intellectual disability. Participants included five target students ages 11 to 14 with IQs ranging from 34 to 55 and six 11-year-old peer tutors from the same inclusive classroom of 26 students. Throughout the study, the general education teacher introduced each science inquiry lesson to the entire class, using the first three letters of a KWHL chart (K = what do you Know?; W = What do you want to know?; H = How will you find out?; L = what did you Learn?) to prompt student responses and thinking. Students then broke into groups of four or five, each group including one target student and one peer tutor, and participated in a hands-on experiment or online activity and reported what they saw.

The primary dependent variable was the number of correct responses by the target students on experimenter-administered assessment probes conducted after each science lesson. Each probe consisted of eight response opportunities: stating two printed science vocabulary words, naming two science pictures (e.g., student shown three flash cards with science vocabulary words or pictures and told, "find kinetic energy"), matching two word/picture combinations, and completing two concept statements (e.g., "Can you find the word that completes this statement? ______ is the energy of motion." [p. 305]). Three different picture sets were created for each vocabulary word. *In vivo* probes, conducted at least once per each unit of instruction, consisted of the target student's performance on the first peer-presented trial for each science response.

During intervention, the peer tutors (1) used a constant time-delay procedure to teach the target students to use the KWHL chart as the teacher led the class to complete their charts, and (2) embedded three constant time-delay learning trials for each science response during the small-group activity.[3] Figure 9.7 shows the results for one of the target students.

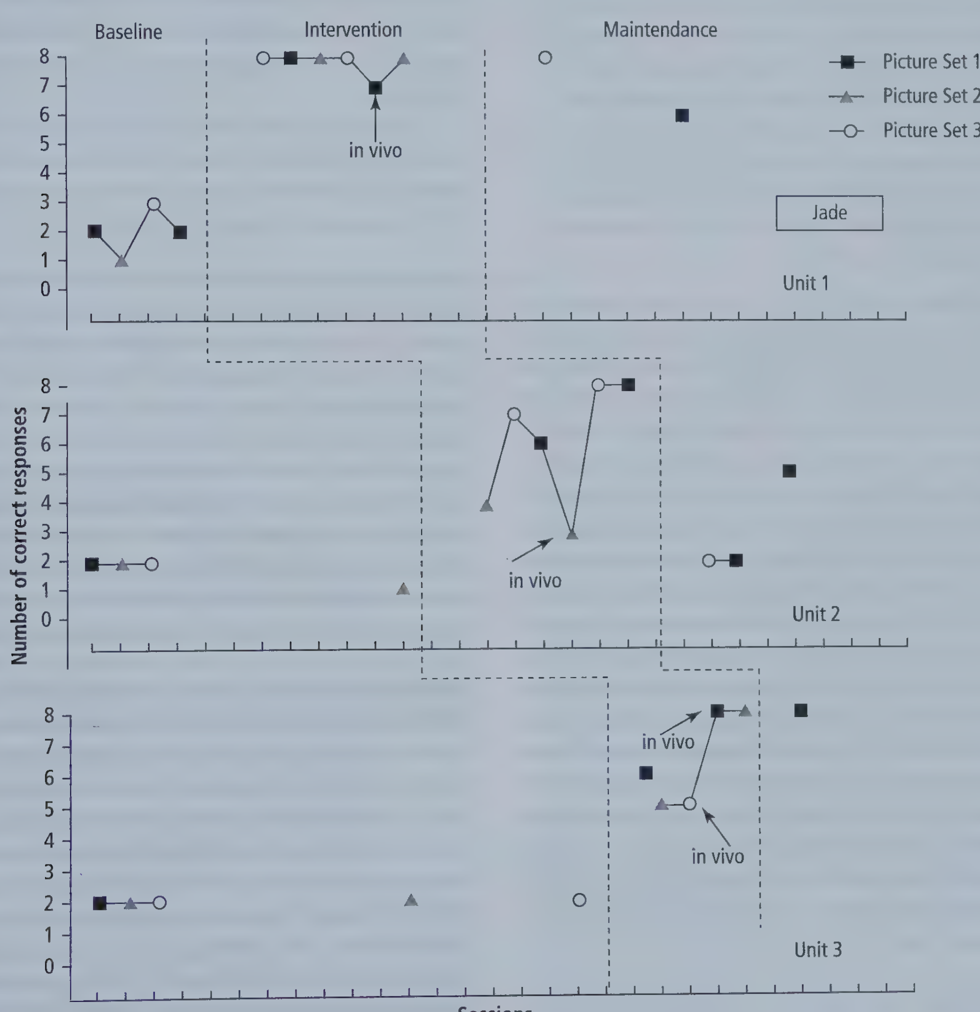

Figure 9.7 A multiple probe design across three curriculum units showing the number of correct responses on probes of science knowledge by a student with moderate intellectual disability as a function of peer-mediated embedded instruction.

From "Inclusive Inquiry Science Using Peer-Mediated Embedded Instruction for Students with Moderate Intellectual Disabilities," by B. A. Jimenez, D. M. Browder, F. Spooner, & D. Dibiase, 2012, *Exceptional Children, 78*, p. 310. Copyright 2012 by the Council for Exceptional Children. Reprinted by permission.

During baseline, Jade averaged 1.75 to 2 correct responses per probe across the three units. Her performance improved during intervention to a mean of 6 to 7.8 correct responses per probe. Jade's performance on maintenance probes remained well above baseline levels for two of the three units. The other four target students obtained similar results, suggesting a functional relation between peer-mediated embedded instruction and acquisition of science knowledge by students with moderate intellectual disability.

The multiple probe design is particularly appropriate for evaluating the effects of instruction on skill sequences in which it is highly unlikely that the subject can improve performance on later steps in the sequence without acquiring the prior steps. For example, the repeated measurement of a student's accuracy in solving division problems when the student possesses no skills in addition, subtraction, and multiplication would add little to an analysis. Horner and Baer (1978) made this point exceedingly well:

> The inevitable zero scores on the division baseline have no real meaning: division could be nothing else than zero (or chance, depending on the test format), and there is no real point in measuring it. Such measures are *pro forma:* they fill out the picture of a multiple baseline, true, but in an illusory way. They do not so much represent zero behavior as zero opportunity for the behavior to occur, and there is no need to document at the level of well-measured data that behavior does not occur when it cannot. (p. 190)

Thus, the multiple probe design avoids the necessity of ritualistic baseline data collection when the performance of any component of a chain or sequence is impossible or unlikely before acquisition of its preceding components. In addition to the two uses already mentioned—analysis of the effects of instruction on complex skill sequences and reduction in the amount of baseline measurement for behaviors that have no plausible opportunity to occur—the multiple probe technique is an effective experimental strategy for situations in which extended baseline measurement may prove reactive, impractical, or costly. The repeated measurement of a skill under nontreatment conditions can prove aversive to some students; and extinction, boredom, or other undesirable responses can occur. In his discussion of multiple baseline designs, Cuvo (1979) suggested that researchers should recognize that "there is a trade-off between repeatedly administering the dependent measure to establish a stable baseline on one hand and risking impaired performance by subjecting participants to a potentially punishing experience on the other hand" (pp. 222–223). Furthermore, complete assessment of all skills in a sequence may require too much time that could otherwise be spent on instruction.

Other examples of the multiple probe design can be found in Aldi et al. (2016; see Figure 21.2 in this text) Arntzen, Halstadtrø, and Halstadtrø (2003); Coleman-Martin and Wolff Heller (2004); Lambert and colleagues (2016); Mechling, Ayres, Purrazzella, and Purrazzella (2012); Werts, Caldwell, and Wolery (2016; see Figure 23.9 in this text) and Yanardag, Akmanoglu, and Yilmaz (2013).

Delayed Multiple Baseline Design

The delayed multiple baseline technique can be used when a planned reversal design is no longer possible or proves ineffective; it can also add additional tiers to an already operational multiple baseline design, as would be the case if new subjects were added to an ongoing study. The **delayed multiple baseline design** is an experimental tactic in which an initial baseline and intervention are begun, and subsequent baselines are added in a staggered or delayed fashion. Figure 9.8 shows a graphic prototype of the delayed multiple baseline design. The design employs the same experimental reasoning as a full-scale multiple baseline design, with the exception that data from baselines begun after the independent variable has been applied to previous behaviors, settings, or subjects cannot be used to verify predictions based on earlier tiers of the design. In Figure 9.8 baseline measurement of Behaviors 2 and 3 was begun early enough for those data to be used to verify the prediction made for Behavior 1. The final four baseline data points for Behavior 3 also verify the prediction for Behavior 2. However, baseline measurement of Behavior 4 began after the independent variable had been applied to each of the previous behaviors, thus limiting its role in the design to an additional demonstration of replication.

A delayed multiple baseline design may allow the behavior analyst to conduct research in certain environments in which other experimental tactics cannot be implemented. Heward (1978) suggested three such situations.

A Reversal Design Is No Longer Desirable or Possible. In applied settings the research environment may shift, negating the use of a previously planned reversal design. Such shifts may involve changes in the subject's environment that make the target behavior no longer likely to reverse to baseline levels, or changes in the behavior of parents, teachers, administrators, the subject/client, or the behavior analyst that, for any number of reasons, make a previously planned reversal design no longer desirable or possible. If other behaviors, settings, or subjects are appropriate for application of the independent variable, the behavior analyst could use a delayed multiple baseline technique and still pursue evidence of a functional relation.

Limited Resources, Ethical Concerns, or Practical Difficulties Preclude a Full-scale Multiple Baseline Design. This situation occurs when the behavior analyst only controls resources sufficient to initially record and intervene with one behavior, setting, or subject, and another research strategy is inappropriate. It may be that as a result of the first intervention, more resources become available for gathering additional baselines. This might occur following the improvement of certain behaviors whose pretreatment topography and/or rate required an inordinate expenditure of staff resources. Or, it could be that a reluctant administrator, after seeing the successful results of the first intervention, provides the resources necessary for additional analysis. Ethical concerns may preclude extended baseline measurement of some behaviors (e.g., Linscheid, Iwata, Ricketts, Williams, & Griffin, 1990). Also under this heading would fall the "practical difficulties" cited by Hobbs and Holt (1976) as a reason for delaying baseline measurement in one of three settings.

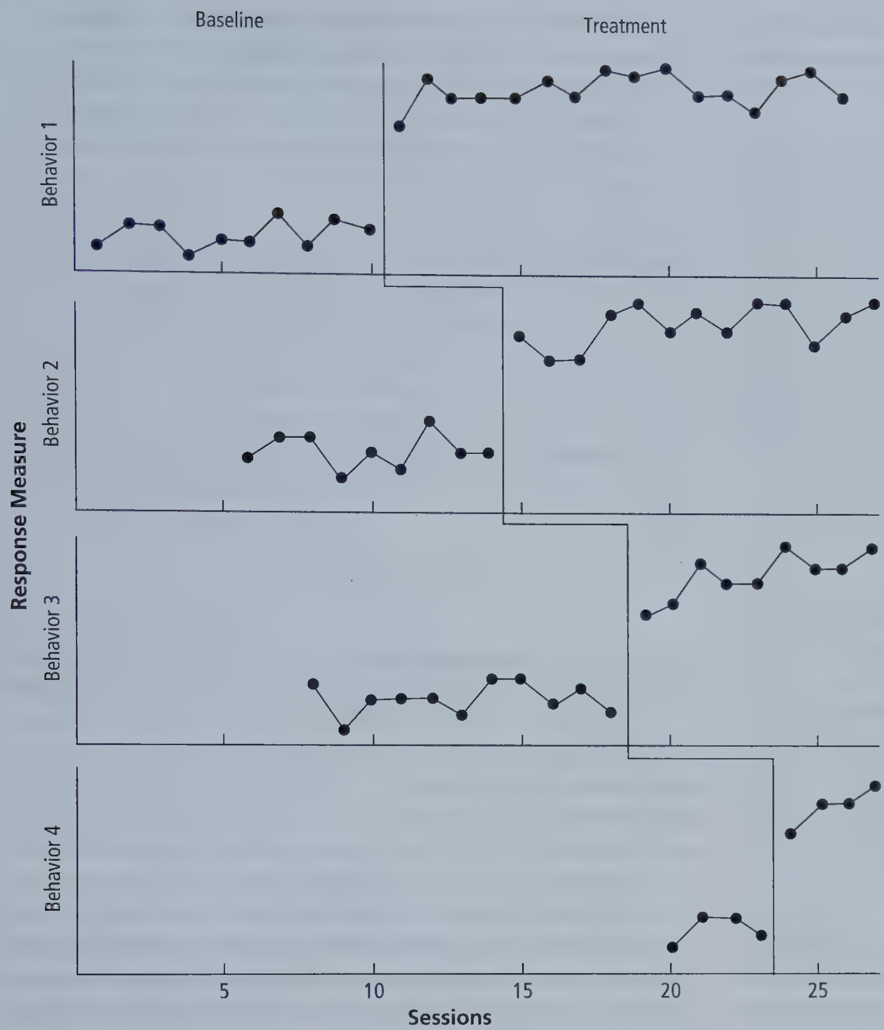

Figure 9.8 Graphic prototype of a delayed multiple baseline design.

"New" Behaviors, Settings, or Subjects Become Available. A delayed multiple baseline technique might become a useful analytic tactic due to changes in the environment (e.g., the subject begins to emit another behavior appropriate for intervention with the experimental variable, the subject begins to emit the original target behavior in another setting, or additional subjects displaying the same target behavior become available [e.g., Halldórsdóttir, Valdimarsdóttir, & Arntzen, 2017; Young & Daly, 2016, Figures 1 and 3]). Todd, Horner, and Sugai (1999) implemented a self-management intervention during Class Period B at the teacher's request because the teacher had noted an immediate and "dramatic change" in the student's performance when the intervention began in praise in Class Period A (see Figure 29.6).

Researchers have used delayed multiple baseline designs to evaluate a wide variety of interventions (e.g., Baer, Williams, Osnes, & Stokes, 1984; Jones, Fremouw, & Carples, 1977; Linscheid et al., 1990; Risley & Hart, 1968; Schepis, Reid, Behrmann, & Sutton, 1998; McKenzie, Smith, Simmons, & Soderlund, 2008, [see Figure 14.3]; Towery, Parsons, & Reid, 2014; White & Bailey, 1990 [see Figure 15.2]).[4] Poche, Brouwer, and Swearingen (1981) used a delayed multiple baseline design to evaluate the effects of a training program designed to prevent children from being abducted by adults. Three typically developing preschool children were selected as subjects because, during a screening test, each readily agreed to leave with an adult stranger. The dependent variable was the level of appropriateness of self-protective responses emitted by each child when an adult suspect approached the child and attempted to lure her away with a simple lure ("Would you like to go for a walk?"), an authoritative lure ("Your teacher said it was all right for you to come with me."), or an incentive lure ("I've got a nice surprise in my car. Would you like to come with me and see it?").

Each session began with the child's teacher bringing the child outdoors and then pretending to have to return to the building for some reason. The adult suspect (a confederate of the experimenters but unknown to the child) then approached the child and offered one of the lures. The confederate also served as observer, scoring the child's response on a 0 to 6 scale, with a score of 6 representing the desired response (saying, "No, I have to go ask my teacher" and moving at least 20 feet away from the suspect within 3 seconds) and a score of 0 indicating that the child moved some distance away from the school building with the suspect. Training consisted of modeling, behavioral rehearsal, and social reinforcement for correct responses.

Figure 9.9 shows the results of the training program. During baseline, all three children responded to the lures with

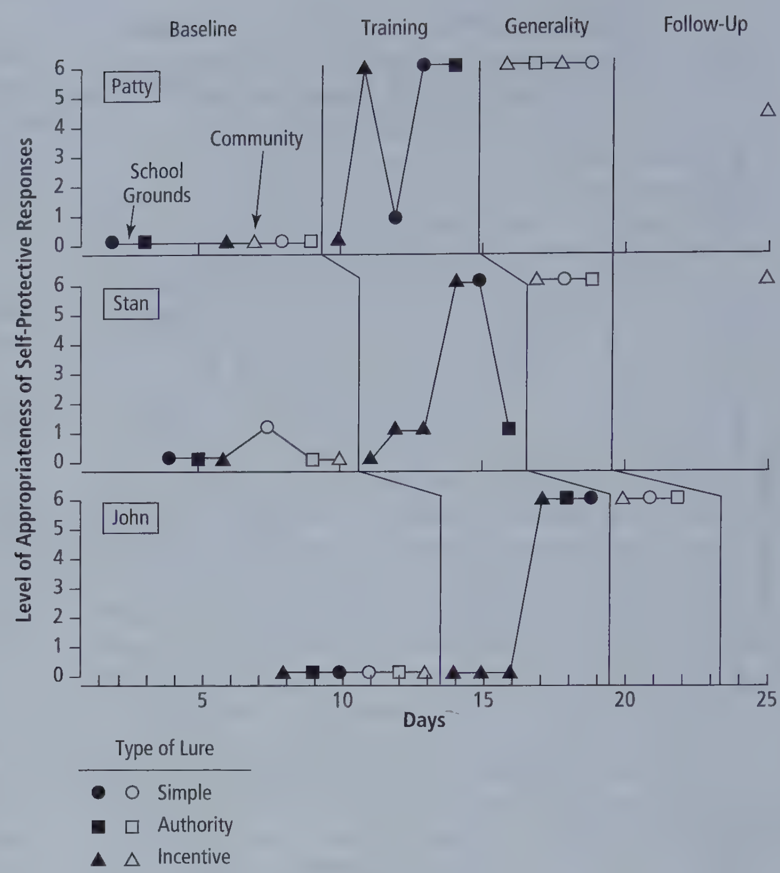

Figure 9.9 A delayed multiple baseline design showing the level of appropriateness of self-protective responses during baseline, training, and generality probes in school and community settings. Closed symbols indicate data gathered near the school; open symbols, in a location away from the school.

Based on "Teaching Self-Protection to Young Children," by C. Poche, R. Brouwer, and M. Swearingen, 1981, *Journal of Applied Behavior Analysis, 14*, p. 174. Copyright 1981 by the Society for the Experimental Analysis of Behavior, Inc.

safety ratings of 0 or 1. All three children mastered correct responses to the incentive lure in one to three training sessions, with one or two more sessions required for each child to master correct responses to the other two lures. Overall, training took approximately 90 minutes per child distributed over five or six sessions. All three children responded correctly when the lures were administered in generalization probes on sidewalk locations 150 to 400 feet from the school.

Although each baseline in this study was of equal length (i.e., had an equal number of data points), contradicting the general rule that the baselines in a multiple baseline design should vary significantly in length, there are two good reasons that Poche and colleagues began training when they did with each subject. First, the nearly total stability of the baseline performance of each child provided an ample basis for evaluating the training program (the only exception to complete susceptibility to the adult suspect's lures occurred when Stan stayed near the suspect instead of actually going away with him on his fourth baseline observation). Second, and more important, the nature of the target behavior required that it be taught to each child as soon as possible. Although continuing baseline measurement for varying lengths across the different tiers of any multiple baseline design is good practice from a purely experimental viewpoint, the ethics of such a practice in this instance would be highly questionable, given the potential danger of exposing the children to adult lures repeatedly while withholding training.

The delayed multiple baseline design entails several limitations. First, from an applied standpoint the design is not a good choice if the behavior analyst must wait too long to modify important behaviors, although this potential problem must be considered in all multiple baseline designs. Second, there is a tendency for the delayed baseline phases to contain fewer data points than found in a standard multiple baseline design, in which all baselines are begun simultaneously, resulting in baseline phases of considerable and varying length. Long baselines, if stable, provide the predictive power that permits convincing demonstrations of experimental control. Behavior analysts using any form of multiple baseline design must ensure that all baselines, regardless of when they begin, are of sufficient and varied length to provide believable bases for comparing experimental effects. A third limitation of the delayed multiple baseline design is that it can mask the interdependence of dependent variables.

> The strength of any multiple baseline design is that little or no change is noticed in the other, as yet untreated, behaviors until, and only until, the experimenter applies the independent variable. In a delayed multiple baseline design, the "delayed baseline" data gathered for subsequent behaviors may represent changed performance due to the experimental manipulation of other behaviors in the design and, therefore, may not be representative of the true, preexperimental operant level. . . . In such instances, the delayed multiple baseline might result in a "false negative," and the researcher may erroneously conclude that the intervention was not effective on the subsequent behavior(s), when in reality the lack of simultaneous baseline data did not permit the discovery that the behaviors covaried. This is a major weakness of the delayed

> multiple baseline design and makes it a research tactic of second choice whenever a full-scale multiple baseline can be employed. However, this limitation can and should be combated whenever possible by beginning subsequent baselines at least several sessions prior to intervention on previous baselines. (Heward, 1978, pp. 8–9)

Both the multiple probe design and the delayed multiple baseline design offer the applied behavior analyst alternative tactics for pursuing a multiple baseline analysis when extended baseline measurement is unnecessary, impractical, too costly, or unavailable. Perhaps the most useful application of the delayed multiple baseline technique is in adding tiers to an already operational multiple baseline design. Whenever a delayed baseline can be supplemented by probes taken earlier in the course of the study, experimental control is strengthened. As a general rule, the more baseline data, the better.

Nonconcurrent Multiple Baseline Across Participants Design

The **nonconcurrent multiple baseline across participants design** consists of a related series of A-B (baseline-intervention) sequences conducted across subjects at different points in time.

Watson and Workman (1981) proposed the nonconcurrent multiple baseline across participants design as a method for experimentally assessing treatment effects when concurrent measurement across subjects is not possible. They wrote, "The requirement [of a standard multiple baseline across subjects design] that observations be taken concurrently clearly poses problems for researchers in applied settings (e.g., schools, mental health centers), since clients with the same target behavior may only infrequently be referred at the same point in time" (p. 257, words in brackets added). The nonconcurrent multiple baseline across participants design is used frequently in applied behavior analysis (e.g., Garcia, Dukes, Brady, Scott, & Wilson, 2016; Greer, Neibert & Dozier, 2016 [see Figure 6.7]; Gunby, Carr, & LeBlanc, 2010; Kelley & Miltenberger, 2016; Speelman, Whiting, & Dixon, 2015).

"The nonconcurrent MB design is essentially a series of A-B replications in which the length of each baseline phase differs. The participant's graphs are then vertically aligned and visually inspected as one would a concurrent MB design" (Carr, 2005, p. 220). Although conjoining the graphs of two or more A-B designs with a doglegged dashed line produces a figure that "looks like" a multiple baseline design, doing so may suggest a greater degree of experimental control than is warranted (Harris & Jenson, 1985).

The nonconcurrent multiple baseline across participants design is inherently weaker than other multiple baseline design variations. Although the design entails two of the three elements of baseline logic—prediction and replication—the absence of concurrent baseline measures precludes the verification of intervention effects. We recommend labeling and scaling the horizontal axes of graphs of nonconcurrent multiple baseline design studies in a manner clearly depicting the actual time periods when data were obtained for each A-B sequence with respect to the others (e.g., see Carr, 2005; Harvey, May, & Kennedy, 2004, Figure 2).

Assumptions and Guidelines for Using Multiple Baseline Designs

Like all experimental tactics, the multiple baseline design entails certain assumptions about how the behavior–environment relations under investigation function, even though discovering the existence and operation of those relations is the very reason for conducting the research. In this sense, the design of behavioral experiments resembles an empirical guessing game—the experimenter guesses; the data answer. The investigator makes assumptions, hypotheses in the informal sense, about behavior and its relation to controlling variables and then constructs experiments designed to produce data capable of verifying or refuting those conjectures.[5]

Because verification and replication in the multiple baseline design depend on what happens, or does not happen, to other behaviors as a result of the sequential application of the independent variable, the experimenter must be particularly careful to plan and carry out the design in a manner that will afford the greatest degree of confidence in any relations suggested by the data. Although the multiple baseline design appears deceptively simple, its successful application requires much more than selecting two or more behaviors, settings, or subjects, collecting some baseline data, and then introducing a treatment condition to one behavior after the other. We suggest the following guidelines for designing and conducting experiments using multiple baseline designs.

Select Independent, yet Functionally Similar, Baselines

Demonstration of a functional relation in a multiple baseline design depends on two occurrences: (a) the behavior(s) still in baseline showing no significant change in level, trend, or variability while the behavior(s) in contact with the independent variable changes; and (b) each behavior changes when, and only when, the independent variable has been applied to it. Thus, the experimenter must make two, at times seemingly contradictory, assumptions about the behaviors targeted for analysis in a multiple baseline design. The assumptions are that the behaviors are functionally independent of one another (the behaviors will not covary with one another), and yet the behaviors share enough similarity that each will change when the same independent variable is applied to it. An error in either assumption can result in a failure to demonstrate a functional relation.

For example, let us suppose that the independent variable is introduced with the first behavior, and changes in level and/or trend are noted, but the other behaviors still in baseline also change. Do the changes in the still-in-baseline behaviors mean that an uncontrolled variable is responsible for the changes in all of the behaviors and that the independent variable is an ineffective treatment? Or do the simultaneous changes in the untreated behaviors mean that the changes in the first behavior were affected by the independent variable and have generalized to the other behaviors? Or, let us suppose instead that the first behavior changes when the independent variable is introduced, but subsequent behaviors do not change when the independent variable is applied. Does this failure to replicate mean that a factor other than the independent variable was responsible for

the change observed in the first behavior? Or does it mean only that the subsequent behaviors do not operate as a function of the experimental variable, leaving open the possibility that the change noted in the first behavior was affected by the independent variable?

Answers to these questions can and should be pursued by further experimental manipulations. In both kinds of failure to demonstrate experimental control, the multiple baseline design does not rule out the possibility of a functional relation between the independent variable and the behavior(s) that did change when the variable was applied. In the first instance, the failure to demonstrate experimental control with the originally planned design is offset by the opportunity to investigate and possibly isolate the variable robust enough to change multiple behaviors simultaneously. Discovery of variables that reliably produce generalized changes across behaviors, settings, and/or subjects is a major goal of applied behavior analysis; and if the experimenter is confident all other relevant variables were held constant before, during, and after the observed behavior changes, the original independent variable is the first candidate for further investigation.

In the second situation, failure to replicate changes from one behavior to another, the experimenter can pursue the possibility of a functional relation between the independent variable and the first behavior, perhaps using a reversal technique, and seek to discover later an effective intervention for the behavior(s) that did not change. Another possibility is to drop the original independent variable altogether and search for another treatment that might be effective with all of the targeted behaviors.

Select Concurrent and Plausibly Related Multiple Baselines

In an effort to ensure the functional independence of behaviors in a multiple baseline design, experimenters should not select response classes or settings so unrelated to one another as to offer no plausible means of comparison. For the ongoing baseline measurement of one behavior to provide the strongest basis for verifying the prediction of another behavior that has been exposed to an independent variable, two conditions must be met: (a) The two behaviors must be measured concurrently, and (b) all of the relevant variables that influence one behavior must have an opportunity to influence the other behavior. Studies that employ a multiple baseline approach across subjects and settings often stretch the logic of the design beyond its capabilities. For example, using the stable baseline measures of one child's compliance with parental requests as the basis for verifying the effect of intervention on the compliance behavior of another child living with another family is questionable practice. The sets of variables influencing the two children are surely differentiated by more than the presence or absence of the experimental variable.

> There are some important limits to designating multiple behavior/setting combinations that are intended to function as part of the same experiment. In order for the use of multiple behaviors and settings to be part of the same design and thus augment experimental reasoning, the general experimental conditions under which the two responses (whether two from one subject or one from each of two subjects) are emitted and measured must be ongoing concurrently. . . . Exposure [to the independent variable] does not have to be simultaneous for the different behavior/setting combinations, [but] it must be the identical treatment conditions along with the associated extraneous variables that impinge on the two responses and/or settings. This is because the conditions imposed on one behavior/setting combination must have the *opportunity* of influencing the other behavior/setting combination at the same time, regardless of the condition that actually prevails for the second. . . . It follows that using responses of two subjects each responding in different settings would not meet the requirement that there be a coincident opportunity for detecting the treatment effect. A treatment condition [as well as the myriad other variables possibly responsible for changes in the behavior of one subject] could not then come into contact with the responding of the other subject, because the second subject's responding would be occurring in an entirely different location. . . . Generally, the greater the plausibility that the two responses would be affected by the single treatment [and all other relevant variables], the more powerful is the demonstration of experimental control evidenced by data showing a change in only one behavior. (Johnston & Pennypacker, 1980, pp. 276–278)

The requirements of concurrency and plausible influence must be met for the verification element of baseline logic to operate in a multiple baseline design. However, replication of effect is demonstrated each time a baseline steady state is changed by the introduction of the independent variable, more or less regardless of where or when the variable is applied. Such nonconcurrent and/or unrelated baselines can provide valuable data on the generality of a treatment's effectiveness. See the previous discussion of the *nonconcurrent multiple baseline design*.

This discussion should not be interpreted to mean that a valid (i.e., logically complete) multiple baseline design cannot be conducted across different subjects, each responding in different settings. Numerous studies using mixed multiple baselines across subjects, response classes, and/or settings have contributed to the development of an effective technology of behavior change (e.g., Dixon et al., 1998; Durand, 1999 [see Figure 26.4]; Ryan, Ormond, Imwold, & Rotunda, 2002).

Let us consider an experiment designed to analyze the effects of a particular teacher training intervention, perhaps a workshop on using tactics to increase each student's opportunity to respond during group instruction. Concurrent measurement is begun on the frequency of student response opportunities in the classrooms of the teachers who are participating in the study. After stable baselines have been established, the workshop is presented first to one teacher (or group of teachers) and eventually, in staggered multiple baseline fashion, to all of the teachers.

In this example, even though the different subjects (teachers) are all behaving in different environments (different classrooms), comparison of their baseline conditions is experimentally sound because the variables likely to influence their teaching styles operate in the larger, shared environment in

which they all behave (the school and teaching community). Nevertheless, whenever experiments are proposed or published that involve different subjects responding in different settings, researchers and consumers should view the baseline comparisons with a critical eye toward their logical relation to one other.

Do Not Apply the Independent Variable to the Next Behavior Too Soon

To reiterate, for verification to occur in a multiple baseline design, it must be established clearly that as the independent variable is applied to one behavior and change is noted, little or no change is observed in the other, as-yet-untreated behaviors. The potential for a powerful demonstration of experimental control has been destroyed in many studies because the independent variable was applied to subsequent behaviors too soon. Although the operational requirement of sequential application in the multiple baseline tactic is met by introduction of the independent variable even in adjacent time intervals, the experimental reasoning afforded by such closely spaced manipulations is minimal.

> The influence of unknown, concomitant, extraneous variables that might be present could still be substantial, even a day or two later. This problem can be avoided by demonstrating continued stability in responding for the second behavior/setting combination during and after the introduction of the treatment for the first combination until a sufficient period of time has elapsed to detect any effect on the second combination that might appear. (Johnston & Pennypacker, 1980, p. 283)

Vary Significantly the Lengths of Multiple Baselines

Generally, the more the baseline phases in a multiple baseline design differ in the number of measures from one another, the stronger the design will be. Baselines with significantly different numbers of data points allow the unambiguous conclusion (assuming an effective treatment variable) that each behavior not only changes when the independent variable is applied, but also that each behavior does not change until the independent variable has been applied. If the different baselines are of the same or similar length, the possibility exists that changes noted when the independent variable is introduced are the result of a confounding variable, such as practice or reactivity to observation and measurement, and not a function of the experimental variable.

> Those effects . . . called practice, adaptation, warm-up, self-analysis, etc.; whatever they may be and whatever they may be called, the multiple baseline design controls for them by systematically varying the length of time (sessions, days, weeks) in which they occur prior to the introduction of the training package. . . . Such control is essential, and when the design consists of only two baselines, then the number of data points in each prior to experimental intervention should differ as radically as possible, at least by a factor of 2. I cannot see not systematically varying lengths of baselines prior to intervention, and varying them as much as possible/practical. Failure to do that . . . weakens the design too much for credibility. (D. M. Baer, personal communication June 2, 1978)

Intervene on the Most Stable Baseline First

In an ideal multiple baseline design, the independent variable is not applied to any of the behaviors until steady state responding has been achieved for each. However, applied behavior analysts are often denied the option of delaying treatment just to increase the strength of an experimental analysis. When intervention must begin before stability is evident across each tier of the design, the independent variable should be applied to the behavior, setting, or subject showing the most stable baseline data path (or counter-therapeutic trend, as with Sara in Figure 9.5). For example, if a study is designed to evaluate the effects of a teaching procedure on the rate of math computation of four students and no *a priori* reason exists for teaching the students in any particular sequence, instruction should begin with the student showing the most stable baseline. However, this recommendation should be followed only when the majority of the baselines in the design show reasonable stability.

Sequential applications of the independent variable should be made in the order of greatest stability at the time of each subsequent application. Again, however, the realities of the applied world must be heeded. The social significance of changing a particular behavior must sometimes take precedence over the desire to meet the requirements of experimental design.

Considering the Appropriateness of Multiple Baseline Designs

The multiple baseline design offers significant advantages, which no doubt have accounted for its widespread use by researchers and practitioners. Those advantages, however, must be weighed against the limitations and weaknesses of the design to determine its appropriateness in any given situation.

Advantages of the Multiple Baseline Design

Probably the most important advantage of the multiple baseline design is that it does not require withdrawing a seemingly effective treatment to demonstrate experimental control. This is a critical consideration for target behaviors that are self-injurious or dangerous to others. This feature of the multiple baseline design also makes it an appropriate method for evaluating the effects of independent variables that cannot, by their nature, be withdrawn and for investigating target behaviors that are likely or that prove to be irreversible (e.g., Duker & van Lent, 1991). Additionally, because the multiple baseline design does not necessitate a reversal of treatment gains to baseline levels, parents, teachers, or administrators may accept it more readily as a method of demonstrating the effects of an intervention.

The requirement of the multiple baseline design to sequentially apply the independent variable across multiple behaviors, settings, or subjects complements the usual practice of many practitioners whose goal is to develop multiple behavior changes. Teachers are charged with helping multiple students learn multiple skills to be used in multiple settings. Likewise, clinicians typically need to help their clients improve more than

one response class and emit more adaptive behaviors in several settings. The multiple baseline design is ideally suited to the evaluation of the progressive, multiple behavior changes sought by many practitioners in applied settings.

Because the multiple baseline design involves concurrent measurement of two or more behaviors, settings, or subjects, it is useful in assessing the occurrence of generalization of behavior change. The simultaneous monitoring of several behaviors gives the behavior analyst the opportunity to determine their covariation as a result of manipulations of the independent variable. Although changes in behaviors still under baseline conditions eliminate the ability of the multiple baseline design to demonstrate experimental control, such changes reveal the possibility that the independent variable is capable of producing behavioral improvements with desirable generality, thereby suggesting an additional set of research questions and analytic tactics (e.g., Odom, Hoyson, Jamieson, & Strain, 1985).

Finally, the multiple baseline design has the advantage of being relatively easy to conceptualize, thereby offering an effective experimental tactic for teachers and parents who are not trained formally in research methodology.

Limitations of the Multiple Baseline Design

The multiple baseline design presents at least three scientific limitations or considerations. First, a multiple baseline design may not allow a demonstration of experimental control even though a functional relation exists between the independent variable and the behaviors to which it is applied. Changes in behaviors still under baseline conditions and similar to concurrent changes in a behavior in the treatment condition preclude the demonstration of a functional relation within the original design. Second, from one perspective, the multiple baseline design is a weaker method for showing experimental control than the reversal design. This is because verification of the baseline prediction made for each behavior within a multiple baseline design is not directly demonstrated with that behavior, but must be inferred from the lack of change in other behaviors. This weakness of the multiple baseline design, however, should be weighed against the design's advantage of providing multiple replications across different behaviors, settings, or subjects. Third, the multiple baseline design provides more information about the effectiveness of the treatment variable than it does about the function of any particular target behavior.

> Consistently [the] multiple baseline is less an experimental analysis of the response than of the technique used to alter the response. In the reversal design, the response is made to work again and again; in the multiple-baseline design, it is primarily the technique that works again and again, and the responses either work once each [if different responses are used] or else a single response works once each per setting or once each per subject. Repetitive working of the same response in the same subject or the same setting is not displayed. But, while repetitive working of the response is foregone, repetitive and diverse working of the experimental technique is maximized, as it would not be in the reversal design. (Baer, 1975, p. 22)

Two important applied considerations that must be evaluated in determining the appropriateness of the multiple baseline design are the time and resources required for its implementation. First, because the treatment variable cannot be applied to subsequent behaviors, settings, or subjects until its effects have been observed on previous behaviors, settings, or subjects, the multiple baseline design requires that intervention be withheld for some behaviors, settings, or subjects, perhaps for a long time. This delay raises practical and ethical concerns. Treatment cannot be delayed for some behaviors; their importance makes delaying treatment impractical. And as Stolz (1978) pointed out, "If the intervention is generally acknowledged to be effective, denying it simply to achieve a multiple-baseline design might be unethical" (p. 33). Second, the resources needed for the concurrent measurement of multiple behaviors must be considered. Use of a multiple baseline design can be particularly costly when behavior must be observed and measured in several settings. However, when the use of intermittent probes during baseline can be justified in lieu of continuous measurement (Horner & Baer, 1978), the cost of concurrently measuring multiple behaviors can be reduced.

CHANGING CRITERION DESIGN

The changing criterion design can be used to evaluate the effects of a treatment that is applied in a graduated or stepwise fashion to a single target behavior. The changing criterion design was first described in the applied behavior analysis literature in two papers coauthored by Vance Hall (Hall & Fox, 1977; Hartmann & Hall, 1976).

Operation and Logic of the Changing Criterion Design

The reader can refer to Figure 9.10 before and after reading Hartmann and Hall's (1976) description of the **changing criterion design**.

> The design requires initial baseline observations on a single target behavior. This baseline phase is followed by implementation of a treatment program in each of a series of treatment phases. Each treatment phase is associated with a step-wise change in criterion rate for the target behavior. Thus, each phase of the design provides a baseline for the following phase. When the rate of the target behavior changes with each stepwise change in the criterion, therapeutic change is replicated and experimental control is demonstrated. (p. 527)

The operation of two elements of baseline logic—prediction and replication—is clear in the changing criterion design. When stable responding is attained within each phase of the design, a prediction of future responding is made. Replication occurs each time the level of behavior changes in a systematic way when the criterion is changed. Verification of the predictions based on each phase is not so obvious in this design but can be approached in two ways. First, varying the lengths of phases systematically enables a form of self-evident verification. The prediction is made that the level of responding will not change if the criterion is not changed. When the criterion is not changed

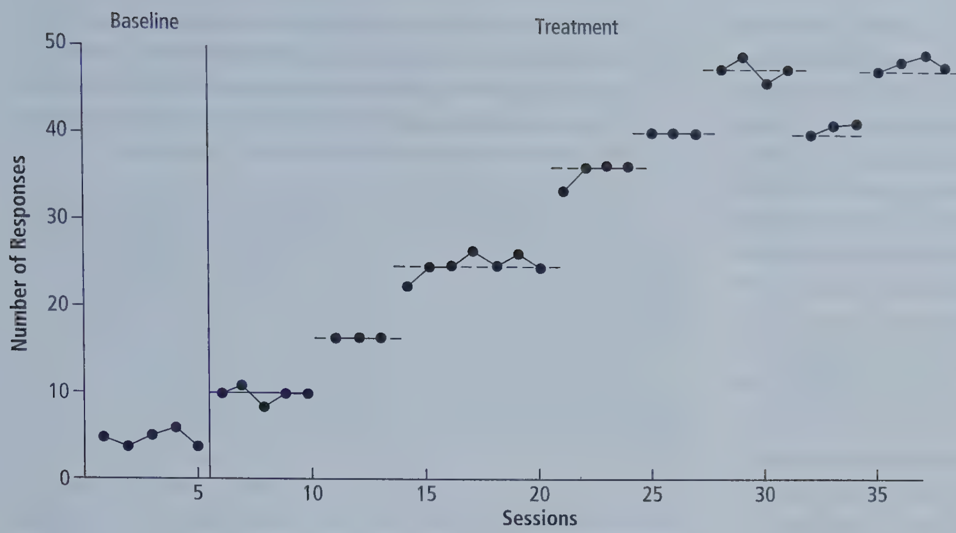

Figure 9.10 Graphic prototype of a changing criterion design.

and stable responding continues, the prediction is verified. When it can be shown within the design that levels of responding do not change unless the criterion is changed, regardless of the varied lengths of phases, experimental control is evident. Hall and Fox (1977) suggested another possibility for verification: "The experimenter may return to a former criterion and if the behavior conforms to this criterion level there is also a cogent argument for a high degree of behavioral control" (p. 154). Such a reversed criterion is shown in the next-to-last phase of Figure 9.10. Although returning to an earlier criterion level requires a brief interruption of the steady improvement in behavior, the reversal tactic strengthens the analysis considerably and should be included in the changing criterion design unless other factors indicate its inappropriateness.

One way to conceptualize the changing criterion design is as a variation of the multiple baseline design. Both Hartmann and Hall (1976, p. 530) and Hall and Fox (1977, p. 164) replotted data from changing criterion design experiments in a multiple baseline format, with each tier of the multiple baseline showing the occurrence or nonoccurrence of the target behavior at one of the criterion levels used in the experiment. A vertical condition change line doglegs through the tiers, indicating when the criterion for reinforcement was raised to the level represented by each tier. By graphing whether the target behavior was emitted during each session at or above the level represented on each tier both before and after the change in criterion to that level, a kind of multiple baseline analysis is revealed. However, the strength of the multiple baseline argument is not convincing because the "different" behaviors represented by each tier are not independent of one another. For example, if a target behavior is emitted 10 times in a given session, all of the tiers representing criteria below 10 responses would have to show that the behavior occurred, and all of the tiers representing criteria of 11 or more would have to show no occurrence of the behavior, or zero responding. The majority of the tiers that would appear to show verification and replication of effect, in fact, could only show these results because of the events plotted on another tier. A multiple baseline design provides a convincing demonstration of experimental control because the measures obtained for each behavior in the design are a function of the controlling variables for that behavior, not artifacts of the measurement of another behavior. Thus, recasting the data from a changing criterion design into a many-tiered multiple baseline format will often result in a biased picture in favor of experimental control.

Even though the multiple baseline design is not completely analogous, the changing criterion design can be conceptualized as a method of analyzing the increasing (or decreasing) performance of a target behavior. As Sidman (1960) pointed out, "It is possible to make reinforcement contingent upon a specified value of some aspect of behavior, and to treat that value as a response class in its own right" (p. 391). The changing criterion design can be an effective tactic for showing the repeated production of new rates of behavior as a function of manipulations of the independent variable (i.e., criterion changes).

Cook, Rapp, and Schulze (2015) used a changing criterion design to evaluate the effects of differential negative reinforcement of other behavior (DNRO) on the duration with which an 8-year-old boy with autism wore a medical alert bracelet. Jonah's parents were worried about their son's history of getting separated from caregivers in public places and purchased a medical alert bracelet that contained their contact information and Jonah's diagnosis.[6] Placing the bracelet on Jonah's wrist evoked problem behavior in the form of yelling, demanding the bracelet be removed, flopping on the floor, hitting people, biting his hand, and trying to remove the bracelet by pulling on it and shaking his wrist. Baseline consisted of 122 escape trials over 4 days. Each trial began with a therapist saying, "Jonah, it's time to wear your bracelet now," and placing the bracelet on Jonah's wrist. Contingent on problem behavior, the therapist immediately removed the bracelet for 30 seconds. When the escape period ended, the next trial began.

Each trial during the DNRO condition began with a therapist telling Jonah, "It's time to wear your bracelet now. If you can wait, I will take it off" (p. 903). The therapist placed the bracelet on Jonah's wrist and set a timer for the predetermined interval. If Jonah complied, the therapist simultaneously provided brief praise and removed the bracelet for the escape period. When the escape period ended, the next trial began. If Jonah was noncompliant, the therapist placed her hand over the bracelet to block his attempts to

remove it, described what Jonah needed to do to remove the bracelet (e.g., "Try to wait again with no yelling"), and reset the time to the current criterion wait time. The DNRO intervention began with a 5-second criterion for compliance time. Each time Jonah met criterion for five consecutive trials, the criterion was raised.

Jonah's mean latency to noncompliance during the escape baseline condition was 6 seconds (range 0 to 75 seconds) (see Figure 9.11; only the last 10 escape trials are plotted on the graph). Cook and colleagues (2015) described the sequence and magnitude of criterion changes and results:

> We introduced DNRO with a 5-s criterion and gradually increased the criterion to 60 s, which required 98 trials over 3 days. We then implemented DNRO with a 2-min criterion and extended the criterion to 45 min (middle panel); this increase required 64 trials over 5 days. We extended the duration that Jonah wore the bracelet from 1 hr to 7 hr in 37 trials over 12 days (bottom panel). Subsequently, therapists extended the intervention to Jonah's home and school (data available from the second author).
>
> Thereafter, apart from brief periods to allow for cleaning, Jonah reportedly wore the bracelet continuously for the next 2 years. (p. 905)

This study illustrates very well the changing criterion design's flexibility: the 21 criterion changes of magnitudes ranged from 5 seconds to 4 hours. Although one or more reversals to a previously attained criterion level may have provided a more convincing demonstration of experimental control (a limitation noted by the authors), the practical and ethical considerations of doing so would be questionable. As always, the applied behavior analyst must balance experimental concerns with the need to improve behavior in the most effective, efficient, ethical manner.

McDougall (2005) proposed a **range-bound changing criterion design** in which each intervention sub-phase includes both a lower and an upper criterion within which the participant

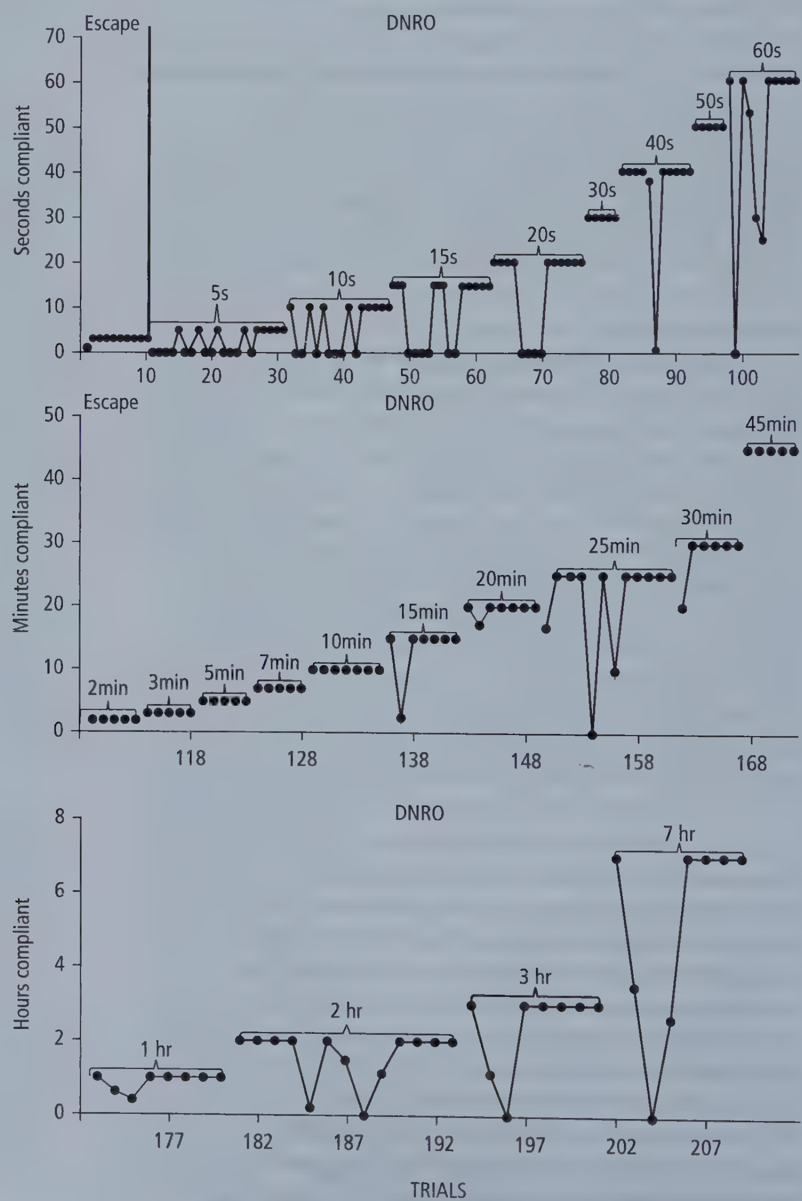

Figure 9.11 A changing criterion design showing how long an 8-year-old boy with autism complied with wearing a medical alert bracelet during baseline and differential negative reinforcement of other behavior (DNRO).

From "Differential Negative Reinforcement of Other Behavior to Increase Wearing of a Medical Bracelet," by J. L. Cook, J. T. Rapp, & K. A. Schulze, 2015, *Journal of Applied Behavior Analysis, 48,* p. 904. Copyright 2015 by the Society for the Experimental Analysis of Behavior, Inc. Reprinted by permission.

is expected to perform. McDougall suggested that behavioral "[i]mprovements as well as demonstrations of experimental control, are demonstrated definitively when the target behavior resides within, or conforms to, the pre-specified range" (p. 130). The author reported a study illustrating the design in which an overweight adult applied goal setting and self-graphing to increase minutes running each day (see Figure 9.12). After a 19-week baseline in which the participant ran on just 3 days, he established an initial aim of running an average of 20 minutes a day for 6 of 7 days of the week. He also created upper and lower ranges of ±10% of 20 minutes to serve as dual criteria for the minimum (18) and maximum (22) number of minutes he should run on any given day. When this aim was met, the participant increased his aim to 40 ± 4 minutes per day, then to 60 ± 6 minutes per day, and so on to a maximum of 100 ± 20 minutes per day, with one sub-phase reversing to lower criteria.

Compared to other single-case designs used in applied behavior analysis, relatively few studies using pure changing criterion designs have been reported (e.g., Allen & Evans, 2001; DeLuca & Holborn, 1992 [see Figure 13.2]; Foxx & Rubinoff, 1979; Kurti & Dallery, 2013; Wilson & Gratz, 2016). Some researchers have employed a changing criterion tactic as an analytic element within a larger experimental design (e.g., Martella, Leonard, Marchand-Martella, & Agran, 1993; Schleien, Wehman, & Kiernan, 1981).

Guidelines for Using the Changing Criterion Design

Proper implementation of the changing criterion design requires the careful manipulation of three design factors: length of phases, magnitude of criterion changes, and number of criterion changes. A survey of behavioral research literature published between 1971 and 2013 yielded 106 articles in 57 different journals reporting studies incorporating a changing criterion design (Klein, Houlihan, Vincent, & Panahon, 2017). The authors reported that just 25% of the graphs they reviewed met all necessary requirements for adequate experimental control. "Specifically, most studies lacked variation in phase magnitude (and did not compensate with a reversal), lacked variation in phase length, or implemented two or fewer changes in criterion; while some restricted responding so that criterions were forcibly met and or could not exceed the criterion" (p. 60).

Length of Phases

Because each phase in the changing criterion design serves as a baseline for comparing changes in responding measured in the next phase, each phase must be long enough to achieve stable responding. "Each treatment phase must be long enough to allow the rate of the target behavior to restabilize at a new and changed rate; it is stability after change has been achieved, and before introduction of the next change in criterion, that is crucial to producing a convincing demonstration of control" (Hartmann & Hall, 1976, p. 531). Target behaviors that are slower to change therefore require longer phases.

The length of phases in a changing criterion design should vary considerably to increase the design's validity. For experimental control to be evident in a changing criterion design, the target behavior not only must change to the level required by each new criterion in a predictable (preferably immediate) fashion, but also must conform to the new criterion for as long as it is in effect. When the target behavior

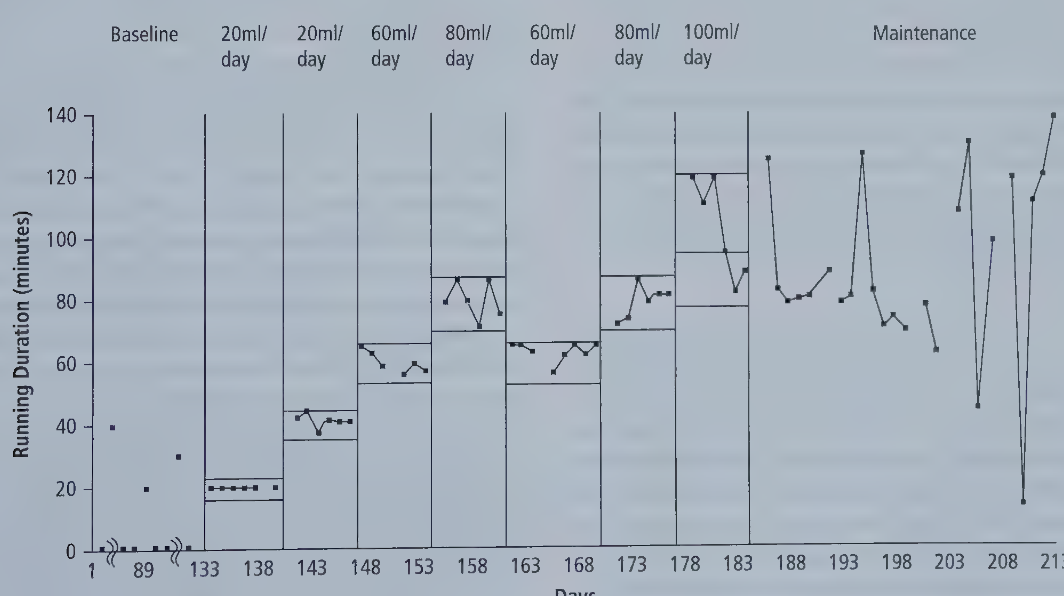

Figure 9.12 Example of a range-bound changing criterion design.

From "The Range-bound Changing Criterion Design," by D. McDougall, 2005, *Behavioral Interventions, 20,* p. 132. Copyright 2005 by John Wiley & Sons. Reprinted by permission.

closely follows successively more demanding criteria that are held in place for varied periods, the likelihood is reduced that the observed changes in behavior are a function of factors other than the independent variable (e.g., maturation, practice effects). In most situations, the investigator should not set a predetermined number of sessions for which each criterion level will remain in effect. It is best to let the data guide ongoing decisions, whether to extend the length of a current criterion phase or introduce a new criterion.

Magnitude of Criterion Changes

Varying the size of the criterion changes enables a more convincing demonstration of experimental control. When changes in the target behavior occur not only at the time a new criterion is implemented but also to the level specified by the new criterion, the probability of a functional relation is strengthened. In general, a target behavior's immediate change to meet a large criterion change is more impressive than a behavior change in response to a small criterion change. However, two problems arise if criterion changes are too large. First, setting aside practical considerations, and speaking from an experimental design standpoint only, large criterion changes may not permit inclusion of a sufficient number of changes in the design (the third design factor) because the terminal level of performance is reached sooner. The second problem is from an applied view: Criterion changes cannot be so large that they conflict with good instructional practice. Criterion changes must be large enough to be detectable, but not so large as to be unachievable. Therefore, the variability of the data in each phase must be considered in determining the size of criterion changes. Smaller criterion changes can be employed with very stable levels of responding, whereas larger criterion changes are required to demonstrate behavior change in the presence of variability.

When using a changing criterion design, behavior analysts must guard against imposing artificial ceilings (or floors) on the levels of responding that are possible in each phase. An obvious mistake of this sort would be to give a student only five math problems to complete when the criterion for reinforcement is five. Although the student could complete fewer than five problems, the possibility of exceeding the criterion has been eliminated, resulting perhaps in an impressive-looking graph, but one that is badly affected by poor experimental procedure.

Number of Criterion Changes

As a general rule, the more times the target behavior changes to meet new criteria, the more convincing the demonstration of experimental control. For example, eight criterion changes, one of which was a reversal to a previous level, were implemented in the changing design illustrated in Figure 9.10, and Cook et al. (2015) introduced 22 criterion changes in their study shown in Figure 9.11. Grey, Healy, Leader, and Hayes (2009) implemented 28 criterion changes in a study lasting 122 sessions. In both of these cases, a sufficient number of criterion changes occurred to demonstrate experimental control. The experimenter cannot, however, simply add any desired number of criterion changes to the design. Kratochwill and colleagues (2017) recommended a minimum of three criterion changes. The number of criterion changes that are possible within a changing criterion design is interrelated with the length of phases and the magnitude of criterion changes. Longer phases mean that the time necessary to complete the analysis increases; with a limited time to complete the study, the greater the number of phases, the shorter each phase can be.

Considering the Appropriateness of the Changing Criterion Design

The changing criterion design is a useful addition to the behavior analyst's set of tactics for evaluating systematic behavior change. Like the multiple baseline design, the changing criterion design does not require that behavioral improvements be reversed. However, partial reversals to earlier levels of performance enhance the design's capability to demonstrate experimental control. Unlike the multiple baseline design, only one target behavior is required.

Several characteristics of the changing criterion design limit its effective range of applications. The design can be used only with target behaviors already in the subject's repertoire and that lend themselves to stepwise modification. However, this is not as severe a limitation as it might seem. For example, students perform many academic skills to some degree, but not at useful rates. Many of these skills (e.g., solving math problems, reading) are appropriate for analysis with a changing criterion design. Allowing students to progress as efficiently as possible while meeting the design requirements of changing criterion analysis can be especially difficult. As Tawney and Gast (1984) noted, "the challenge of identifying criterion levels that will permit the demonstration of experimental control without impeding optimal learning rates" (p. 298) is problematic with all changing criterion designs.

Although the changing criterion design is sometimes suggested as an experimental tactic for analyzing the effects of shaping programs, it is not appropriate for this purpose. In shaping, a new behavior that initially is not in the person's repertoire is developed by reinforcing responses that meet a gradually changing criterion, called successive approximations, toward the terminal behavior (see Chapter 22). However, the changing response criteria employed in shaping are topographical in nature, requiring different forms of behavior at each new level. The multiple probe design is more appropriate for analyzing a shaping program because each new response criterion (successive approximation) represents a different response class whose frequency of occurrence is not wholly dependent on the frequency of behaviors meeting other criteria in the shaping program. Conversely, the changing criterion design is best suited for evaluating the effects of instructional techniques on stepwise changes in the rate, accuracy, duration, or latency of a single target behavior.

SUMMARY

Multiple Baseline Design

1. In a multiple baseline design, simultaneous baseline measurement is begun on two or more behaviors. After stable baseline responding has been achieved, the independent variable is applied to one of the behaviors while baseline conditions remain in effect for the other behavior(s). After maximum change has been noted in the first behavior, the independent variable is applied in sequential fashion to the other behaviors in the design.
2. Experimental control is demonstrated in a multiple baseline design by each behavior changing when, and only when, the independent variable is applied.
3. The multiple baseline design takes three basic forms: (a) a multiple baseline across behaviors design consisting of two or more different behaviors of the same subject; (b) a multiple baseline across settings design consisting of the same behavior of the same subject in two or more different settings; and (c) a multiple baseline across subjects design consisting of the same behavior of two or more different participants.

Variations of the Multiple Baseline Design

4. The multiple probe design is effective for evaluating the effects of instruction on skill sequences in which it is highly unlikely that the participant's performance on later steps in the sequence can improve without instruction or mastery of the earlier steps in the chain. The multiple probe design is also appropriate for situations in which prolonged baseline measurement may prove reactive, impractical, or too costly.
5. In a multiple probe design, intermittent measures, or probes, are taken on all of the behaviors in the design at the outset of the experiment. Thereafter, probes are taken each time the subject masters one of the behaviors or skills in the sequence. Just prior to instruction on each behavior, a series of baseline measures is taken until stability is achieved.
6. The delayed multiple baseline design provides an analytic tactic in situations in which (a) a planned reversal design is no longer desirable or possible; (b) limited resources preclude a full-scale multiple baseline design; or (c) a new behavior, setting, or subject appropriate for an ongoing multiple baseline analysis becomes available.
7. In a delayed multiple baseline design, baseline measurement of subsequent behaviors is begun sometime after baseline measurement began on earlier behaviors in the design. Only baselines begun while earlier behaviors in the design are still under baseline conditions can be used to verify predictions made for the earlier behaviors.
8. Limitations of the delayed multiple baseline design include the following: (a) The behavior analyst may have to wait too long to modify certain behaviors; (b) baseline phases may contain too few data points, and (c) baselines begun after the independent variable has been applied to earlier behaviors in the design can mask the interdependence (covariation) of behaviors.
9. The nonconcurrent multiple baseline across participants design consists of a series of A-B (baseline-intervention) sequences conducted across subjects at different points in time.
10. The nonconcurrent multiple baseline across participants design is inherently weaker than other multiple baseline design variations. The nonconcurrent design entails two of three elements of baseline logic—prediction and replication—but the absence of concurrent baseline measures does not enable verification of intervention effects.

Assumptions and Guidelines for Using Multiple Baseline Designs

11. Behaviors that are part of multiple baseline designs should be functionally independent (i.e., they do not covary) and share a reasonable likelihood that each will change when the independent variable is applied to it.
12. Behaviors in a multiple baseline design should be measured concurrently and have an equal opportunity of being influenced by the same set of relevant variables.
13. In a multiple baseline design, the independent variable should not be applied to the next behavior until the previous behavior has changed maximally and a sufficient period of time has elapsed to detect any effects on behaviors still in baseline conditions.
14. The length of the baseline phases for the different behaviors making up a multiple baseline design should vary significantly.
15. All other things being equal, the independent variable should be applied first to the behavior showing the most stable level or counter-therapeutic trend of baseline.
16. Conducting a reversal phase in one or more tiers of a multiple baseline design can strengthen the demonstration of a functional relation.

Considering the Appropriateness of Multiple Baseline Designs

17. Advantages of the multiple baseline design include the fact that (a) it does not require withdrawing a seemingly effective treatment; (b) sequential implementation of the independent variable parallels the practice of many teachers and clinicians whose task is to change multiple behaviors in different settings and/or subjects; (c) the concurrent measurement of multiple behaviors allows direct monitoring of generalization of behavior change; and (d) the design is relatively easy to conceptualize and implement.

18. Limitations of the multiple baseline design include the fact that (a) if two or more behaviors in the design covary, the multiple baseline design may not demonstrate a functional relation even though one exists; (b) because verification must be inferred from the lack of change in other behaviors, the multiple baseline design is inherently weaker than the reversal design in showing experimental control between the independent variable and a given behavior; (c) the multiple baseline design is more an evaluation of the independent variable's general effectiveness than an analysis of the behaviors involved in the design; and (d) conducting a multiple baseline design experiment requires considerable time and resources.

Changing Criterion Design

19. The changing criterion design can be used to evaluate the effects of a treatment on the gradual or stepwise improvement of a behavior already in the subject's repertoire.

20. After stable baseline responding has been achieved, the first treatment phase is begun, in which reinforcement is usually contingent on the subject performing at a specified level (criterion). The design entails a series of treatment phases, each requiring an improved level of performance over the previous phase. Experimental control is demonstrated when the subject's behavior closely conforms to the changing criteria.

21. In a range-bound changing criterion design, each intervention sub-phase includes both a lower and an upper criterion within which the subject is expected to perform.

22. Three features combine to determine the potential for a changing criterion design to demonstrate experimental control: (a) the length of phases, (b) the magnitude of criterion changes, and (c) the number of criterion changes. The believability of the changing criterion design is enhanced if a previous criterion is reinstated and the subject's behavior reverses to the level previously observed under that criterion.

Considering the Appropriateness of the Changing Criterion Design

23. Advantages of the changing criterion design are (a) it does not require a withdrawal or reversal of a seemingly effective treatment; and (b) it enables an experimental analysis within the context of a gradually improving behavior, thus complementing the goals of practitioners.

24. Limitations of the changing criterion design are (a) the target behavior must already be in the subject's repertoire, and (b) incorporating the necessary features of the design may impede optimal learning rates.

KEY TERMS

changing criterion design
delayed multiple baseline design
multiple baseline across behaviors design
multiple baseline across settings design
multiple baseline across subjects design
multiple baseline design
multiple probe design
nonconcurrent multiple baseline across participants design
range-bound changing criterion design

MULTIPLE-CHOICE QUESTIONS

1. Simultaneous measurement of two or more behaviors of a single participant describes which type of experimental design?

   a. Multiple baseline across behaviors
   b. Multiple baseline across settings
   c. Multiple baseline across subjects
   d. Multiple baseline across probes

   Hint: (See "Multiple Baseline Design")

2. In a multiple baseline design, the functional relationship between the independent variable and the change in the subject's behavior is determined by:

   a. Systematic introduction and withdrawal across phases
   b. Observation of unchanged behaviors in other tiers
   c. Observation of behavior change in the treated tier
   d. Replication of behavior change with each new criterion

   Hint: (See "Multiple Baseline Design")

3. Which experimental design is most appropriate for evaluating the effect of video modeling on the acquisition of the skills for preparing a meal by adults with developmental disabilities?
   a. Multiple baseline across behaviors
   b. Changing criterion
   c. Multiple probe
   d. Delayed multiple baseline

   Hint: (See "Variations of the Multiple Baseline Design")

4. All of the following are appropriate situations to use a delayed multiple baseline except:
   a. A planned reversal design is no longer possible
   b. The researcher has limited resources to conduct data collection
   c. A reversal design is too challenging to implement
   d. Additional subjects become available after the start of the study

   Hint: (See "Variations of the Multiple Baseline Design")

5. All of the following are advantages of the multiple baseline design except:
   a. Easy to conceptualize
   b. Lack of treatment withdrawal
   c. Mimics common practice of practitioners
   d. Takes less time to implement

   Hint: (See "Assumptions and Guidelines for Using Multiple Baseline Designs")

6. All of the following are limitations of the multiple baseline design except:
   a. It may not reveal the functional relationship, even if one exists
   b. Verification of predicted behavior change must be inferred from other behaviors.
   c. The behavior under study must be within the subject's repertoire already
   d. It is weaker than the reversal design

   Hint: (See "Assumptions and Guidelines for Using Multiple Baseline Designs")

7. When an intervention that is known to be effective is withheld from a subject for achieving a multiple baseline design, this presents a(n) ________ challenge for researchers.
   a. Practical
   b. Ethical
   c. Experimental
   d. Logical

   Hint: (See "Assumptions and Guidelines for Using Multiple Baseline Designs")

8. One method of addressing the practical concern of costly measurement when using a multiple baseline design across settings is to:
   a. Include only one setting in the study
   b. Reduce the number of baseline data points
   c. Use intermittent probes during baseline
   d. Use a changing criterion design instead of the multiple baseline

   Hint: (See "Assumptions and Guidelines for Using Multiple Baseline Designs")

9. When a subject's behavior changes each time a new criterion is introduced, this is an example of
   a. Prediction
   b. Function
   c. Replication
   d. Systematic manipulation

   Hint: (See "Changing Criterion Design")

10. Which of the following is not a design factor to be considered when using a changing criterion design?
    a. Length of phase
    b. Magnitude of behavior change
    c. Number of criterion changes
    d. Verification of behavior change

    Hint: (See "Guidelines for Using the Changing Criterion Design")

ESSAY-TYPE QUESTIONS

1. Explain how a researcher uses prediction and verification of behavior change in a multiple baseline across behaviors design.

   Hint: (See "Multiple Baseline Design")

2. Identify the three types of multiple baseline designs and give an example of when each is appropriate.

   Hint: (See "Multiple Baseline Design")

3. Briefly describe how prediction and replication are demonstrated in the changing criterion design.

   Hint: (See "Operation and Logic of the Changing Criterion Design")

4. Describe the five guidelines for using a multiple baseline design.

   Hint: (See "Assumptions and Guidelines for Using Multiple Baseline Designs")

5. Describe a situation in which the most ethical experimental design would be the multiple probe design.

   Hint: (See "Variations of the Multiple Baseline Design")

NOTES

1. Although most of the graphic displays created or selected for this text as examples of experimental design tactics show data plotted on noncumulative vertical axes, the reader is reminded that repeated measurement data collected within any type of experimental design can be plotted with a variety of graphic displays. For example, Lalli, Zanolli, and Wohn (1994) and Mueller, Moore, Doggett, and Tingstrom (2000) used cumulative graphs to display the data they collected in multiple baseline design experiments; and Raiff, Jarvis, and Dallery (2016) presented the results of a multiple baseline design experiment with a graphic display consisting of a horizontal sequence of boxes in different shades to illustrate participants' performances during baseline and treatment conditions. Students of applied behavior analysis should be careful not to confuse the different techniques for graphically displaying data with tactics for experimental analysis.
2. Functional analysis and automatic reinforcement are described in Chapters 11 and 27, respectively.
3. Time delay, a procedure for transferring stimulus control from a response prompt (e.g., teacher says "apple" while pointing to an apple) to a natural stimulus (e.g., an apple), is described in Chapter 17.
4. In most of these studies, the experimental designs were described as multiple probe designs. However, the graphic displays show that baselines were added in a time-delayed fashion.
5. *Hypothesis*, as we are using the term here, should not be confused with formal hypothesis testing models that use inferential statistics to confirm or reject a hypothesis deduced from a theory. As Johnston and Pennypacker (2009) pointed out, "Researchers do not need to state hypotheses if they are asking a question about nature. When the experimental question simply asks about the relation between independent and dependent variables, there is no scientific reason to make a prediction about what will be learned from the data. Whatever is learned will describe something about that relationship that was presumably not known before. Whether it matches anyone's expectations has nothing to do with its truth or importance (Sidman)." (p. 50)
6. Negative reinforcement and differential reinforcement of other behavior (DRO) are detailed in Chapters 12 and 25, respectively.

CHAPTER 10

Planning and Evaluating Applied Behavior Analysis Research

LEARNING OBJECTIVES

- Explain the importance of the individual subject in behavioral research.
- Explain the importance of flexibility when designing experiments.
- Identify and design systems for evaluating internal validity.
- Identify and design systems for evaluating social validity.
- Identify and design systems for monitoring external validity.
- Explain the importance of evaluating applied behavior analysis research.

Previous chapters outlined considerations and procedures for selecting and defining target behaviors, detailed strategies for designing and implementing measurement systems, presented guidelines for displaying and interpreting behavioral data, and described experimental tactics for revealing whether observed changes in behavior can be attributed to an intervention. This chapter supplements the information described thus far by examining additional questions and considerations that should be addressed when designing, replicating, and evaluating behavioral research. We begin by reviewing the central role of the individual subject in behavioral research, and follow with discussions of the value of flexibility in experimental design, how researchers using single-subject and between-groups designs pursue internal and external validity, and the importance and means of assessing the applied value of treatments and the behavior changes they bring about. The chapter concludes with suggestions for evaluating the believability and usefulness of research in applied behavior analysis.

IMPORTANCE OF THE INDIVIDUAL SUBJECT IN BEHAVIOR ANALYSIS RESEARCH

The research methods of any science must match the defining characteristics of that science's subject matter. Behavior analysis—a science devoted to discovering and understanding the controlling variables of *behavior*—defines its subject matter as the activity of living organisms, a dynamic phenomenon that occurs at the level of the individual organism. It follows that behavior analysis research methods feature direct and repeated measures of the behavior of individual organisms (the only place, by definition, where behavior takes place). This focus on the behavior of individual subjects has enabled applied behavior analysts to discover and refine effective assessment tools and interventions for a wide range of socially significant behavior.

To further explain the importance this focus on the individual subject or client holds for applied behavior analysis, we contrast it with a research model that compares data representing the aggregate measures of different groups of subjects. This between-groups approach to experimental design has predominated "behavioral research" in psychology, education, and other social sciences for decades.

Brief Outline of a Between-groups Experiment

The basic format of a between-groups experiment is as follows.

1. A pool of subjects (e.g., 60 first-grade nonreaders) is selected randomly from the population (e.g., all first-grade nonreaders in a school district) relevant to the research question (e.g., Will the XYZ intensive phonics program improve first-grade nonreaders' ability to decode unpredictable text?).
2. The subjects are divided randomly into two groups: the experimental group and the control group.
3. An initial measure (pretest) of the dependent variable (e.g., score on a test of decoding skills) is obtained for all subjects in the study, the individual pretest scores for the subjects in each group are combined, and the mean and standard deviation are calculated for each group's performance on the pretest.
4. Subjects in the experimental group are then exposed to the independent variable (e.g., 6 weeks of the XYZ program), which is not provided to subjects in the control group.
5. After the treatment program has been completed, a posttest measure of the dependent variable is obtained for all subjects, and the mean and standard deviation posttest scores for each group are computed.[1]
6. The researcher compares any changes in each group's scores from pretest to posttest, applying various statistical tests to the data that enable inferences regarding the likelihood that any differences between the two

groups' performances can be attributed to the independent variable. For example, assuming the mean pretest scores for the experimental and control groups were similar, and the posttest revealed an improved score for the experimental group but not for the control group, statistical analyses would indicate the mathematical probability that the difference was due to chance. When a statistical test limits the role of chance to a predetermined acceptable degree—usually 5% (1 chance in 20) or 1% (1 chance in 100)—the researcher concludes that the independent variable was responsible for changes to the dependent variable (e.g., the experimental group's improvement from pretest to posttest).[2]

Researchers who compare measures of groups of subjects in this way do so for two primary reasons, each of which was introduced in Chapter 7. First, the assumption that averaging the measures of many subjects' performance controls for intersubject variability enables the belief that any changes in performance are brought about by the independent variable. A second rationale for large groups of subjects is the notion that increasing the number of subjects increases the study's external validity. That is, a treatment variable found effective with the subjects in the experimental group will also be effective with other subjects in the population from which the sample subjects were selected.

In the next section we comment on the first reason for the use of groups of subjects—that doing so controls for intersubject variability. We identify four fundamental concerns with typical between-groups designs that bear heavily on experimental reasoning. The assumption of increased generality of findings is discussed later in this chapter in the section on replication.[3]

Group Data May Not Represent the Performance of Individual Subjects

Knowing that the average performance of a group of subjects changed may reveal nothing about the performance of individual subjects. The average performance of subjects in the experimental group may improve, while the performance of some subjects in the group stayed the same, and the performance of others deteriorated. It is even possible for the majority of subjects to show no improvement, for some subjects to get worse, and for a few subjects to improve sufficiently to yield an overall average improvement.

Between-groups studies can show that a treatment is generally effective, that no treatment works with everyone, that people respond differently to the same treatment, and so on. However, the fact that the average performance of a group of subjects improved when they were exposed to a treatment is insufficient reason to adopt it. The factors responsible for one subject's improvement and another's lack of improvement must be discovered. To be most useful, a treatment must be understood at the level at which people contact it and are affected by it: the individual level.

The two graphs in Figure 10.1 illustrate some of the faulty conclusions possible when interpreting a study on the basis of group mean scores. Each graph presents hypothetical data for a two-subject group. The group data showing no change from pretest to posttest in both graphs suggest that the independent variable had no effect on the subjects' behavior. However, the left-hand graph in Figure 10.1 shows that Subject A's performance improved from pretest to posttest while Subject B's behavior deteriorated over the same period.[4] The right-hand graph shows identical pre- and posttest measures for Subjects C and D, while repeated measures between the pretest and posttest reveals significant variability within and between the two subjects.

Group Data Mask Variability

A second problem associated with the mean performance of a group of subjects is that it hides variability in the data. Even if repeated measures of Subject C's and Subject D's behavior between the pre- and posttest had been conducted as shown in Figure 10.1, a researcher who relied on the group's mean performance as the primary indicator of behavior change would be ignorant of the variability that occurred within and between subjects.

When repeated measurement reveals significant levels of variability, an experimental search with the goal of identifying and controlling the factors responsible for the variability is in order. The widespread belief that the effects of uncontrolled variables in a study can be controlled by statistical manipulation of the dependent variable is faulty.

> Statistical control is never a substitute for experimental control. . . . The only way to determine whether or not uncontrolled variables are influencing the data is to inspect the data at the finest available level of decomposition,

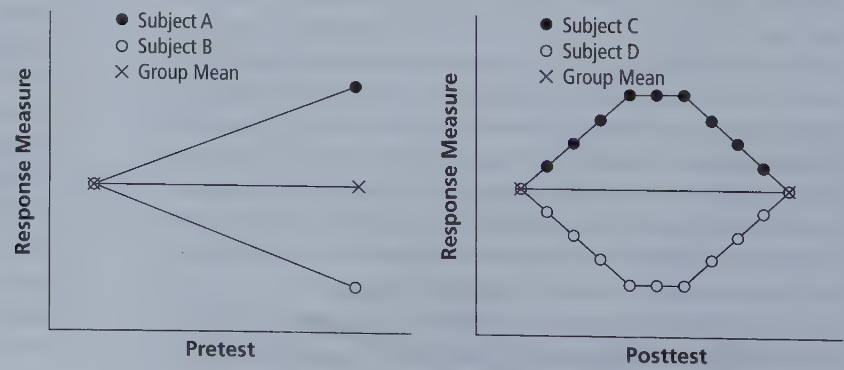

Figure 10.1 Hypothetical data showing that the mean performance of a group of subjects may not represent the behavior of individual subjects.

> usually point-by-point for each individual subject. No purpose is served by combining the data statistically to obscure such effects. (Johnston & Pennypacker, 1980, p. 371)

Attempting to "cancel out" variability through statistical manipulation neither eliminates it nor controls the variables responsible for it. And the researcher who attributes the effects of unknown or uncontrolled variables to chance forgoes the opportunity to identify and analyze important variables. In his monumental work *Tactics of Scientific Research*, Sidman (1960) dealt repeatedly and forcefully with this critical issue.

> To some experimenters, chance is simply a name for the combined effects of uncontrolled variables. If such variables are, in fact, controllable, then chance in this sense is simply an excuse for sloppy experimentation, and no further comment is required. If the uncontrolled variables are actually unknown, then chance is, as Boring (1941) has pointed out, a synonym for ignorance. . . . One of the most discouraging and at the same time challenging aspects of behavioral science is the sensitivity of behavior to a tremendous array of variables. . . . But variables are not canceled statistically. They are simply buried so that their effects cannot be seen. The rationale for statistical immobilization of unwanted variables is based on the assumed random nature of such variables. . . . Not only is the assumption of randomness with respect to the uncontrolled variables an untested one but it is also highly improbable. There are few, if any, random phenomena in the behavioral world. (pp. 45, 162–163)

Sidman (1960) also commented on an experimenter's use of statistics in an attempt to deal with troublesome sequence effects.

> He has a neat trick up his sleeve. By averaging together the data for both subjects under Condition A, and again under Condition B, he "cancels out" the order effect, and completely bypasses the problem of irreversibility. By a simple arithmetical operation, two subjects have become one, and a variable has been eliminated.
>
> It has not, in fact, gone anywhere. Numbers may be made to disappear by adding and subtracting them from each other. Five apples minus three apples are two apples. The numbers are easily changed by a few strokes of the pen, but some eating has to be done before the apples themselves will vanish. (p. 250)

The "eating" that must be done to control the effects of any variable can be accomplished in only two ways: (a) holding the variable constant throughout the experiment, or (b) isolating the suspected factor as an independent variable and manipulating its presence, absence, and/or value during the experiment.

Group Data Do Not Represent Real Behavioral Processes

Skinner (1938) contended that researchers must demonstrate behavior–environment relations at the level of the individual organism or risk discovering synthetic phenomena that represent mathematical, not behavioral, processes. Sidman (1960) described the challenges faced by an investigator interested in the relation between the number of times a behavior is reinforced during initial acquisition and responding during a subsequent extinction condition. A single-case approach would entail presenting an individual subject with a series of acquisition-extinction events, each acquisition condition consisting of a different number of reinforcements. The subject's performance during each successive extinction phase would be confounded by the subject's experience with all previous reinforcement-then-extinction events. Behavior during extinction would decrease to zero more rapidly as a function of that cumulative experience, rather than the number of reinforcements obtained in the acquisition phase immediately prior to each extinction test.

A between-groups design solution to the problem that no individual subject can be exposed to differing amounts of reinforcement during an initial acquisition phase would be to assign multiple subjects to different groups, expose subjects in each group to different values of the independent variable (e.g., 5, 10, and 20 reinforcements), and compare the mean rate of responding by subjects in each group during a subsequent extinction condition. Such a design may reveal a relation between number of reinforcements during initial acquisition and responding during extinction, but . . .

> The function does not represent a behavioral process. The use of separate groups destroys the continuity of cause and effect that characterizes an irreversible behavioral process. . . . If it proves impossible to obtain an uncontaminated relation between the number of reinforcements and resistance to extinction in a single subject, because of the fact that successive extinctions interact with each other, then the "pure" relation simply does not exist. The solution is . . . to direct our research toward the study of behavior as it actually exists . . . [and] not be deceived into concluding that the group type of experiment in any way provides a more adequately controlled or more generalizable substitute for individual data. (Sidman, 1960, p. 53)

Acknowledging that studies comparing group data describe "some kind of order in the universe" and may form the basis of a science, Sidman (1960) noted they:

> cannot, however, be a science of individual behavior except of the crudest sort. . . . It is a science of averaged behavior of individuals who are linked together only by the averaging process itself. Where this science fits in the scheme of natural phenomena is a matter of conjecture. My own feeling is that it belongs to the actuarial statistician, and not the investigator of behavior processes. (pp. 274–275)

Between-groups Designs Lack Intrasubject Replication

A fourth weakness of the between-groups research model is that the power of replicating effects within and across individual subjects is lost. One of the great strengths of single-case experimental designs is the convincing demonstration of functional relations made possible by replication of treatment effects within the designs. Although multiple subjects typically participate in

single-case studies and investigators often describe and display the data for all subjects as a group, data from individual subjects are the basis for interpreting experimental effects. Applied behavior analysts are wise to heed Johnston and Pennypacker's (1980) admonition: "An effect that emerges *only* after individual data have been combined is probably artifactual and not representative of any real behavioral processes" (p. 257).

This discussion should not be interpreted to mean that the overall performance of groups of subjects cannot, or should not, be studied with the research strategies and tactics of applied behavior analysis. Improving overall performance of a group is socially significant in many applied situations (Donaldson, Fisher, & Kahng, 2017; Friman, Finney, Rapoff, & Christophersen, 1985; Luyben, 2009). Brothers, Krantz, and McClannahan (1994) used a multiple baseline across three settings to evaluate an intervention that increased the number of pounds of office paper recycled by 25 school staff members. Cope, Allred, and Morsell (1991) employed a multiple treatment reversal design to reveal which of three experimental conditions most effectively reduced illegal parking by drivers of 558 vehicles in spaces designated for individuals with disabilities at a supermarket.

Still, it is important to remember that group data may not represent the performance of individual participants, and vice versa. Lloyd, Eberhardt, and Drake (1996) compared the effects of group versus individual reinforcement contingencies within the context of collaborative group study conditions on quiz scores by students in a Spanish language class. The results showed that the group contingencies resulted in higher mean quiz scores for the class as a whole compared to the individual contingencies condition. However, overall benefits at the class level were mitigated by differential results for individual students. When group results do not represent individual performances, researchers should supplement group data with individual results, ideally in the form of graphic displays (e.g., Lloyd et al., 1996; Ryan & Hemmes, 2005).

In some instances, the behavior analyst may not be able to control potential subjects' access to the experimental setting and contingencies or even be able to identify who the subjects are. The dependent variable must then consist of responses emitted by individuals who enter the experimental setting. This approach is used frequently in community-based behavior analysis research. For example, group data have been collected and analyzed on such dependent variables as recycling on a university campus (O'Conner, Lerman, & Fritz, 2010), car pooling by university students (Jacobs, Fairbanks, Poche, & Bailey, 1982), motorists yielding at pedestrian crosswalks (Crowley-Koch, Van Houten, & Lim, 2011), the use of child safety belts in shopping carts (Barker, Bailey, & Lee, 2004), and reducing graffiti on restroom walls (Watson, 1996).

IMPORTANCE OF FLEXIBILITY IN EXPERIMENTAL DESIGN

On one level, an effective experimental design is any sequence of independent variable manipulations that produces data that are interesting and convincing to the researcher and the audience. In this context *design* is appropriate as a verb as well as a noun; the effective behavioral researcher must actively *design* each experiment so that each achieves its own unique *design*. The prototype designs presented in Chapters 8 and 9 are examples of analytic tactics that afford a form of experimental reasoning and control that has proven effective in advancing the scientific understanding of a wide range of phenomena of interest to applied behavior analysts.

An investigator should not fall into the trap of believing that a certain type of research question, treatment, behavior, or setting indicates which analytic tactic(s) should be employed. While the experimental designs in published studies exploring similar research questions should be mined for methodological ideas, no ready-made experimental designs await selection, nor is there a set of rules that must be followed. Sidman (1960) was adamant in his warning regarding the undesirable effects of researchers' believing in the existence of a given set of rules for experimental design.

> The examples may be accepted as constituting a set of rules that must be followed in the design of experiments. I cannot emphasize too strongly that this would be disastrous. I could make the trite statement that every rule has its exception, but this is not strong enough. Nor is the more relaxed statement that the rules of experimental design are flexible, to be employed only where appropriate. The fact is that *there are no rules of experimental design*. (p. 214)

We agree with Sidman. The student of applied behavior analysis should not be led to believe that any of the analytic tactics described in Chapters 8 and 9 constitute experimental designs per se.[5] Still, we believe that it is useful to present the most commonly used analytic tactics in design form for two reasons. First, the vast majority of studies that have advanced the knowledge base of applied behavior analysis have used experimental designs featuring one or more of these analytic tactics. Second, we believe examining specific examples of isolated experimental tactics and their application is an important step in learning the assumptions and strategic principles that guide the selection and arrangement of analytic tactics into experimental designs that effectively and convincingly address the research questions at hand.

Experimental Designs Combining Analytic Tactics

An experimental design that combines analytic tactics may allow a more convincing demonstration of experimental control than a design using a single analytic tactic. For example, withdrawing the treatment variable (a return to baseline) and then reapplying it within one or more tiers in a multiple baseline design may enable the researcher to determine the existence of a functional relation between the independent variable and each behavior, setting, or subject of the multiple baseline, in addition to analyzing the effectiveness of the independent variable across the tiers (e.g., Barker et al., 2004; Donaldson et al., 2017; Heward & Eachus, 1979; Miller & Kelley, 1994 [see Figure 28.14]; Zhou, Goff, & Iwata, 2000).

Whereas a design with a single analytic tactic may function like a belt that effectively holds up a pair of jeans, a design

that combines analytic tactics is akin to adding a pair of suspenders that more firmly answers the research or adds a bit of stylistic flair. However, beginning researchers should not assume that designs with multiple tactics are inherently better than single-tactic designs. A design featuring multiple analytic tactics may be weaker than a single-tactic design, if the additional analytic tactics overshadow the powerful answer provided by data with a simple, yet elegant single-tactic design.

Experimental designs combining multiple baseline, reversal, and/or multielement tactics can provide the basis for comparing the effects of two or more independent variables. Haring and Kennedy (1990) used multiple baseline across settings and reversal tactics in an experiment comparing the effectiveness of time-out and differential reinforcement of other behavior (DRO) on the occurrence of problem behaviors by two secondary students with severe disabilities (see Figure 10.2).[6] Sandra and Raff each frequently engaged in repetitive, stereotypic problem behaviors (e.g., body rocking, loud vocalizations, hand flapping, spitting) that interfered with classroom and community activities. In addition to assessing the effects of the time-out and DRO interventions against a no-treatment baseline condition, the design also enabled the researchers to conduct two comparisons of the relative effects of each treatment during an instructional task and leisure context. The design enabled Haring and Kennedy to discover that the time-out and DRO interventions produced different outcomes depending on the activity context in which they were applied. For both students, DRO was more effective than time-out in suppressing problem behavior in the task context; the opposite results were obtained in the leisure context, where time-out suppressed problem behavior and DRO proved ineffective.

Experimenters have also incorporated alternating treatments into experimental designs containing multiple baseline elements. For example, Ahearn, Kerwin, Eicher, Shantz, and

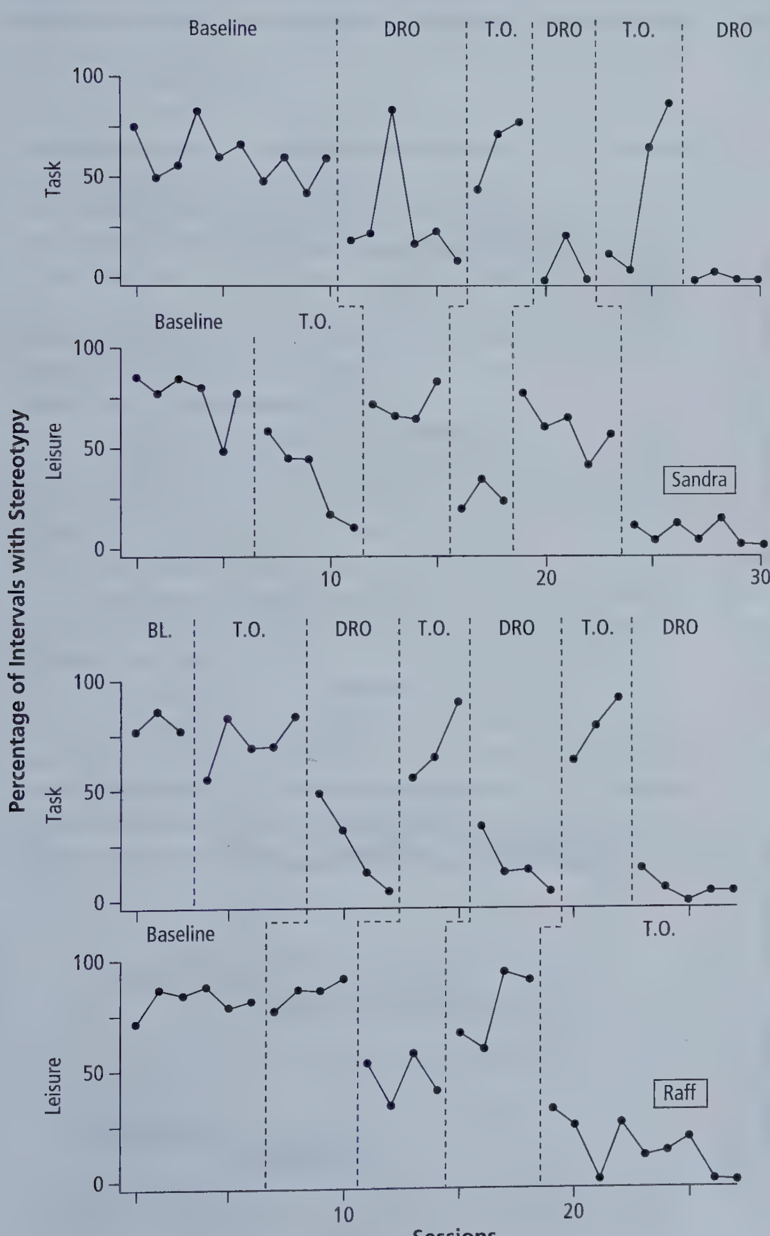

Figure 10.2 Experimental design employing multiple baselines across settings and reversal tactics counterbalanced across two subjects to analyze the effects of time-out (TO) and differential reinforcement of other behavior (DRO) treatment conditions.

Based on "Contextual Control of Problem Behavior" by T. G. Haring and C. H. Kennedy, 1990, *Journal of Applied Behavior Analysis*, *23*, pp. 239–240. Copyright 1990 by the Society for the Experimental Analysis of Behavior, Inc.

Swearingin (1996; see Figure 12.5) evaluated the relative effects of two treatments for food refusal in an alternating treatments design implemented in a multiple baseline across subjects format. Likewise, Mcgee Krantz, and McClannahan (1985) evaluated the effects of several procedures for teaching language to children with autism with an experimental design that incorporated alternating treatments within a multiple baseline across behaviors component that was, in turn, nested within an overall multiple baseline across subjects format. Zanolli and Daggett (1998) investigated the effects of reinforcement rate on the spontaneous social initiations of socially withdrawn preschoolers with an experimental design consisting of multiple baseline, alternating treatments, and reversal tactics.

Sisson and Barrett (1984) incorporated multiple probe, multielement, and a multiple baseline across behaviors tactics in a design comparing the effects of two language-training procedures (see Figure 10.3). The design enabled the investigators to discover the superiority of the total communication method for these two children, as well as the fact that direct application of the treatment was required for learning to occur on specific sentences. Results for a third subject revealed a functional relation of the same form and direction as that found for the two children whose results are shown in Figure 10.3, but one not so strongly in favor of the total communication procedure.

Component Analyses

When a behavioral intervention consists of multiple components, it is termed a **treatment package**. An effective toilet training program, for example, might entail replacing diapers with underwear or training pants, a schedule of sitting on the toilet for various durations, increased fluid intake, reinforcement for proper eliminations, and contingencies for accidents (Greer, Neibert, & Dozier, 2016 [see Figure 6.7]). Multicomponent interventions are common for treating complex feeding disorders. Treatment packages for food packing (holding or pocketing food in the oral cavity without swallowing) have included combinations of the following components: presenting highly preferred food on the spoon behind a bite of previously packed food; removing packed food and placing it on the child's tongue; a liquid chaser; inserting food

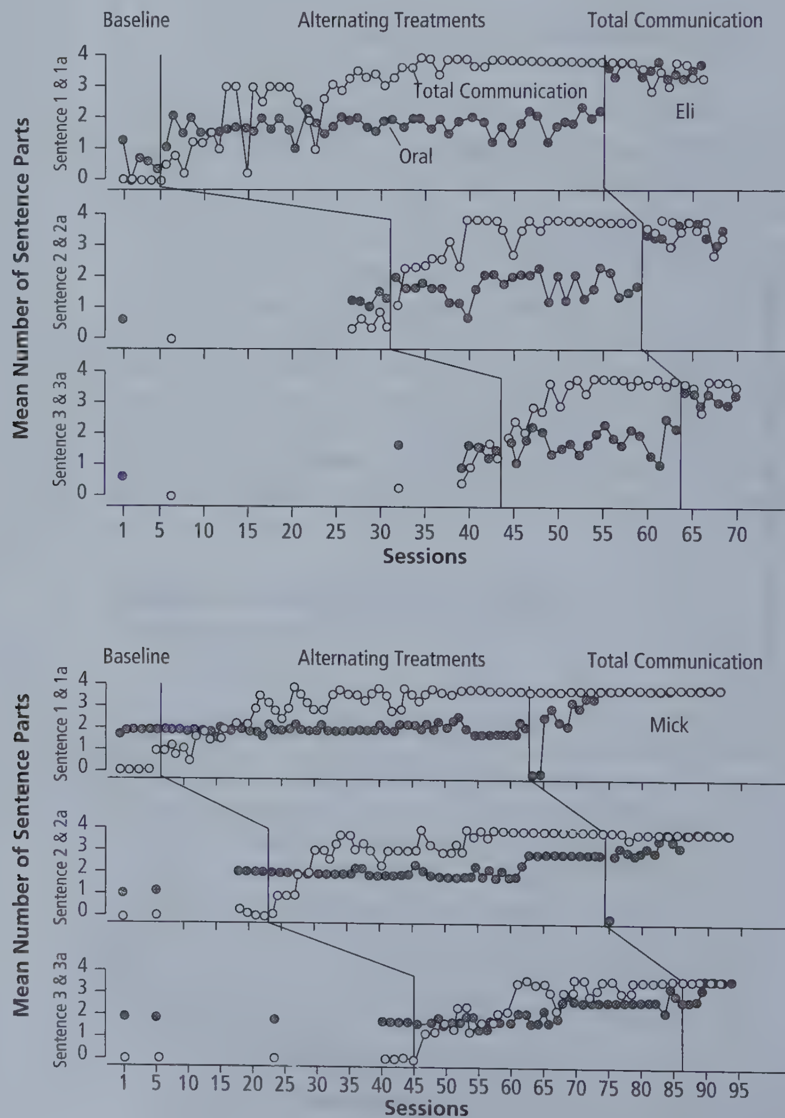

Figure 10.3 Experimental design employing a multiple probe, multielement, and multiple baseline analytic tactics.

"Alternating Treatments Comparison of Oral and Total Communication Training with Minimally Verbal Retarded Children", L. A. Sisson and R. P. Barrett, 1984, *Journal of Applied Behavior Analysis*, *17*, p. 562. Reproduced with permission of John Wiley & Sons Inc.

into the child's mouth with a spoon, then flipping the spoon 180° and dragging the bowl of the spoon toward the lips to deposit the food on the child's tongue; removing packed food with a spoon; facilitating swallowing with a light touch on the tongue's posterior; response cost for packing or expulsion; and various forms of positive reinforcement (e.g., preferred toy) and negative reinforcement (e.g., break from feeding) for swallows (Levin, Volkert, & Piazza, 2014; Sharp, Odom, & Jaquess, 2012).

Practitioners and researchers create, implement, and evaluate treatment packages for many reasons. Here are several: A practitioner may believe two or more research-based interventions will be more effective than any of the component interventions in isolation. Interventions consisting of multiple components may be effective across a wider range of settings or participant characteristics. An intervention known to be mildly effective in isolation may, when implemented in conjunction with other research-based interventions, yield an additive, value-enhancing effect. In an effort to change a behavior that has resisted numerous interventions, a practitioner might combine some or all of the failed interventions, perhaps adding new ones, into a treatment package.

When desired behavior change coincides with or follows implementation of a treatment package, an analysis of whether or not a functional relation exists between the package and behavioral improvement is in order. Other important questions can then be pursued: Must every component of a treatment package be implemented to achieve clinically meaningful behavior change? If not, which components are necessary? Is one component, or a subset of components, sufficient to bring about behavior change? How does the presence or absence of each component impact overall effectiveness?

A **component analysis** is any experiment designed to identify the active elements of a treatment package, the relative contributions of different components in a treatment package, and/or the necessity and sufficiency of treatment components. The effectiveness of a treatment package requires the presence of all *necessary* components. A *sufficient* component, or subset of components, ensures treatment effectiveness in the absence of any other components.

In their review of component analyses using single-subject experimental designs, Ward-Horner and Sturmey (2010) described the potential outcomes of component analyses using reversal designs of a treatment package consisting of two components (Y and Z). In their hypothetical examples shown in Figure 10.4, Component Y is praise and Component Z is a primary reinforcer.

> *Outcome 1* suggests that Y is necessary and sufficient, because Y is effective whether or not Z is present.
> *Outcome 2* suggests an *additive effect* because the sum of the components produced behavior changes greater than either component alone.
> *Outcome 3* illustrates a *multiplicative effect* because neither Y nor Z is effective in isolation, but the combination of these components produces substantial behavior change.
> *Outcome 4* indicates components Y and Z are sufficient but neither component is necessary, whereas Outcomes 2 and 3 indicate that neither Component Y nor Component Z is sufficient but both are necessary.
> *Outcome 5* is challenging to interpretations: (a) the possibility that presenting the components together establishes relations between or among themselves that influence subsequent effects when presented alone; (b) perhaps Y is effective only because of its prior presentation with Z; or (c) Y may be effective only when preceded by Z, but Y may be ineffective when it precedes Z. (Adapted from Ward-Horner & Sturmey, 2010, p. 687)

Ward-Horner and Sturmey (2010) described two methods for conducting component analyses. In a **drop-out component analysis**, the investigator presents the treatment package and then systematically removes components. If the treatment's effectiveness wanes when a component is removed, the researcher has identified a necessary component.

> The main advantage of this approach is that the target behavior will improve immediately, within the first or second experimental phase, and that the subsequent removal of components may provide information on the components necessary to maintain treatment goals (L. J. Cooper et al., 1995). One disadvantage is that the behavioral effects of combining components might mask the effectiveness of individual components, which makes it difficult to determine the necessity and sufficiency of components. (p. 687)

A drop-out analysis by Wacker and colleagues (1990) revealed that both components of a training package consisting of functional communication training and consequences for inappropriate behavior were necessary for three individuals with severe disabilities and behavior problems.

An **add-in component analysis** assesses components individually or in combination before the complete treatment package is presented. The add-in method can identify sufficient components. Ward-Horner and Sturmey (2010) noted that sequence and floor or ceiling effects may mask the effects of components added in toward the end of the analysis.

After data from a reversal design demonstrated the effectiveness of a treatment package of noncontingent reinforcement, response cost, and response blocking for wearing prescription glasses by three individuals with intellectual disabilities, DeLeon and colleagues (2008) used add-in or drop-out and component analyses to determine which components were sufficient and/or necessary for each participant.

Our intent in describing several experiments that combined analytic tactics or analyzed the relative effects of treatment components is not to offer any of these studies as model designs. They are presented instead as illustrations of the infinite number of experimental designs that are possible by arranging different combinations and sequences of independent variable manipulations. In every instance the most effective (i.e., convincing) experimental designs are those that use an ongoing evaluation of data from individual subjects as the basis for employing the three elements of baseline logic—prediction, verification, and replication.

INTERNAL VALIDITY: CONTROLLING POTENTIAL SOURCES OF CONFOUNDING IN EXPERIMENTAL DESIGN

An experiment is interesting and convincing, and yields the most useful information for application, when it provides an unambiguous demonstration that the independent variable was solely responsible for the observed behavior change. Experiments that demonstrate a clear functional relation have a high degree of internal validity. An experimental design's strength is determined by the extent to which it (a) demonstrates a reliable effect (i.e., repeated manipulation of the independent variable produces a consistent pattern of behavior) and (b) eliminates or reduces the likelihood that factors other than the independent variable produced the behavior change (i.e., controls for confounding variables).

Implicit in the term *experimental control*, which is often used to signify a researcher's ability to reliably produce a specified behavior change by manipulating an independent variable, is the idea that the researcher controls the subject's behavior. However, "control of *behavior*" is inaccurate because the experimenter can control only some aspect of the subject's *environment*. Therefore, the level of experimental control obtained by a researcher refers to the extent to which she controls all relevant variables in a given experiment. The researcher exerts this control within the context of an experimental design that, even though carefully planned at the outset, takes its ultimate form from the researcher's ongoing examination and response to the data.

As noted in Chapter 7, an effective experimental design simultaneously reveals a reliable functional relation between independent and dependent variables (if one exists) and minimizes the likelihood that the observed behavior changes are the result of unknown or uncontrolled variables. An experiment has high internal validity when changes in the dependent variable are demonstrated to be a function only of the independent variable. When planning an experiment and later when examining the data from an ongoing study, the investigator must always be alert to threats to internal validity. Uncontrolled factors known or suspected to have exerted influence on the dependent variable are called *confounding variables* (see Chapter 7). Much of a researcher's efforts during the course of a study are aimed at identifying and controlling confounding variables.

The attainment of steady state responding is the primary means by which applied behavior analysts assess the degree of experimental control. Separating the effects of the independent variable from the effects of a potentially confounding variable requires clear, empirical evidence that the potentially confounding variable is no longer present, has been held constant across experimental conditions, or has been isolated for manipulation as an independent variable. Any experiment can be affected by a nearly unlimited number of potential confounds; and as with every aspect of experimental design, there are no set rules for identifying and controlling confounding variables to which researchers can turn. However, common and likely sources of confounding can be identified as well as tactics that can be considered to control them. Confounding variables can be viewed as related primarily to one of four elements of an experiment: subject, setting, measurement of the dependent variable, and independent variable.

Subject Confounds

A variety of subject variables can confound the results of a study. *Maturation*, which refers to changes that take place in a subject over the course of an experiment, is a potential confounding variable. For example, a subject's improved performance during the later phases of a study may result from physical growth or the acquisition of academic, social, or other behaviors and may be unrelated to manipulations of the independent variable. Experimental designs that incorporate rapidly changing conditions or multiple introductions and withdrawals of the independent variable over time usually control for maturation effectively.

In most applied behavior analysis research, a subject is in the experimental setting and contacting the contingencies implemented by the investigator for only a portion of the day. As in any study, the assumption is made that a subject's behavior during each session will be primarily a function of the experimental conditions in effect. In reality, however, a subject's behavior may also be influenced by events that occur outside the experiment. For example, suppose that the rate of contributions to a class discussion is the dependent variable. Now suppose that a student who has been contributing to discussions at a high rate gets into a fight in the lunchroom just prior to a session and then emits substantially fewer contributions compared to his level of responding in previous sessions. This change in the student's behavior may, or may not, be a result of the lunchroom fight. If the lunchroom fight coincided with a change in the independent variable, it would be especially difficult to detect or separate any effects of the experimental conditions from those of the extra-experimental event.

Although the researcher may be aware of some events that are likely causes of variability during a study, many other potential confounds go undetected. Repeated measurement is both the control for and the means to detect the presence and effects of such variables. The uncontrolled variables responsible for a subject's having a "bad day" or an unusually "good day" are particularly troublesome in research designs with few and/or widely spaced measurements of the dependent variable. This is one of the major weaknesses of using data from pretest-posttest comparisons to evaluate the effects of a treatment program.

Because between-groups experiments are predicated on subjects' similarity in relevant characteristics (e.g., gender, age, ethnicity, cultural and linguistic background, current skills and background knowledge), they are vulnerable to confounding by differences among subjects. Concern that the characteristics of one or more subjects may confound an experiment's results is generally not an issue in the single-case experiments. First, a person should participate in a study because she will benefit if the target behavior is changed successfully. Second, a subject's idiosyncratic characteristics cannot confound a study using a true intrasubject experimental design. With the exception of the multiple baseline across subjects analysis design, each participant in a single-case study serves as her own control, a strategy that guarantees identically matched subjects in all experimental conditions *because those subjects are the same person*. Third, the external validity of the findings of a single-subject analysis is not dependent on the extent to which the subject(s) shares certain characteristics with others. The extent to which a functional relation applies to other subjects is established by replicating the experiment with different subjects (replication is discussed later in this chapter).

Setting Confounds

Most applied behavior analysis studies are conducted in natural settings where a host of variables are beyond the investigators' control. Studies in natural settings are more prone to confounding by uncontrolled events than are studies conducted in laboratories where extraneous variables can be eliminated

or held consistent. Even so, the applied experimenter is not without resources to mitigate the detrimental effects of setting confounds. For instance, when the applied researcher observes that an uncontrolled event has coincided with changes in the data, he should hold all possible aspects of the experiment constant until repeated measurement again reveals stable responding. If the unplanned event appears to have had a robust effect on the target behavior, or is otherwise of interest to the investigator, and is amenable to experimental manipulation, the investigator should treat the unplanned event as an independent variable and explore its possible effects experimentally.

Applied researchers concerned about setting confounds must also be on the lookout for "bootleg" reinforcement within and outside the experimental situation. A good example of how a setting confound operates occurs when, unbeknownst to the experimenter, subjects have access to the same items or events to be used as putative reinforcers in the study. In such a case, the potential effectiveness of those consequences as reinforcers may be diminished considerably.

Measurement Confounds

Chapters 4 and 5 discussed factors that should be considered in designing an accurate and nonreactive measurement system. Still, numerous sources of confounding may exist within a well-planned measurement system. For instance, data might be confounded by observer drift, the influence of the experimenter's behavior on observers, and/or observer bias. Although admittedly difficult to accomplish in applied settings where observers often see the independent variable being implemented, keeping observers naive to the conditions and expected outcomes of an experiment reduces the potential of confounding by observer bias. On a related note, when observers score permanent products, the products should not contain identifying marks that indicate who produced each product and under what experimental conditions it was produced. Having observers score papers from baseline and treatment conditions in randomized order reduces the likelihood that observer drift or bias will confound the data within one treatment condition phase. (This procedure is more suitable to controlling for drift or bias by observers conducting postexperiment accuracy or interobserver agreement [IOA] assessments.)

Unless a completely unobtrusive measurement system is devised (e.g., a covert system using one-way mirrors, or observations conducted at some distance from the subject), reactivity to the measurement procedure must always be considered as a possible confound. To offset this possible confound, the experimenter must maintain baseline conditions long enough for any reactive effects to run their course and stable responding to be obtained. If reactivity to measurement produces undesirable effects (e.g., aggressive behavior, cessation of productivity) and a more unobtrusive measurement procedure cannot be devised, intermittent probes should be considered. Practice, adaptation, and warm-up effects can also confound measures, especially during the initial stages of baseline. Again, the proper procedure is to continue baseline conditions until stable responding is obtained or variability is reduced to minimal levels. Intermittent probes should not be used for baseline measurement of behaviors for which practice effects would be expected. This is because, if the target behavior is susceptible to practice effects, those effects will occur during the intervention condition when more frequent measures are conducted, thereby confounding any effects of the independent variable.

Independent Variable Confounds

Most independent variables are multifaceted; that is, there is usually more to a treatment condition than the specific variable of interest to the investigator. For example, the effects of a token economy on students' academic productivity may be confounded by variables such as the personal relationship between the students and the teacher who delivers the tokens, social interactions associated with delivering and exchanging tokens, the expectation of teacher and students that performance will improve when the token system is implemented, and so on. If the intent is to analyze the effects of token reinforcement per se, these potentially confounding variables must be controlled.

Schwarz and Hawkins (1970) provided a good example of a control procedure for ruling out an aspect associated with a treatment as responsible for behavior change. The researchers evaluated the effects of token reinforcement on three maladaptive behaviors of an elementary student who was described as severely withdrawn. During treatment, the therapist and the girl met each day after school and viewed a videotape that had been made earlier that day of the student's classroom behavior. The therapist also administered tokens contingent on the girl's videotaped behavior displaying progressively fewer occurrences of maladaptive behaviors.

Schwarz and Hawkins recognized an independent variable confound potentially lurking in the design of their study. They reasoned that if improvement occurred as a function of the treatment, the question would remain whether the student's behavior had improved because the therapist-delivered positive attention and rewards improved her self-concept, which in turn changed her maladaptive behaviors in the classroom, which were symptomatic of her poor self-concept. In that case, Schwarz and Hawkins could not be certain that the contingent tokens played an important role in changing the behavior. Anticipating this possible confound, Schwarz and Hawkins controlled for it in a simple and direct way. Following baseline, they implemented a condition in which the therapist met with the girl each day after school and provided her with social attention and token reinforcement contingent on improvements in handwriting. During this control phase, the three target behaviors—face touching, slouching, and low voice volume—showed no change, thereby increasing their confidence in a conclusion that the girl's ultimate behavioral improvements during the subsequent intervention phases were due to the token reinforcement.

When medical researchers design experiments to test the effects of a drug, they use a technique called a **placebo control** to separate effects that may be produced by a subject's perceived expectations of improvement because of taking the drug apart from the effects actually produced by the drug. In the typical between-groups design, the subjects in the experimental group receive the real drug, and subjects in the control group receive

placebo pills. Placebo pills contain an inert substance, but they look, feel, and taste exactly like the pills containing the real drug being tested.

Applied behavior analysts have also employed placebo controls in single-subject experiments. For example, in their study evaluating a pharmacological treatment of the impulsivity by students with attention-deficit hyperactivity disorder (ADHD), Neef, Bicard, Endo, Coury, and Aman (2015) had a pharmacist prepare placebos and medications in identical gelatin capsules in 1-week supplies for each child. Neither the students nor the observers knew if a child had taken the medication or had taken the placebos. When neither the subject(s) nor the observers know whether the independent variable is present or absent from session to session, this type of control procedure is called a **double-blind control**. A double-blind control procedure eliminates confounding by subject expectations, parent and teacher expectations, differential treatment by others, and observer bias.

Treatment Integrity/Procedural Fidelity

Researchers must ensure that the independent variable is implemented exactly as planned and that no other unplanned variables are administered inadvertently along with the planned treatment. **Treatment integrity** refers to the extent to which the independent variable is implemented as planned. Although often used interchangeably with treatment integrity, **procedural fidelity** more accurately refers to the extent to which procedures in all conditions of an experiment, including baseline, are correctly implemented (Ledford & Gast, 2014).

Low treatment integrity invites a major source of confounding into an experiment, making it difficult, if not impossible, to interpret the results with confidence. Data from an experiment in which the independent variable was administered improperly, applied inconsistently, conducted piecemeal, and/or delivered in overdose or underdose form often lead to conclusions that—depending on the results obtained—represent either a false positive (claiming a functional relation when no such relation exists) or a false negative (failing to detect a functional relation when one actually does exist). If a functional relation is apparent from the analysis of the data, one cannot be sure whether the treatment variable as described by the experimenter was responsible or whether the effects were a function of extraneous, uncontrolled elements of the intervention as it was actually applied. However, it may be equally erroneous to interpret the failure to produce significant behavior change as evidence that the independent variable is ineffective. In other words, had the independent variable been implemented as planned, it might have been effective.

Numerous threats to treatment integrity exist in applied settings (Billingsley, White, & Munson, 1980; Ledford & Gast, 2014; Peterson, Homer, & Wonderlich, 1982). Experimenter bias can influence the researcher to administer the independent variable in such a way that it enjoys an unfair advantage over baseline or comparative conditions. **Treatment drift** occurs when the application of the independent variable differs from the way it was applied at the study's outset. Treatment drift can occur when the complexity of the independent variable makes it difficult for practitioners to implement all elements consistently over the course of an experiment. Contingencies influencing the behavior of those responsible for implementing the independent variable can also produce treatment drift. For example, a practitioner might implement only those aspects of a procedure she favors and implement the full intervention only when the investigator is present.

The following discussion and examples of methods for ensuring and measuring treatment integrity also apply to ensuring consistency of procedures during baseline and nontreatment comparison conditions (i.e., procedural fidelity).

Precise Operational Definition. Achieving a high level of treatment integrity begins with developing a complete and precise operational definition of the treatment procedures. Besides providing the basis for training the persons who will implement an intervention and judging the level of treatment integrity attained, operational definitions of treatment conditions are requisite for meeting the technological dimension of applied behavior analysis (Baer, Wolf, & Risley, 1968). An investigator's failure to provide explicit operational definitions of the treatment variable hampers the dissemination and proper use of the intervention by practitioners, and makes it difficult for other researchers to replicate and ultimately validate the findings.

Gresham, Gansle, and Noell (1993) recommended that descriptions of the independent variable be judged by the same standards of explicitness used in assessing the quality of definitions of the dependent variable. That is, they should be clear, concise, unambiguous, and objective. More specifically, Gresham and colleagues also suggested that treatments be operationally defined in each of four dimensions: verbal, physical, spatial, and temporal. They used Mace, Gresham, Ivancic, and O'Brien's (1986) definition of a time-out procedure as an example of an operational definition of an independent variable.

> (a) Immediately following the occurrence of a target behavior (temporal dimension), (b) the therapist said "No, go to time-out" (verbal dimension), (c) led the child by the arm to a prepositioned time-out chair (physical dimension), and (d) seated the child facing the corner (spatial dimension). (e) If the child's buttocks were raised from the time-out chair or if the child's head was turned more than 45° (spatial dimension), the therapist used the least amount of force necessary to guide compliance with the time-out procedure (physical dimension). (f) At the end of 2 min (temporal dimension), the therapist turned the time-out chair 45° from the corner (physical and spatial dimensions) and walked away (physical dimension). (pp. 261–262)

Simplify, Standardize, and Automate. Simplifying and standardizing the independent variable and providing criterion-based training and practice for the people who will be responsible for implementing it enhance treatment integrity. Treatments that are simple, precise, and brief, and that require relatively little effort, are more likely to be delivered with consistency than those that are not. Simple, easy-to-implement techniques also have a higher probability of being accepted and used by practitioners than those that are not, and thus possess a certain

degree of self-evident social validity. Simplicity is, of course, a relative concern, not a mandate; effecting change in some socially important behaviors may require the application of intense, complex interventions over a long period and may involve many people. Baer (1987) made this point succinctly when he stated:

> Long problems are simply those in which the task analysis requires a series of many behavior changes, perhaps in many people, and although each of them is relatively easy and quick, the series of them requires not so much effort as time, and so it is not arduous but merely tedious. (pp. 336–337)

Neither researchers nor practitioners need be thwarted or dismayed by complex interventions; they do, however, need to realize the treatment integrity implications. All things being equal, a simple and brief treatment will probably be applied more accurately and consistently than will a complex and extended one.

To ensure the consistent implementation of the independent variable, experimenters should standardize as many of its aspects as cost and practicality allow. They can accomplish the standardization of treatment in a variety of ways. When a treatment requires a complex and/or extended sequence of behaviors, a script for the person administering it may improve the accuracy and consistency with which the independent variable is applied. For example, Heron, Heward, Cooke, and Hill (1983) used a scripted lesson plan to ensure that a classwide peer tutor training program was implemented consistently across groups of children.

If automating the intervention will not compromise it in any way, researchers might consider "canning" the independent variable so that an automated device can be used for its delivery. Although a tutor training video in Heron and colleagues' (1983) study would have eliminated any potential confounding caused by the teacher's slightly different presentations of the lesson from group to group and across sets of tutoring skills, using a canned presentation would also have eliminated desired interactive and personal aspects of the training program. Some treatment variables are well suited to automated presentation in that automation neither limits the desirability of the treatment nor seriously reduces its social validity in terms of acceptability or practicability (e.g., use of video programs to model residential energy conservation).

Training, Practice, and Feedback. Training and practice in properly implementing the independent variable provides the person(s) who will be responsible for conducting the treatment or experimental sessions with the necessary skills and knowledge to carry out the treatment. It would be a mistake for the researcher to assume that a person's general competence and experience in the experimental setting (e.g., a classroom) guarantee correct and consistent application of an independent variable in that setting (e.g., implementing a peer-mediated tutoring program).

As stated earlier, scripts detailing treatment procedures and cue cards or other devices that remind and prompt people through steps of an intervention can be helpful. Researchers should not, however, assume that providing a procedural manual or script to intervention agents will ensure a high degree of treatment integrity. Mueller and colleagues (2003) found that a combination of verbal instructions, modeling, and/or rehearsal was required for parents to implement pediatric feeding protocols with a high level of treatment integrity.

Howard and DiGennaro Reed (2014) found that after written instructions produced little or no improvement in trainers' implementation of a dog obedience training procedure with shelter volunteers, a single viewing of a video that included correct and incorrect examples of the routine "produced marked improvement" in the correct implementation of the training procedure. Nevertheless, a brief one-on-one training session consisting of modeling, descriptive praise, and feedback until 100% integrity was obtained in a role-play was required for trainers to reach satisfactory levels of treatment integrity (means of 88%, 97%, and 93% for three trainers over 6 to 14 sessions) (Figure 10.5).

Rating the integrity with which video models implement a treatment can also improve the fidelity with which the raters implement the treatment. After an initial 30-min training session in which trainer-reviewed written protocol of functional analysis (FA) procedures produced moderate levels of treatment fidelity (below 85% accuracy) by 17 of 20 graduate students, Field, Frieder, McGee, Peterson, and Duinkerken (2015) had the students rate the fidelity with which video models implemented the FA procedures. The treatment fidelity of 16 of the 17 students who participated in the observation and rating of video models increased further. In a final condition, 7 participants whose execution of FA procedures was still below mastery observed and rated a 2-min video of themselves conducting the intervention in a previous session. The self-observation and rating resulted in 5 of the 7 students achieving further increases in treatment integrity.

Various prompting tactics might promote treatment integrity. In a parametric analysis of teacher praise rates on the on-task behavior of elementary students with autism, the teacher wore a MotivAider®, which vibrated at preset intervals of 1, 2, and 8 per minute to prompt praise statements (Kranak, Alber-Morgan, & Sawyer, 2017).

Craig (2010) reported an interesting method for assessing the treatment integrity of a self-monitoring and self-administering intervention on reduced nail biting. Tokens were exchanged for evening leisure time contingent on no occurrences of nail biting during daily, 1-hour intervals. Craig described the procedure as follows:

> I recorded the time of each occurrence of nail biting and the time of each token reinforcer delivery. Using a cellular camera phone, I took digital photographs (with timestamps) of the condition of my fingernails at the beginning of each DRO interval, after each token delivery, and after each occurrence of nail biting (see Figure 1). During token exchange periods each evening, my cohabitant compared the times of the occurrences of nail biting and of token deliveries to the timestamps of each photograph. If there was no noticeable difference in the condition of my fingernails between the photograph from the beginning of an interval and the photograph taken upon token delivery, token delivery was recorded as "correct." Tokens

> associated with incorrect deliveries would have been removed; incorrect token delivery did not, however, occur during the course of this study. (p. 39)

Performance feedback and self-monitoring have also been shown to improve the integrity with which practitioners and parents implement behavior support plans and explicit teaching techniques (e.g., Codding, Feinberg, Dunn, & Pace, 2005; Pinkelman & Horner, 2016; Plavnick, Ferreri, & Maupin, 2010; Sarokoff & Strumey, 2004; Sanetti, Luiselli, & Handler, 2007).

Assessing and Reporting Treatment Integrity. Simplification, standardization, training, and practice help increase the degree of treatment integrity, but do not guarantee it. When any reasonable doubt exists about the correct and consistent application of the independent variable, investigators should provide data on the accuracy and reliability of the independent variable. Procedural fidelity data reveal the extent to which the actual implementation of all experimental conditions over the course of a study matches their descriptions in the method section of a research report.[7]

Even though effective control of the independent variable is requisite to an internally valid experiment, applied behavior analysts have not always made sufficient efforts to ensure treatment integrity. Two reviews of articles published in the *Journal of Applied Behavior Analysis (JABA)* from 1968 to 1990 found that the majority of authors did not report data assessing the degree to which the independent variable was properly and consistently applied (Gresham et al., 1993; Peterson et al., 1982). Peterson and colleagues noted that a "curious double standard" had developed in applied behavior analysis in which data on the interobserver agreement of dependent variable measures were required for publication, but such data were seldom provided or required for the independent variable.

Although more recent reviews of treatment integrity data in articles published in *JABA* and other behavioral journals have found some improvement, the overall results are disappointing (e.g., Andzik, Cannella-Malone, & Sigafoos, 2016; Ledford & Wolery, 2013; Wheeler, Baggett, Fox, & Blevins, 2006). For example, McIntyre, Gresham, DiGennaro, and Reed (2007) reported that only 30% of 152 studies of school-based interventions published in *JABA* from 1991 to 2005 provided treatment integrity data. These authors judged 69 (45%) of those studies "to be at high risk for treatment inaccuracies in

that information on the implementation of treatments or the assessment of independent variables was not included but should have been" (p. 664) per guidelines for monitoring or measuring treatment (Peterson et al., 1982).

Treatment integrity data have value beyond their critical role in helping reviewers, practitioners, and consumers judge the believability of a study's results. Increasingly, data documenting that the independent variable was implemented as described is criterion for inclusion in systematic reviews of literature conducted by professional and government organizations. Treatment integrity is one of five dimensions by which the National Autism Center (NAC; 2015) judges the scientific merit of a study (the others are research design, measurement of the dependent variable, eligibility and description of participants, and measure of generalization of treatment effects). For a study to achieve the highest score on the NAC's Scientific Merit Rating Scale, treatment integrity must be measured during a minimum of 25% of sessions, at or above 80% accuracy, with IOA of ≥80%. An expert panel tasked by the U.S. Department of Education to establish parameters for considering fidelity of intervention implementation in single-case design studies noted that "Because interventions in single-case studies are applied over time, continuous measurement of implementation is a relevant consideration" (What Works Clearinghouse, 2018, p. A-6).

Methods for assessing and increasing the accuracy and believability of measures of the dependent variable (see Chapter 5) are fully applicable to the collection of procedural fidelity data. Importantly, observation and recording of the independent variable provide the experimenter with data indicating whether calibration of the treatment agent is necessary (i.e., bringing the intervention agent's behavior into agreement with the true value of the independent variable). Observation and calibration give the researcher an ongoing ability to use retraining and practice to ensure a high level of treatment integrity over the course of an experiment.

Figure 10.6 shows the data collection form trained observers used to collect treatment integrity data in a study evaluating the effects of different qualities and durations of reinforcement for problem behavior, compliance, and communication within a treatment package for escape-maintained problem behavior (Van Norman, 2005). The observers viewed videotapes of randomly selected sessions representing approximately one third to one half of all sessions in each condition and phase of the study. The percentage of treatment integrity for each condition was calculated by dividing the number of steps the experimenter completed correctly during a session by the total number of steps completed.

Graphic displays of treatment integrity data may help researchers and consumers of a study judge the intervention's effectiveness (e.g., Kranak et al., 2017). Detailed information on assessing, promoting, and reporting procedural fidelity can be found in a special issue of the *Journal of Behavioral Education* (DiGennaro Reed & Codding, 2014) and Ledford and Gast (2014).

This overview of sources of potential confounding variables is, of necessity, incomplete. A complete inventory of all possible threats to the internal validity of experimental research would be well beyond the scope of this text. And presenting such a list might suggest that a researcher need only control for the variables listed and not worry about anything else. In truth, the list of potential confounds is unique to every experiment. The effective researcher is the one who questions and probes the influence of as many relevant variables as possible. No experimental design can control all potential confounds; the challenge is to reduce, eliminate, or identify the influence of as many potentially confounding variables as possible.

Van Norman, 2005, p. 204. Unpublished doctoral dissertation. Columbus, OH: The Ohio State University. Used by permission.

SOCIAL VALIDITY: ASSESSING THE APPLIED VALUE OF BEHAVIOR CHANGES AND THE TREATMENTS THAT ACCOMPLISH THEM

In his landmark article "Social Validity: The Case for Subjective Measurement or How Applied Behavior Analysis Is Finding Its Heart," Montrose Wolf (1978) proposed the then "radical concept that clients (including parents and guardians of dependent people, and even those whose taxes support social programs) must understand and admire the goals, outcomes, and methods of an intervention" (Risley, 2005, p. 284). Wolf recommended that the **social validity** of an applied behavior analysis study be assessed in three ways: the social significance of the behavior change goals, the appropriateness of the intervention, and the social importance of the results.

Validating the Social Importance of Behavior Change Goals

The social validity of behavior change goals begins with a clear description of those goals.

> To assess the social importance of goals, the researcher must be precise about the goals of the behavior change effort at the levels of (a) the broad social goal (e.g., improved parenting, enhanced social skills, improved cardiovascular health, increased independence), (b) the categories of behavior hypothesized to be related to the broad goal (e.g., parenting—providing instructional feedback, using time-out, etc.), and/or (c) the responses that comprise the behavioral category of interest (e.g., using time-out—directing the child to a location away from other people, instructing the child to "sit out" for a specified duration, etc.). Social validation may be conducted for any of these levels of goals. (Fawcett, 1991, pp. 235–236)

Experts can inform the selection of socially valid target behaviors. Kelley and Miltenberger (2016), for example, identified the task analyses of correct rider positions for horseback-riding skills "by consulting with an expert instructor as well as comparing many photos of expert riders considered to have good position" (p. 141). In their studies on the effects of behavioral teaching strategies on performance by high school football players, Harrison and Pyles (2013) and Stokes, Luiselli, and Reed (2010) targeted tackling skills recommended by the American Football Coaches Association (1995). In another study teaching football skills to high school athletes, Stokes, Luiselli, Reed, and Fleming (2010) validated their 10-step task analysis for pass-blocking by consulting with experienced offensive linemen coaches (see Figure 21.5).

Persons who use the prospective skill in natural environments can help researchers identify socially valid target behaviors. In their study teaching sequences of basketball skills to an adolescent with disabilities, Lambert and colleagues (2016) asked "groups of adults who we observed playing games of 'pick up' basketball . . . to rate the utility of each sequence during a typical game of 'pick up' basketball" (p. 206).

Van Houten (1979) suggested two basic approaches for determining socially valid goals: (a) assess the performance of persons considered competent and (b) experimentally manipulate different levels of performance to determine empirically which produces optimal results. The performance of typical performers can be used to identify and validate behavior change goals and target levels of performance. To arrive at a socially valid performance criterion for a social skills training program for two adults with disabilities who worked in a restaurant, Grossi, Kimball, and Heward (1994) observed four restaurant employees without disabilities over a period of 2 weeks to determine the extent to which they acknowledged verbal initiations from coworkers. Results from these observations revealed that the employees without disabilities acknowledged an average of 90% of initiations directed toward them. This level of performance was selected as the goal for the two target employees in the study.

Warren, Rogers-Warren, and Baer (1976) provide a good example of testing the effects of different levels of performance to determine socially valid outcomes. The researchers assessed the effect of different frequencies of children's offers to share play materials with their peers on the peers' reactions to those offers. They found that peers accepted offers to share most consistently when those offers were made at a middle frequency—that is, not too frequently, not too seldom.

Validating the Social Acceptability of Interventions

Several scales and questionnaires for obtaining consumers' opinions of the acceptability of behavioral interventions have been developed. The *Intervention Rating Profile* (IRP-15) is a 15-item Likert-type scale for assessing teachers' perceptions of the acceptability of classroom interventions (Martens, Witt, Elliott, & Darveaux, 1985). The *Behavior Intervention Rating Scale*, a revision and extension of the IRP-15, includes nine additional items on treatment effectiveness (Elliot & Brock Treuting, 1991). The *Treatment Acceptability Rating Form* (TARF) consists of 20 questions with which parents rate the acceptability of behavioral treatments (Reimers & Wacker, 1988). For a review of these and six other treatment acceptability instruments, see Carter (2007).

Figure 10.7 shows the experimenter-modified version of the TARF Van Norman (2005) used to obtain treatment acceptability information from each participant's parents, teachers, therapists, and behavior support staff. Although some of the people whose opinions were being sought had witnessed or watched a video of the intervention being used with the student, the following description of the intervention was read to each consumer before he or she was asked to answer each of the questions:

> First we conducted an assessment to find out what motivated Zachary to engage in challenging behavior(s) such as throwing materials, hitting people, and dropping to the floor. We found that Zachary engaged in challenging behavior(s), at least in part, in order to escape or avoid task demands.
>
> Next, we taught Zachary to ask for a break as a replacement behavior for challenging behavior by using physical prompting and attaching the response of asking for

Figure 10.7 Examples of questions adapted from the Treatment Acceptability Rating Form—Revised (Reimers and Wacker, 1988) to obtain consumers' opinions of the acceptability of intervention procedures used to treat challenging behaviors of secondary students with severe disabilities.

Treatment Acceptability Rating Form—Revised (TARF-R)

1. How clear is your understanding of the suggested procedures?

______	______	______	______	______	______	______
Not at all clear			Neutral			Very clear

2. How acceptable do you find the strategies to be regarding your concerns about the identified learner?

______	______	______	______	______	______	______
Not at all acceptable			Neutral			Very acceptable

3. How willing are you to implement the suggested procedures as you heard them described?

______	______	______	______	______	______	______
Not at all willing			Neutral			Very willing

4. Given the learner's behavior issues, how reasonable do you find the suggested procedures?

______	______	______	______	______	______	______
Not at all reasonable			Neutral			Very reasonable

5. How costly will it be to implement these strategies?

______	______	______	______	______	______	______
Not at all costly			Neutral			Very costly

11. How disruptive will it be to your classroom to implement the suggested procedures?

______	______	______	______	______	______	______
Not at all disruptive			Neutral			Very disruptive

13. How affordable are these procedures?

______	______	______	______	______	______	______
Not at all affordable			Neutral			Very affordable

14. How much do you like the proposed procedures?

______	______	______	______	______	______	______
Do not like them at all			Neutral			Like them very much

17. How much *discomfort* is your learner likely to experience as a result of these procedures?

______	______	______	______	______	______	______
No discomfort at all			Neutral			Very much discomfort

19. How willing would you be to change your classroom routine to implement these procedures?

______	______	______	______	______	______	______
Not at all willing			Neutral			Very willing

20. How well will carrying out these procedures fit into your classroom routine?

______	______	______	______	______	______	______
Not at all well			Neutral			Very well

From *The Effects of Functional Communication Training, Choice Making, and an Adjusting Work Schedule on Problem Behavior Maintained by Negative Reinforcement*, by R. K. Van Norman, 2005, pp. 248–256. Unpublished doctoral dissertation. Columbus, OH: The Ohio State University. Used by permission.

a break to access to a highly preferred item, lots of attention, and a long duration break (3 min).

Then we gave Zachary the choice to ask for work by simply touching the work materials (essentially engaging in the first step of the task) and getting access to highly preferred items, attention, and long duration break (1 min) or asking for a break and getting access to moderately preferred items for a shorter duration break (30 sec). At any time during this procedure if Zachary engaged in problem behavior he was given a 10 s break with no attention and no activities/items.

Finally, we continued to give Zachary the choice to ask for work, a break or engage in problem behavior, however now we required Zachary to comply with a greater number of task-related instructions before he was given access to the highly preferred activities, attention, and a 1 min break. Each session we increased the number of task-related instructions that were given and needed to be complied with before access to the highly preferred break.

Physical prompting was only used during the initial phase to teach Zachary new responses, specifically how to ask for a break and how to ask for work. Otherwise Zachary was making all independent choices as they were presented. (p. 247)

Some investigators present graphic displays of treatment acceptability data. Kurti and Dallery (2013) administered a treatment acceptability questionnaire to 12 adults who participated in Internet-based contingency management intervention to increase walking. Participants ranked 10 items about the intervention (e.g., easy to use, fun, I would recommend to others) using a visual analogue scale ranging from 0 (not at all) to 100 (extremely). The researchers used a graph to present the treatment acceptability results, showing the mean, range, and individual participant ratings for each item (see Figure 10.8).

Preference for interventions can be assessed directly by letting practitioners or clients choose which of multiple treatments to implement or receive. After training four parents and one teacher to implement each of three reinforcement-based interventions for problem behavior to 90% treatment integrity, Gabor, Fritz, Roath, Rothe, and Gourley (2016) provided a sequence of choice sessions in which each caregiver selected which intervention to implement. Jowett Hirst, Dozier, and Payne (2016) assessed preschool children's preference for token economy procedures based on differential reinforcement or response cost with a "choice" phase in which only the treatment selected by each participant was implemented (see Figure 8.17 and accompanying discussion).

Hanley and colleagues have used concurrent chains experimental designs (see Chapter 8) to assess clients' treatment preferences (e.g., Hanley, Piazza, Fisher, Contrucci, & Maglieri, 1997; Luczynski, & Hanley, 2009; Heal, Hanley, & Layer, 2009). After reversal and multielement designs revealed that functional

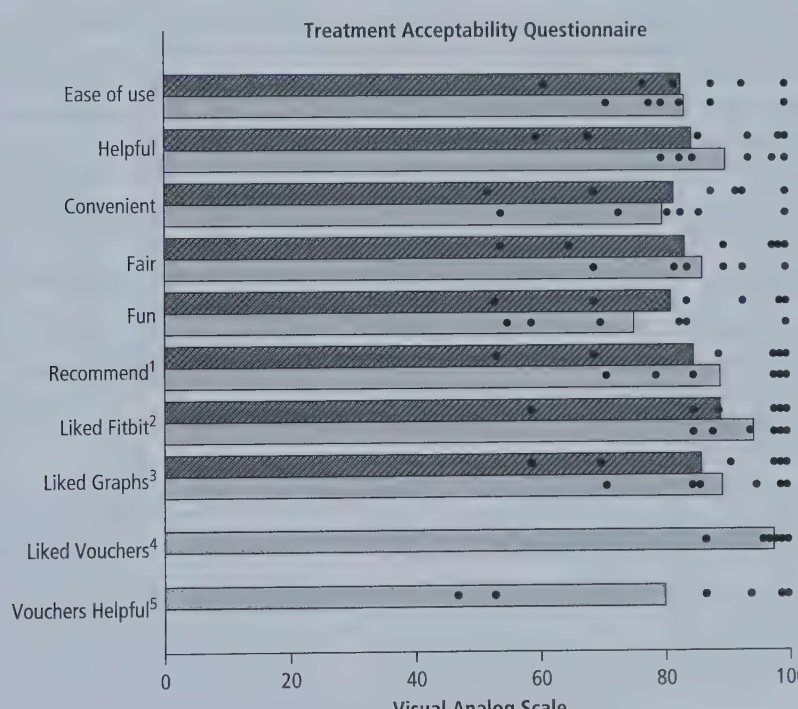

Figure 2. Experiment 1 (gray bars) and Experiment 2 (dark gray bars) participants' responses to the treatment acceptability questionnaire, where bars represent the mean rating for each item (1 = *I would recommend the Internet-based walking intervention to others*, 2 = *I liked using the Fitbit to monitor my progress*, 3 = *I liked seeing my progress on the graph*, 4 = *I liked earning vouchers*, 5 = *Earning vouchers helped me increase my activity levels*).

Figure 10.8 Example of graphic reporting treatment acceptability data.

Based on "Internet-based Contingency Management Increases Walking in Sedentary Adults" by A. N. Kurti and J. Dallery, 2013, *Journal of Applied Behavior Analysis*, *46*, p. 574. Copyright 2013 by the Society for the Experimental Analysis of Behavior, Inc.

communication training (FCT) with punishment was the most effective of three functional-based treatments in reducing two children's severe problem behavior, the children's choices during the concurrent chains condition showed they each preferred functional communication training (FCT) with punishment over FCT alone, or punishment only (Hanley, Piazza, Fisher, & Maglieri, 2005; see Figure 8.18 and accompanying discussion).

The social acceptability of a proposed intervention can be judged by the extent it meets the standards of best practice (Peters & Heron, 1993) and the ethical, legal, and professional standards of relevant learned and professional societies. In general, these standards require the use of evidence-based, and least restrictive practices, full disclosure to all participants, informed consent, and the right to discontinue treatments that the participants believe are not beneficial or therapeutic.

Validating the Social Importance of Behavior Changes

Applied behavior analysts assess the social validity of outcomes with a variety of methods: (a) have consumers rate the social validity of participants' performance, (b) ask experts to evaluate participants' performance, (c) compare participants' performance to that of a normative sample, (d) assess with standardized assessment instruments, and (e) test participants' performance in the natural environment.

Consumer Opinion

The most frequently used method for assessing social validity is to ask consumers, including subjects or clients whenever possible, whether they thought behavior changes occurred during the study or program, and if so, whether they thought those behavior changes were important and valuable. Figure 10.9 shows the questionnaire Van Norman (2005) used to obtain opinions of consumers (i.e., the subjects' parents, teachers, and instructional aides; school administrators; behavior support staff; an occupational therapist; a school psychologist; and a psychology aide) on the social validity of results of an intervention designed to reduce challenging behavior maintained by escape. Van Norman created a series of 5-minute video clips from randomly selected before-intervention and after-intervention sessions and placed the clips in random order on a CD. The social validity evaluators did not know whether each clip

Social Validity of Results Questionnaire

Directions: Video Clip # _____

Please view the video and then circle one of the five choices that best describes the extent to which you agree or disagree with each of the three statements below.

1. The student is engaged in academic or vocational work tasks, sitting appropriately (bottom in seat), and attending to the teacher or materials.

1	2	3	4	5
Strongly Disagree	Disagree	Undecided	Agree	Strongly Agree

2. The student is engaged in challenging behavior and not attending to the teacher or materials.

1	2	3	4	5
Strongly Disagree	Disagree	Undecided	Agree	Strongly Agree

3. The student appears to have a positive affect (e.g., smiling, laughing).

1	2	3	4	5
Strongly Disagree	Disagree	Undecided	Agree	Strongly Agree

Comments about the student's behavior in the video clip: ______________________

represented a before- or after-intervention session. After viewing each clip, the consumer completed the questionnaire shown in Figure 10.9.

Expert Evaluation

Experts can be called on to judge the social validity of some behavior changes. For example, as one measure of the social validity of changes in the unaided notetaking skills of high school students with learning disabilities in social studies lectures as a result of having been exposed to teacher-prepared guided notes, White (1991) asked 16 secondary social studies teachers to rate the students' baseline and postintervention lecture notes on three dimensions: (1) accuracy and completeness compared to lecture content; (2) usefulness for study for tests over the lecture content; and (3) how the notes compared to those taken by typical general education students. (The teachers did not know whether each set of notes they were rating was from baseline or the postintervention condition.)

Howard and DiGennaro Reed (2014) recruited 186 certified dog trainers from across the United States to evaluate the social validity of behavior changes in dog shelter volunteers and the dogs they were paired with during the study. The researchers compiled brief baseline (before training) and intervention (after training) videos of one of the volunteer+dog dyads. The experts watched the videos online, and using a 9-item SurveyMonkey questionnaire, the experts rated the appropriateness and effectiveness of the dog obedience training procedures used by the shelter volunteer before and after training and whether the before- or after training dog would be more adoptable, better in a home with children, and a better dog for first-time pet owners.

To assess the social validity of changes in participants' horseback-riding skills, Kelley and Miltenberger (2016) showed two expert riders and instructors three videos from the end of baseline and three videos from the end of the intervention for each participant. The experts rated each video with a Likert-type scale (1 = strongly disagree, 9 = strongly agree) according to whether the rider was in the correct position based on the riding style target for the rider shown in the video. The experts who viewed the videos in random order were blind to whether each video was from baseline or intervention.

Normative Comparison

Van den Pol and colleagues (1981) used the performance of a sample of typical fast-food restaurant customers to assess the social validity of the posttraining performance of the young adults with disabilities whom they had taught to order and pay for a meal without assistance. The researchers observed 10 randomly selected, typical customers who ordered and ate a meal in fast-food restaurants and recorded the accuracy with which these customers performed each step of a 22-step task analysis. The students' performance at the follow-up probe equaled or exceeded that of the customers in the normative sample in all but 4 of 22 specific skills.

Using normative samples to assess the social validity of behavior change is not limited to posttreatment comparisons. Comparing subjects' behavior to ongoing probes of the behavior of a normative sample provides a formative assessment measure of how much improvement has been made and how much is still needed. Grossi and Heward (1998) used the typical rate at which employees without disabilities performed restaurant tasks (e.g., scrubbing pots and pans, loading a dishwasher, mopping and sweeping floors) as a socially valid performance standard for restaurant trainees with developmental disabilities (see Figure 29.3).

In their study evaluating behavioral coaching strategies on the offensive line pass-blocking skills of high school football athletes, Stokes, Luiselli, Reed, and Fleming (2010) recorded the three highest-rated starting offensive linemen from videotaped games from the previous season. The mean correct performance on the 10-step task analysis by the three lineman was 80% (range, 70% to 90%). The researchers "adopted a range of 70% to 90% as our acceptable performance criterion" (p. 466).

Rhode, Morgan, and Young (1983) provide an excellent example of formative social validity assessment. In their study, token reinforcement and self-evaluation procedures were used to improve the classroom behavior of six students with behavior disorders. The overall goal of the study was to help the students improve their appropriate classroom behavior (e.g., following classroom rules, completing teacher-assigned tasks, volunteering relevant responses) and decrease inappropriate behavior (e.g., talking out, noncompliance, aggression) so that they would be accepted and successful in regular (general education) classrooms. At least once per day throughout the course of the 17-week study, the researchers randomly selected classmates in the regular classrooms for observation. The same observation codes and procedures that were used to measure the six target students' behavior were used to obtain the normative sample data.

Figure 10.10 shows the mean and range of the six students' appropriate behavior during each condition and phase of the study compared to the normative sample. (Individual graphs showing the percentage of appropriate behavior in the resource and regular classroom of all six subjects in each of nearly 90 sessions were also included in Rhode and colleagues' article.) During baseline, the six boys' levels of appropriate behavior were well below those of their peers without disabilities. During Phase I of the study, in which the subjects learned to self-evaluate, their behavior in the resource room improved to a level matching that of their regular classroom peers. However, when the subjects were in the regular classroom during Phase I, their behavior compared poorly with that of the other students in the normative sample. As Phase II progressed, which involved various strategies for generalization and maintenance of the treatment gains, the mean level of appropriate behavior by the six students matched that of their peers without disabilities, and variability among the six students decreased (except for one subject who exhibited no appropriate behavior on one session in the next-to-last condition).

Standardized Tests

Although standardized tests provide indirect measures of the behaviors typically targeted by applied behavior analysts, policymakers and the public view scores from such tests as important indicators of performance. Improvements in intelligence quotient (IQ) test scores by children who participated in the pioneering studies by Lovaas and colleagues (Lovaas, 1987; McEachin,

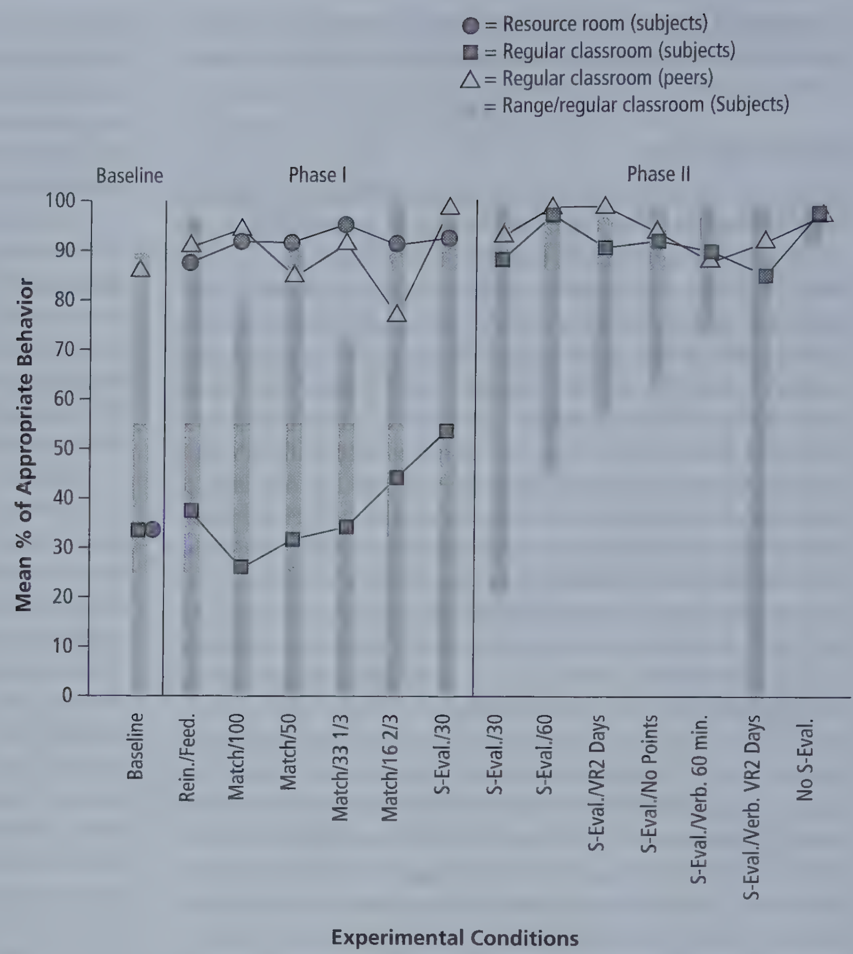

Figure 10.10 Example of using measures of the behavior of a normative sample to assess the social validity of outcomes of a behavior change program.

Based on "Generalization and Maintenance of Treatment Gains of Behaviorally Handicapped Students from Resource Rooms to Regular Classrooms Using Self-Evaluation Procedures" by G. Rhode, D. P. Morgan, and K. R. Young, 1983, *Journal of Applied Behavior Analysis*, *16*, p. 184. Copyright 1984 by the Society for the Experimental Analysis of Behavior, Inc.

Smith, & Lovaas, 1993; Smith, Eikeseth, Klevstrand, & Lovaas, 1997) were key to the recognition and eventual acceptance of early intensive behavior intervention for children with autism as an evidence-based treatment (e.g., Maine Administrators of Services for Children with Disabilities, 2000; Myers, Johnson, & the American Academy of Pediatrics Council on Children with Disabilities, 2007; New York State Department of Health Early Intervention Program, 1999). Subsequent research reporting improvements in scores on standardized tests of adaptive behavior (e.g., *Vineland Adaptive Behavior Scales*, Sparrow, Balla, & Cicchetti, 2005) and child development (e.g., *Bayley Scales of Infant and Toddler Development*, Bayley, 2005) in addition to IQ scores has further strengthened the awareness and widespread acceptance of ABA-informed education and treatment for individuals with autism (e.g., Eikeseth, 2009; Eldevik et al., 2009, 2010; Howard, Sparkman, Cohen, Green, & Stanislaw, 2005).

Scores on tests of academic achievement can also attest to the social validity of behavior change. In their study evaluating the effects of Headsprout Comprehension[8] on the reading comprehension of six elementary students with high-incidence disabilities, Cullen, Alber-Morgan, Schnell, and Wheaton (2014) measured students' performance on comprehension passages based on the Ohio Achievement Assessment, a "high-stakes" test, and on AIMSweb Maze probes. AIMSweb Maze is a norm-referenced curriculum-based measurement (CBM) of reading comprehension (Shinn & Shinn, 2002).

Behavior analysts have created tests that can be used to assess the social validity of some behavior change program outcomes. Iwata, Pace, Kissel, Nau, and Farber (1990) developed the *Self-Injury Trauma Scale (SITS)* to enable researchers and therapists to measure the number, type, severity, and location of injuries produced by self-injurious behavior. The *SITS* yields a Number Index and Severity Index with scores of 0 to 5, and an estimate of current risk. Although the data collected in a treatment program may show significant decreases in the behaviors that produce self-injury (e.g., eye poking, face slapping, head banging), the social significance of the treatment must be validated by evidence of reduced injury. Iwata and colleagues wrote:

> . . . the social relevance of the behavior lies in its traumatic outcome. The measurement of physical injuries prior to treatment can establish the fact that a client or subject actually displays behavior warranting serious attention. . . . Conversely, injury measurement following treatment can corroborate observed changes in behavior because reduction of an injury-producing response below a certain level should be reflected in the eventual disappearance of observable trauma. In both of these instances, data on injuries provide a means of assessing social validity. (pp. 99–100)

Twohig and Woods (2001) used the *SITS* to validate the outcomes of a habit-reversal treatment for the chronic skin

picking of two typically developing adult males. Both men reported that they had engaged in skin picking since childhood, digging the fingernails into the ends of a finger and pulling or scraping the skin, which sometimes caused bleeding, scarring, and infections. Two observers independently rated pretreatment, posttreatment, and follow-up photographs of the two men's hands with the *SITS*. The Number Index (NI) and Severity Index (SI) *SITS* scores on the pretreatment photographs for both men were 1 and 2, respectively, indicating one to four injuries on either hand and distinct but superficial breaks in the skin. NI and SI scores of 0 on the posttreatment photos for both men indicated no apparent injuries. On the follow-up photos taken 4 months after treatment had ended, both men had *SITS* NI and SI scores of 1, indicating red or irritated skin.

Real-World Test

Perhaps the most socially valid way to assess a learner's newly acquired behavior is to put it to an authentic test in the natural environment. For instance, the validity of what three adolescents with learning disabilities had learned about road signs and traffic laws was validated when they passed the Ohio Department of Motor Vehicles test and earned their temporary driver's permits (Test & Heward, 1983). In a similar way, the social validity of the cooking skills being learned by three secondary students with developmental disabilities and visual impairments was tested frequently when their friends arrived at the end of probe sessions to share the food they had just prepared (Trask-Tyler, Grossi, & Heward, 1994). In addition to providing authentic assessments of social validity, real-world tests put the learner's repertoire in contact with naturally occurring contingencies of reinforcement, which may promote maintenance and generalization of the newly acquired behaviors.

Observing desired behavior change in real-world settings may not equate with socially valid improvements in a client's repertoire. This mismatch is most likely to occur when (a) the target behavior differs from the behavior of ultimate value in the natural environment, or (b) the behavior changes are observed during situations in the natural environment that differ from situations when the client's performance of the behavior is most crucial. Stokes, Luiselli, Reed, and Fleming's (2010) study on teaching pass-blocking skills to high school football players provides an example of the first kind of mismatch. The researchers found that participants' performance of a 10-step task analysis for pass-blocking by offensive linemen improved from practice drills to games (see Figure 23.5), but they acknowledged that "the relation between the tackling of a ball carrier in practice and games and performance of the 10 skills remains unknown because we did not measure successful tackles during practice or games" (p. 512).

Directly observing participants' reliable performance of the behavior of ultimate value in real-world settings is no guarantee of socially valid behavior change. If children's ability to use in the natural environment what they had learned in a classroom-based program on safe street crossing behavior was assessed only during days or times when traffic was very light, the results may give a false and overly optimistic impression of the children's ability to safely cross during heavy traffic at rush hour.

A tremendous strength of single-case research designs is transparency: The dependent and independent variables must be described sufficiently to allow implementation by others and to make the data demonstrating behavior changes directly available for anyone to examine. This transparency enables scientific reviewers, practitioners, consumers, and policymakers to judge for themselves the social validity of behavior changes.[9]

EXTERNAL VALIDITY: REPLICATING EXPERIMENTS TO DETERMINE THE GENERALITY OF RESEARCH FINDINGS

External validity refers to the degree to which a functional relation found reliable and socially valid in a given experiment operates under different conditions. An intervention that works only within a circumscribed set of conditions and proves ineffective when any aspect in the original experiment is altered makes a limited contribution to the development of a reliable and useful technology of behavior change. When a carefully controlled experiment has shown that a particular treatment produces consistent and socially significant improvements in the target behavior of a given subject, a series of important questions should then be asked: Will the treatment be as effective if it is applied to other behaviors? Will the procedure continue to work if it is changed in some way (e.g., implemented at a different time of day, by another person, on a different schedule)? Will it work in a setting different from the original experiment? Will it work with participants of different ages, backgrounds, and repertoires? Questions about external validity are neither abstract nor rhetorical; they are empirical questions that if judged important can be addressed by empirical methods.

A functional relation with external validity, or generality, will continue to operate under a variety of conditions. External validity is a matter of degree, not an all-or-nothing property. A functional relation that cannot be reproduced under any conditions other than the exact set of original variables (including the original subject) possesses no external validity. At the other end of the continuum, a procedure that is effective at any time, under any conditions, in any setting, with any behavior, and for any subject has complete generality (a most improbable situation). Most functional relations fall somewhere between the two ends of this continuum, and those found to have higher degrees of generality make the greater contribution to applied behavior analysis. Investigators who use between-groups research methods pursue external validity quite differently than do investigators who use within-subjects research methods.

External Validity and Between-groups Research Design

As stated previously, researchers who use between-groups experimental designs claim two advantages for using large groups of subjects. In addition to the assumption that aggregating the data from individual subjects controls for intersubject variability,[10] group design researchers assume that including many subjects in an experiment increases the external validity of the results. On the surface this assumption is perfectly logical, and it is true when viewed at the proper level of extrapolation.

The more subjects with which a functional relation has been demonstrated, the greater the likelihood it will also be effective with untested subjects who share similar characteristics. And in fact, demonstrating a functional relation with various subjects in different settings is exactly how applied behavior analysts document external validity.

The investigator who claims that the findings of a between-groups study possess generality to other *individuals* in the population from which the experimental subjects were chosen violates a fundamental premise of the between-groups method and ignores a defining characteristic of behavior. The proper inference about the results of a groups-design study is from the *sample* to the *population*, not from the sample to the individual. The random sampling methods in a well-executed between-groups study are followed to ensure that the study's participants exemplify a heterogeneous sample of all relevant characteristics found in the population from which they were selected. The better the sample represents the population from which it is drawn, the less meaningful are the results for any individual subject.

A second problem inherent in extending the results of a between-groups study to other people (and unless care is taken, sometimes even to a subject who participated in the study, as was illustrated in Figure 10.1) is that a between-groups experiment does not demonstrate a functional relation between the behavior of any subject and some aspect of his or her environment. From the perspective of behavior analysis, there is nothing in the results of a between-groups experiment that can have external validity; there is nothing to generalize. Johnston and Pennypacker (2009) made this point repeatedly and well.

> The researcher's primary objective is to obtain data that truly represent the relationship between the independent variable and the dependent variable. If this is not accomplished, nothing else matters. Only when the findings are "true" does the question of the meaningfulness under other circumstances become relevant. (p. 247)
>
> Between groups designs tend to put the cart before the horse. The tactics of exposing different levels of the independent variable to different groups, insuring that these groups contain a large number of participants, and treating their responses collectively provide comparisons that describe no member of any group. By failing to focus on individuals with careful attention to experiment control, these traditional methods greatly decrease the chances of discovering orderly relations in the first place. This makes the question of generality across individuals moot. (p. 346)

Between-groups designs and statistical inference have long dominated research in psychology, education, and other social sciences. Despite its long-standing dominance, the extent to which this research tradition has contributed to an effective technology of behavior change is highly questionable (Baer, 1977; Branch, 2014; Michael, 1974). The field of education is a telling example of the inability of groups-design research to provide data that lead to improved practice (Greer, 1983; Heward & Cooper, 1992). Classroom instruction and curricular decisions are often influenced more by fad, fashion, and ideology than by the cumulative knowledge and understanding provided by rigorous and sustained experimental analysis of the variables of which learning is a function (Heron, Tincani, Peterson, & Miller, 2005; Heward, 2005; Kauffman, 2011; Zane, Weiss, Blanco, Otte, & Southwick, 2015).

Between-groups experimentation is inappropriate for answering the questions of primary interest to applied behavior analysts—empirical questions that can be pursued only by analysis of repeated measures of individual behavior under all relevant conditions. We agree with Johnston and Pennypacker (1993b):

> We find the reasoning underlying all such procedures alien to both the subject matter and the goals of a natural science of behavior and regard the utility of group comparisons as extremely limited, no matter how elegant the mathematical treatment of data they afford. . . . [group comparison experimentation constitutes] a process of scientific inquiry that is almost totally inverted; instead of using questions about natural phenomena to guide decisions about experimental design, models of design are allowed to dictate both the form and content of the questions asked. Not only is this antithetical to the established role of experimentation in science, the types of questions allowed by groups comparison designs are largely inappropriate or irrelevant to gaining an understanding of the determinants of behavior. (pp. 94–95)

Our discussion of the limitations of between-groups designs for behavior analysis should not be confused with a position that group designs and statistical inference have no value as research methods for seeking scientific knowledge about the world. On the contrary, between-groups designs and statistical inference are highly effective tools for seeking answers to the kinds of questions for which they were devised. Properly designed and well-executed between-groups experiments provide answers with a specific degree of confidence (i.e., probability) to questions central to many large-scale evaluations. For example, a government body is less interested in the effects of a new regulation on any individual person (and perhaps even less interested in whether a functional relation exists between the regulation and that person's behavior) than it is in the probability that the behavior of a predictable percentage of the population will be affected by the regulation (see Box 10.1). The former concern is behavioral and best pursued with single-case experimental designs that encompass the methods to address it. The latter concern is actuarial; random sampling and statistical inference of between-groups designs are appropriate tools for addressing it.

External Validity and Applied Behavior Analysis

Behavior analysts assess, establish, and specify the external validity, or *scientific generality* (Branch & Pennypacker, 2013), of single-case research findings by replicating experiments. **Replication** in this context means repeating a previous experiment.[11] Sidman (1960) described two major types of replication—direct and systematic.

BOX 10.1

Between-Groups Research and Applied Behavior Analysis

Between-groups research designs dominate the larger world of behavioral and social sciences. In studies using a between-groups design called the *random control trial* (RCT), each participant is randomly assigned to the treatment group or the no-treatment (control) group. A "double-blind" RCT eliminates potential bias by keeping membership in the two groups hidden from investigators and participants. Various statistical tools are used to determine if pre- and posttreatment measures of the dependent variable differ between the groups. Some policymaking bodies and researchers consider RCTs the gold standard for experimental evidence (e.g., U.S. Department of Education, 2003; Interactive Autism Network, 2019).

Can RCTs and other types of between-groups designs help advance applied behavior analysis, a science whose basic principles and practices for changing behaviors have been discovered, refined, and demonstrated effective by single-case experiments? In our view, between-groups research designs can support applied behavior analysis in two principal ways.

First, results from group studies showing positive effects of behavioral treatments may lead to increased awareness of ABA-informed interventions by policymakers, government officials, education and healthcare administrators who fund treatment initiatives, and consumers who might advocate for evidence-based treatments. "A positive outcome of a group study may not make behavior analysts know more about control of an individual client's behavior, yet such an outcome may nonetheless make more people know about behavior analysis" (Iverson, 2013, p. 26). Although hundreds of single-subject studies had shown the positive effects of early intensive behavioral intervention for children with autism, widespread recognition of the effectiveness of behavioral treatment for autism resulted, in large measure, from group comparison studies (see Eldevik et al., 2009, 2010; Smith, Groen, & Wynn, 2000). In the public health sector, between-groups studies in the United Kingdom demonstrating that the Food Dudes program—a behavioral intervention package that includes peer modeling, video recording, rewards for eating healthy foods, and a parent packet—increased school children's consumption of fruits and vegetables contributed to the Irish Government making the program available to all primary schools in Ireland (Horne et al., 2004, 2009).

Second, disseminating between-groups studies evaluating behavioral interventions in journals and at conferences that do not typically feature single-case design research increases awareness of treatments derived from behavior analysis by scientists in other disciplines, which may lead to collaboration and expansion of research agendas. When behavior analysts publish between-group studies in nonbehavioral journals, as has been the case with transportation safety (Van Houten, Retting, Farmer, Van Houten, & Malenfant, 2000), health care regimens (Raiff, Barry, Ridenour, & Jitnarin, 2016), smoking cessation (Dallery et al., 2017), and drug addiction (Madden, Petry, Badger, & Bickel, 1997), a wider audience learns how the principles and procedures of applied behavior analysis can improve the human condition.

For additional discussion and examples of how group studies can contribute to the science and practice of applied behavior analysis, see Critchfield and Kollins (2001), Critchfield and Reed (2017), and Hanley (2017).

Direct Replication

In a **direct replication**, the researcher makes every effort to duplicate exactly the conditions of an earlier experiment. If the same subject is used in a direct replication, the study is an *intrasubject direct replication*. Intrasubject replication within experiments is a defining characteristic of applied behavior analysis research and the primary tactic for establishing the existence and reliability of a functional relation. An *intersubject direct replication* maintains every aspect of a previous experiment except that different, although similar (e.g., same age, similar repertoires), subjects are involved. Intersubject replication is the primary method for determining the extent to which research findings have generality across subjects.

The many uncontrolled variables in natural settings make the direct replication of experiments outside the laboratory extremely difficult. Nevertheless, intersubject replication is the rule rather than the exception in applied behavior analysis. Although numerous single-case studies involve just one subject (e.g., Ahearn, 2003; Dixon & Falcomata, 2004; Fahmie, Iwata, & Mead, 2016; Tarbox, Williams, & Friman, 2004), the vast majority of published studies in applied behavior analysis include direct intersubject replications. This is because each subject can be considered an intact experiment. For example, a behavior analysis study in which the independent variable is manipulated in exactly the same way for six subjects in the same setting yields five intersubject replications.

Systematic Replication

The direct replication of experiments demonstrates the reliability of a functional relation, but the generality of that finding to other conditions can be established only by a series of experiments in which the conditions of interest are purposefully and systematically varied. In a **systematic replication** the researcher purposefully varies one or more aspects of a previous experiment. When a systematic replication successfully reproduces the results of previous research, it not only demonstrates the reliability of the earlier findings but also adds to the external validity of the earlier findings by showing that the same effect can be obtained under different conditions. In a systematic replication, any aspect of a previous experiment can be altered: subjects, setting, administration of the independent variable, target behaviors.

Because systematic replication can provide new knowledge about the variables under investigation, it offers greater potential rewards than direct replication. Although systematic replication entails some risk, Sidman (1960) described it as a gamble well worth taking.

> If systematic replication fails, the original experiment will still have to be redone, else there is no way of determining whether the failure to replicate stemmed from the introduction of new variables in the second experiment, or whether the control of relevant factors was inadequate in the first experiment.
>
> On the other hand, if systematic replication succeeds, the pay-off is handsome. Not only is the reliability of the original finding increased, but also its generality with respect to other organisms *and* to other experimental procedures is greatly enhanced. Furthermore, additional data are now available which could not have been obtained by a simple repetition of the first experiment. (pp. 111–112)

Sidman went on to explain that economic husbandry of limited resources must also play an important role in the scientist's determination of how a research program should proceed. Direct replication of a long and costly experiment can provide data on only the reliability of a functional relation, whereas systematic replication can provide information on the reliability and generality of the phenomena under investigation.

The external validity of results of between-groups research is viewed as an inherent characteristic of a given experiment, as something that can be directly assessed by examining the methods used to conduct the study (e.g., sampling procedures, statistical tests). But as Birnbrauer (1981) pointed out, external validity is not something a single study *has*, but rather the product of many studies. External validity can be pursued only through the active process of systematic replication.

> Generality is established, or more likely limited, by accumulating studies that are internally valid *and* by placing the results into a systematic context, i.e., seeking out the principles and parameters that particular procedures appear to be enunciating. The most informative studies ask *how* can an earlier positive result be repeated in the present circumstances, with the present problem? (p. 122)

Systematic replications make up much of the applied behavior analysis literature. Indeed, one could argue persuasively that any applied behavior analysis study is a systematic replication of at least some aspect of an earlier experiment. Even when the authors have not pointed it out, virtually every published experiment reveals significant procedural similarity with previous experiments. However, as we are using the term here, systematic replication refers to concerted and directed efforts to establish and specify the generality of a functional relation. For example, Hamlet, Axelrod, and Kuerschner (1984) found a functional relation between demanded eye contact (e.g., "[Name], turn around") and compliance with adult instructions in two 11-year-old school children. Included in the same published report were the results of six replications conducted by the same researchers over a period of 1 year with nine students aged 2 to 21 years. Similar results were reproduced in eight of the nine replication subjects. Although some might consider this an example of direct intersubject replication, Hamlet and colleagues' replications were conducted in various settings (i.e., classrooms, homes, institutions) and therefore should be viewed as a series of systematic replications that demonstrated not only the reliability of the results but also considerable generality across subjects of different ages in different settings.

Systematic replications across subjects sometimes reveal different patterns of effects, which the researcher might then study as a function of specific subject characteristics or contextual variables. For example, Hagopian, Fisher, Sullivan, Acquisto, and LeBlanc (1998) reported the results of a series of systematic replications with 21 inpatient cases of functional communication training with and without extinction and punishment.[12] Lerman, Iwata, Shore, and DeLeon (1997) found that thinning FR 1 schedules of punishment (in which each response is punished) to intermittent punishment produced different effects on the self-injurious behavior of five adults with profound intellectual disabilities.

Some systematic replications are attempts to reproduce the results reported by another researcher in a different situation or context. For example, Saigh and Umar (1983) successfully reproduced in a Sudanese classroom the positive results originally reported with the Good Behavior Game in an American classroom (Barrish, Saunders & Wolf, 1969; see Chapter 28). Saigh and Umar reported that a "considerable degree of support for the cross-cultural utility of the game was established" (p. 343). Subsequent systematic replications of the Good Behavior Game in Northern Ireland (Lynch & Keenan, 2018) and the Netherlands (van Lier, Muthen, van der Sar, & Crijnen, 2004) lend additional support for the cross-cultural generality of the intervention's effectiveness.

Researchers sometimes report multiple experiments, each experiment serving as a systematic replication investigating the variables influencing a given functional relation. For example, Fisher and colleagues (1993) conducted four studies designed to explore the effectiveness of functional communication training (FCT) with and without extinction and punishment.

Systematic replication is evident when a research team pursues a consistent line of related studies over time. Examples of this approach to replication can be found in Neef and colleagues' experiments on the impulsivity of students with attention-deficit hyperactivity disorder (ADHD) (e.g., Bicard & Neef, 2002; Neef, Bicard, & Endo, 2001; Neef, Bicard, Endo, Coury, & Aman, 2005; Neef, Markel, et al., 2005); Miltenberger and colleagues' line of research on teaching safety skills to children (e.g., Himle, Miltenberger, Gatheridge, & Flessner, 2004; Johnson et al., 2006; Knudson et al., 2009; Miltenberger, 2008; Miltenberger et al., 2004; Miltenberger et al., 2005); and Van Houten and colleagues' studies investigating variables affecting motorists' behavior and pedestrian safety spanning four decades (e.g., Huitema, Van Houten, & Manal, 2014; Lebbon, Austin, Van Houten, & Malenfant, 2007; Van Houten, Malenfant, Van Houten, & Retting, 1997; Van Houten, Nau, & Marini, 1980).

The systematic replications necessary to extend a significant line of research often require the independent efforts of investigators at different sites who build upon one another's

work. When independent teams of researchers at different geographical locations report similar findings, the net result is a body of knowledge with significant scientific integrity and technological value. This collective effort speeds and enhances the refinement and rigorous testing of interventions that is necessary to the development and refinement of evidence-based practices (Hitchcock, Kratochwill, & Chezan, 2015; Horner & Kratochwill, 2012).

An example of independent research teams at various sites reporting systematic replications across several decades is a body of studies analyzing the effects of response cards on students' academic engagement, learning, and deportment during group instruction.[13] Investigators have reported a similar pattern of results—increased participation during instruction, improved retention of lesson content, and/or reductions in off-task and disruptive behaviors—with response cards used with a wide range of students (general education students, special education students, English as a second language [ESL] learners), curriculum content (e.g., math, science, social studies, spelling), and instructional settings (e.g., preschool, elementary, middle, secondary, and college classrooms) (e.g., Armendariz & Umbreit, 1999; Bondy & Tincani, 2018; Cakiroglu, 2014; Cavanaugh, Heward, & Donelson, 1996; Davis & O'Neill, 2004; Gardner, Heward, & Grossi, 1994; Hott & Brigham, 2018; Kellum, Carr, & Dozier, 2001; Lambert, Cartledge, Lo, & Heward, 2006; Marmolejo, Wilder, & Bradley, 2004; Wood, Mabry, Kretlow, Lo, & Galloway, 2009).

Recognizing the crucial role replications play in the continued development of applied behavior analysis, the editorial board of the *Journal of Applied Behavior Analysis* in 2017 instituted a new category of articles labeled *Replications*.

> It will be expected that the more direct the replication, the shorter the article. More space, but not much more space, will be needed to describe systematic replications that duplicate procedures and their effects under an ever broadening set of conditions. A lengthy article may indeed be published in *Replications* if, for example, authors duplicate procedures, initially fail to replicate results, but then either demonstrate alternative controlling variables or isolate the conditions under which a functional relation occurs and the conditions under which it does not occur. (Hanley, 2017, p. 4)

Planning, conducting, and presenting the results of an applied behavior analysis study requires a great deal of time, energy, and expertise. Increasingly, organizations representing scientific bodies, practitioner groups, and consumers are seeking systematic presentation of single-case studies. The What Works Clearinghouse, a program within the U.S. Department of Education's Institute of Education Sciences, may have been the first to develop rubrics for evaluating and determining whether single-case studies would be included in research syntheses that they published. Maggin, Briesh, Chafouleas, Ferguson, and Clark (2014) compared five rubrics for identifying empirically supported practices with single-case research. The consensus report from a group of 26 researchers offers guidance to researchers about what to include when submitting a research paper for journal publication using single-case experimental designs (Tate et al., 2016a, 2016b).

EVALUATING APPLIED BEHAVIOR ANALYSIS RESEARCH

Thus far we have identified a considerable number of requirements for good applied behavior analysis. Our purpose now is to summarize those requirements in a sequence of questions one might ask in evaluating the quality of research in applied behavior analysis. Those questions can be organized under four major categories: internal validity, social validity, external validity, and scientific and theoretical significance.

Internal Validity

To determine whether an analysis of behavior has been made, the reader of an applied behavior analysis study must decide whether a functional relation has been demonstrated. This decision requires a close examination of the measurement system, the experimental design, and the degree to which the researcher controlled potential confounds, as well as a careful visual analysis and interpretation of the data.

Definition and Measurement of the Dependent Variable

The initial step in evaluating internal validity is to decide whether to accept the data as valid and accurate measures of the target behavior over the course of the experiment. Some of the important issues to be considered in this decision are captured by the questions shown in Figure 10.11.

Graphic Display

If the data are accepted as a valid and accurate representation of the dependent variable over the course of the experiment, the reader should next assess the extent of stability of the target behavior during each phase of the study. Before evaluating the stability of the data paths, however, the reader should examine the graphic display for any sources of distortion (e.g., scaling of axes, distortions of time on the horizontal axis; see Chapter 6). The researcher or consumer who suspects that any element of the graph may encourage interpretations unwarranted by the data should replot the data using a new set of appropriately scaled axes. In an assessment of the stability of the dependent variable within the different phases of an experiment, the length of the phase or condition must be considered as well as the presence of trends in the data path. The reader should ask whether the conditions in effect during each phase were conducive to practice effects. If so, were these effects allowed to play themselves out before experimental variables were manipulated?

Meaningfulness of Baseline Conditions

The representativeness or fairness of the baseline conditions as the basis for evaluating subsequent performance in the presence of the independent variable should be assessed. In other words, were the baseline conditions meaningful in relation to the target behavior, setting, and research questions addressed by the experiment? For example, consider two experiments by Miller, Hall, and Heward (1995) that evaluated the effects of two procedures for conducting 1-minute time trials during a daily 10-minute practice session on the rate and accuracy with which students

Figure 10.11 Questions that should be asked when evaluating the definition and measurement of the dependent variable in an applied behavior analysis study.

- Was the dependent variable precisely, completely, and unambiguously defined?
- Were examples and nonexamples of the target behavior provided, if doing so would enhance clarity?
- Were the most relevant, measurable dimensions of the target behavior specified (e.g., rate, duration)?
- Were important concomitant behaviors also measured?
- Were the observation and recording procedures appropriate for the target behavior?
- Did the measurement provide valid (i.e., meaningful) data for the problem or research question addressed?
- Was the measurement scale broad and sensitive enough to capture socially significant changes in the target behavior.
- Have the authors provided sufficient information on the training and calibration of observers?
- What procedures were used to assess and ensure the accuracy of measurement?
- Were interobserver agreement (IOA) assessments reported at the levels at which the study's results are presented (e.g., by subject and experimental condition)?
- Were observation sessions scheduled during the times, activities, and places most relevant to the problem or research question?
- Did observations occur often enough and closely enough in time to provide a convincing estimate of behavior change over time?
- Were any contingencies operating in the study that may have influenced the observers' behavior?
- Was there any expectation or indication that the dependent variable may have been reactive to the measurement system? If so, were procedures taken to assess and/or control reactivity?
- Were appropriate accuracy and/or reliability assessments of the data reported?

answered math problems. Throughout all conditions and phases of both experiments, the students were instructed to answer as many problems as they could and they received feedback on their performance. Throughout both experiments, students' worksheets were marked and scored as follows:

> Experimenters marked each student's worksheets by putting an 'X' next to incorrect answers. The number of correct answers over the total number of problems attempted was marked at the top of the first worksheet along with a positive comment to encourage the students to keep trying. If a student's score was lower than his or her highest previous score, comments such as "Keep trying, Sally!" "Work faster!" or "Keep working on it!" were written. Whenever a student achieved his or her highest score to date, comments such as "Great job, Jimmy! This is your best ever!" were written on the packet. In the event a student equaled her highest previous score, "You tied your best score!" was written on the packet.

At the beginning of each session, scored and marked worksheets from the prior day's session were returned to the students. Each session during the 10-minute continuous work period condition that functioned as the baseline condition began with the classroom teachers saying to the students: "I want you to work hard and try to do your best. Answer as many problems as you can. Don't worry if you do not answer all of the problems. There are more problems in the packet than anyone can do. Just try your best" (p. 326).

The initial baseline (A) phase was followed by the two time-trial conditions (B and C) in an A-B-A-B-C-B-C design. Results for students in both classrooms showed a clear functional relation between both of the time-trial conditions and increased correct rate and accuracy over the baseline condition. However, if the classroom teachers had not instructed and reminded the students to do their best and to answer as many problems as they could prior to each baseline session, and if the students had not received feedback on their worksheets, the improved performance during the time-trial conditions would have been suspect. Even if a clear functional relation had been demonstrated against such baseline conditions, applied researchers and consumers could, and should, question the importance of such results. Maybe the children simply did not know they were expected to work fast. Perhaps the students would have solved problems in the baseline condition at the same high rates that they did in the time-trial conditions if they had been told to "go fast" and received feedback on their performance, praise for their improvements, and encouragement to answer more problems. By including the daily instruction to work hard and answer as many problems as they could and by returning the worksheets to the students as components of the baseline condition, Miller and colleagues obtained meaningful data paths during baseline against which to test and compare the effects of the two time-trial conditions.

Experimental Design

The experimental design should be examined to determine the type of experimental reasoning it affords. What elements of the design enable prediction, verification, and replication? Is the design appropriate for the research questions addressed by the study? Does the design effectively control for confounding variables? Does the design provide the basis for component and/or parametric analyses if such questions are warranted?

Brossart, Vannest, Davis, and Patience (2014) introduced the term *design analysis* for assessing single-case experimental designs for threats to internal validity and distinguished design analysis from visual analysis.

> A design analysis examines the structure of the experiment to see if it is valid for asserting a functional relationship, whereas a visual analysis looks at means, trends, immediacy and consistency of change in assessing type and amount of behaviour change. This visual analysis may inform a determination about a functional relationship, but not in isolation from evaluation of the design. (p. 468)

Researcher Concludes Functional Relation Exists	Functional Relation Exists in Nature: Yes	Functional Relation Exists in Nature: No
Yes	Correct Conclusion	Type I Error (false positive)
No	Type II Error (false negative)	Correct Conclusion

Figure 10.12 Ideally, an experimental design and methods of data analysis help a researcher conclude correctly that a functional relation between the independent and dependent variables exists (or does not exist) when in fact such a relation does (or does not) exist in nature. Concluding that the results of an experiment reveal a functional relation when no such relation exists in nature is a Type I error. Conversely, concluding that that independent variable did not have an effect on the dependent variable when such a relation did occur is a Type II error.

Visual Analysis and Interpretation

Although statistical methods for evaluating behavioral data and determining the existence of functional relations in single-subject experimental designs have been proposed for more than 40 years (e.g., Gentile, Roden, & Klein, 1972; Hartmann, 1974; Jones, Vaught, & Weinrott, 1977; Manolov & Solanas, 2013; Pfadt & Wheeler, 1995; Solomon, Howard & Stein, 2015), visual inspection remains the most commonly used, and we believe the most appropriate, method for interpreting data in applied behavior analysis. Chapter 6 describes procedures and guidelines for visual analysis of level, trend, and variability behavioral data within and between experimental conditions. We will briefly present four factors that favor visual analysis in applied behavior analysis.

First, applied behavior analysts have little interest in knowing that a behavior change is a statistically significant outcome of an intervention. Applied behavior analysts are concerned with producing socially significant behavior changes. If a test of statistical inference is required to determine whether an individual client or participant's behavior has changed enough to improve his or her quality of life, the answer is no. Or, as Don Baer noted, "If a problem has been solved, you can *see* that; if you must test for statistical significance, you do not have a solution" (Baer, 1977, p. 171).

Second, visual analysis is well suited for identifying variables that produce strong, large, and reliable effects, which contribute to an effective, robust technology of behavior change. On the other hand, powerful tests of statistical analysis can detect the slightest possible correlation between the independent and dependent variables, which may lead to the inclusion of weak, unreliable variables in the technology.

Two types of errors are possible when determining experimental effect (see Figure 10.12). A **Type I error** (also called a *false positive*) is made when the researcher concludes that the independent variable had an effect on the dependent variable, when in truth no such relation exists in nature. A **Type II error** (also called a *false negative*) is the opposite of a Type I error. In this case, the researcher concludes that an independent variable did not have an effect on the dependent variable, when in truth it did.[14] Ideally, a researcher using well-reasoned experimental tactics coupled with a sound experimental design and buttressed by appropriate methods of data analysis will conclude correctly that a functional relation between the independent and dependent variables exists (or does not exist).

Baer (1977) pointed out that the behavior analyst's reliance on visual inspection to determine experimental effects results in a low incidence of Type I errors but increases the commission of Type II errors. The researcher who relies on tests of statistical significance to determine experimental effects makes many more Type I errors than the behavior analyst, but misses few, if any, variables that might produce some effect.

> Scientists who commit relatively many Type 1 errors are bound to memorize very long lists of variables that are supposed to affect diverse behaviors, some predictable portion of which are not variables at all. By contrast, scientists who commit very few Type 1 errors have relatively short lists of variables to remember. Furthermore, and much more important, it is usually only the very robust, uniformly effective variables that will make their list. Those who will risk Type 1 errors more often will uncover a host of weak variables. Unquestionably, they will know more, although some of that more is wrong, and much of it is tricky. . . . Those who keep their probability of Type 2 errors low do not often reject an actually functional variable, relative to those whose Type 2 error probability is higher. Again, unquestionably, the practitioner with the lower probability of Type 2 errors will know more; but again, the nature of that more is seen often in its weakness, inconsistency of function, or its tight specialization. . . . Individual-subject-design practitioners . . . necessarily fall into very low probabilities of Type 1 errors and very high probabilities of Type 2 errors, relative to their group-paradigm colleagues. As a result, they learn about fewer variables, but these variables are typically more powerful, general, dependable, and—very important—sometimes actionable. These are exactly the variables on which a technology of behavior might be built. (Baer, 1977, pp. 170–171)

A third problem with using statistical methods to determine the existence of functional relations in behavioral data occurs with borderline data sets containing significant amounts of variability. Such data sets should motivate a researcher to engage in additional experimentation in an effort to achieve more consistent experimental control and to discover the factors causing the variability. The researcher who forgoes the additional experimentation in favor of accepting the results of a test of statistical significance as evidence of a functional relation risks leaving important findings in the realm of the unknown. Statistical manipulation of data, no matter how elegant or sophisticated, will never replace manipulation of the variables of which behavior is a function.

> The situation where a significance test might seem helpful is typically one involving sufficient uncontrolled variability in the dependent variable that neither the experimenter nor his readers can be sure that there is an interpretable relationship. This is evidence that the relevant behavior is not under good experimental control, a situation calling for more effective experimentation, not a more complex judgmental aid. (Michael, 1974, p. 650)

Fourth, most statistical tests of significance involve certain assumptions can be applied only to data sets that conform to predetermined criteria (Solomon et al., 2015). If those statistical methods for determining experimental effects were to become highly valued in applied behavior analysis, researchers might begin to design experiments so that such tests could be computed. The resultant loss of flexibility in experimental design would be counterproductive to the continued development of behavioral science.

Visual analysis is not without limitations. Poor interrater agreement on whether various data patterns demonstrate experimental control has long been a concern (e.g., Franklin, Gorman, Beasley, & Allison, 1996; Matyas & Greenwood, 1990; Ottenbacher, 1993). In one of the first studies assessing interrater agreement with visual analysis, DeProspero and Cohen (1979) asked 108 editorial board members and guest reviewers of *JABA* and *Journal of the Experimental Analysis of Behavior (JEAB)* to evaluate hypothetical data displayed in nine ABAB graphs on how convincingly (using a scale of 0 [low] to 100 [high]) each graph demonstrated experimental control. Except for the most obvious graphs, those with "ideal patterns," interrater agreement was relatively low (a 0.61 Pearson correlation coefficient). Diller, Barry, and Gelino (2016) asked 19 *JABA* and *JEAB* editorial board members and 90 Board Certified Behavior Analysts (BCBAs) to evaluate the extent to which pairs of hypothetical data paths displayed in 18 multielement design graphs demonstrated experimental control. These researchers also reported inconsistent agreement among reviewers. In contrast, Kahng and colleagues (2010) found high interrater agreement among 45 editorial board members and associate editors of *JABA* from 2002 to 2004 on the extent to which and whether (yes or no) hypothetical data in 36 ABAB graphs demonstrated experimental control.

A limitation of these studies examining interrater agreement with visual analysis is that participants were provided no context for the data. Without knowledge of crucial contextual factors, an applied behavior analyst cannot interpret graphed data properly. Who was the subject? What behavior was measured? How was it measured? What were the behavior change goals? What was the treatment variable? How, when, where, and by whom was treatment implemented? What scales of behavior change and time do the vertical and horizontal axes represent?

Various structured criteria, formal decision rules, and visual aids for interpretation of single-case data have been proposed (e.g. Fisch, 1998; Fisher, Kelley, & Lomas, 2003; Hagopian et al., 1997; Pfadt, Cohen, Sudhalter, Romanczyk, & Wheeler, 1992). Although multiple raters using the same set of rules or test of statistical aids will—if they apply the rules or compute the math correctly—achieve 100% agreement, that may not necessarily be a desirable outcome. What might be meaningful behavior change in one participant-treatment-setting context may not be in another.

Visual analysis of graphed data has served applied behavior analysis well. Behavior analytic researchers and practitioners will continue to rely on it as the primary means of interpreting behavior change and identifying experimental control. However, statistical analysis of behavioral data can support and promote ABA research in several ways (see Box 10.2), and we encourage behavior analysts to follow the development of statistical tools.

Social Validity

The reader of a published study in applied behavior analysis should judge the social significance of the target behavior, the appropriateness of the procedures, and the social importance of the outcomes (Wolf, 1978).

Chapter 3 detailed many considerations that should guide the applied behavior analyst's selection of target behaviors. The social validity of the dependent variable should be assessed in light of those factors. Ultimately, all of the issues and considerations relative to target behavior selection point to one question: Will an increase (or decrease) in the measured dimension of this behavior improve the person's life directly or indirectly?

The independent variable should be evaluated not only in terms of its effects on the dependent variable, but also in terms of its acceptability, practicality, and cost. Regardless of their effectiveness, treatments perceived by practitioners, parents, and/or clients as unacceptable or undesirable for whatever reason are unlikely to be used. Consequently, such treatments will never have the chance to contribute to a technology of behavior change. The same can be said of independent variables that are extremely complex and thus difficult to learn, teach, and apply. Similarly, treatment procedures that require excessive time and/or money to implement have less social validity than do procedures that can be applied quickly and inexpensively.

Even though behavior change is clearly visible on a graphic display, it may not represent a socially valid improvement for the participant and/or significant others in his environment. In evaluating the results of an applied behavior analysis study, the reader should ask questions such as these: Is the participant (or significant others in the participant's life) better off now that the behavior has changed? Will this new level of performance

BOX 10.2

Supplementing Visual Analysis with Statistical Assessments

When evaluating the effects of behavioral interventions, no amount of statistical computation can replace experimental control of variables and visual analysis of the data. However, visual analysis of data from single-case designs can be supplemented with statistical assessment. Behavioral researchers are using statistical tools with increasing frequency to calculate a standard metric of effect and to calculate the overall effect of multiple studies investigating a common research question.

Effect Size: Quantifying the Magnitude of Treatment Impact

Effect size, a statistical measure of how much a treatment variable influenced a dependent variable, is widely used in group design studies. One type of effect size calculated with *Cohen's d* formula ranges from -1.00 to $+1.00$. Cohen (1988) described effect sizes of $+0.2$ as small, $+0.5$ as medium, and $+0.8$ as large. A negative effect size indicates that a treatment variable has a reductive or harmful effect. Cohen acknowledged the danger of using such terms without noting the study's context and the resources required to obtain the effect (e.g., a small effect from an easy-to-implement treatment accepted by staff and clients may be a more valuable outcome than a large effect obtained with a costly treatment disfavored by staff and clients).

There is no current consensus on how to derive effect sizes for single-case design studies. The U.S. Department of Education's What Works Clearinghouse (2018) recommends calculating the magnitude of treatment effects in single-case studies with a variety of tools, suggesting that stronger conclusions may be drawn if similar results are obtained from multiple approaches. If the magnitude of treatment effects is properly calculated, anyone using the same statistical tools will obtain the same result. The difficulty is "choosing from the bewildering number of statistical methods available" (Brossart, Vannest, Davis, & Patience, 2014, p. 467).

To explore the question of whether different statistical tools can be used for determining the magnitude of effects from single-case studies, Shadish (2014) asked the developers of five different statistical approaches to analyze the nine ABAB data sets from Lambert, Cartledge, Heward, and Lo's (2006) study on the effects of response cards on disruptive behavior during math lessons by nine fourth-grade students (Figure 8.3 shows data for four of the students). The different approaches found effects "not identical but reasonably consistent with each other and with visual inspection" of the data (Shadish, 2014, p. 112). In commenting on these results, Fisher and Lerman (2014) noted that the data sets in Lambert et al.'s study showed "mostly large and unambiguous treatment effects" and that Shadish "acknowledged that more definitive comparison of visual and statistical analyses will require further refinements in statistical methods" (p. 247).

Meta-Analysis: Statistical Synthesis of Related Studies

Meta-analysis entails a variety of statistical techniques for aggregating the effect sizes of a group of studies in a specific area (Borenstein, Hedges, Higgins, & Rothstein, 2009). Two examples are Maggin, O'Keefe, and Johnson's (2011) synthesis of 25 years of special education studies, and Stockard, Wood, Coughin, and Khoury's (2018) quantitative review of 328 studies on Direct Instruction published over a half century.

Meta-analyses that aggregate the individual participant's data across studies are sometimes called *mega-analysis* (H. Cooper & Patall, 2009). An example is Eldevik et al.'s (2009) mega-analysis of 16 group design studies on behavioral intervention for children with autism. The investigators analyzed the results for 453 individual participants (309 children who received behavioral intervention, 39 children who received comparison interventions, and 105 children who were in control groups). Results showed that a far higher percentage of children who received behavioral intervention achieved reliable change in IQ score (at least $+27$ points) and adaptive behavior (at least 21 points) than did children in the comparison and control groups.

Readers interested in learning more about statistical tools for single-case data can examine the What Works Clearinghouse (2018) *Standards Handbook*; explore the free web-based calculators and manuscripts archived by Vannest, Parker, Gonen, and Adiguzel (2016); and study articles by single-case researchers with expertise in statistical methods (e.g., Fisher & Lerman, 2014; Kratochwill & Levin, 2014; Solomon, Howard, & Stein, 2015).

result in increased reinforcement (or decreased punishment) for the subject now or in the future? In some instances it is relevant to ask whether the subject (or significant others) believes that her behavior has improved (Wolf, 1978).

Maintenance and Generalization of Behavior Change

Improvements in behavior are most beneficial when they are long-lasting, appear in other appropriate environments, and spill over to other related behaviors. Producing these kinds of effects is a major goal of applied behavior analysis. (Chapter 30 examines strategies and tactics that promote generalized behavior change.) When evaluating applied behavior analysis research, consumers should consider the maintenance and generalization of behavior change in their evaluation of a study. An impressive behavior change that does not last or is restricted to a specialized training setting has limited value.

Did the researchers report the results of assessing maintenance and generalization through follow-up observations and

measurement in nontraining environments? If maintenance and/or generalization were not evident in follow-up observations, did the experimenters modify their design and implement procedures in an attempt to produce and analyze the occurrence of maintenance and/or generalization? Additionally, the reader should ask whether response generalization—changes in functionally similar but untreated behaviors concomitant with changes in the target behavior(s)—is an appropriate concern in a given study. If so, did the experimenters attempt to assess, analyze, or discuss this phenomenon?

External Validity

As discussed earlier, the generality of an experiment's findings to other subjects, settings, and behaviors cannot be assessed by inherent aspects of the study itself. The generality of a behavior–environment relation can be established only through the active process of systematic replication. Therefore, the reader of an applied behavior analysis study should compare the study's results with those of other published studies sharing relevant features. The authors of a published report identify in the paper's introduction the experiments that they believe are most relevant. To judge whether and the extent to which a given study contributes to the generality of previous findings, the reader must examine previous studies in the literature and compare the results of these studies with those of the current experiment.

Although external validity should not be considered a characteristic of a study per se, various features of a single-case experiment suggest an expected, or likely, level of generality for the results. For example, an experiment that demonstrated a functional relation of similar form and degree in six subjects of different ages, cultural and linguistic backgrounds, and skills levels suggests a higher probability of generality to other subjects than would an identical study demonstrating the same results across six subjects of the same age, background, and skill level.[15] Additional confidence in the generality of the results may be warranted if the experiment was conducted in various settings and different people administered the independent variable.

A research finding without extensive external validity can make a meaningful contribution to scientific knowledge. Johnston and Pennypacker (2009) point out, "A procedure can be quite valuable even though it is effective in a narrow range of conditions, as long as we know what those conditions are" (pp. 343–344).

Theoretical Significance and Conceptual Sense

A published experiment should also be evaluated in terms of its scientific merit. It is possible for a study to demonstrate a functional relation between the independent variable and a socially important target behavior—and thus be judged significant from an applied perspective—yet contribute little to the advancement of the field.[16] It is possible to reliably reproduce an important behavior change while at the same time not fully understand which variables are responsible for the observed functional relation. Sidman (1960) differentiated this kind of simple reliability from "knowledgeable reproducibility," a more complete level of analysis in which all of the important factors have been identified and controlled.

After examining the majority of experimental articles published in the first 10 volumes of the *Journal of Applied Behavior Analysis* (1968 to 1977), Hayes, Rincover, and Solnick (1980) concluded that a technical drift had occurred in the field away from conceptual analyses and toward an emphasis on client cure. They warned of a likely loss of scientific understanding as a result of focusing purely on the technical aspects of improving behavior in applied settings, and they recommended an increased effort to perform more thorough analyses of behavior.

> [T]hese more complicated analyses may increase our knowledge of the actual functional variables and subsequently increase our ability to generate more efficient and general behavioral programs. Perhaps, we have gone too far in our attempt to be *immediately* applied at the expense of being *ultimately* more effective, in failing to encourage more analogue and analytical studies that have treatment implications. (Hayes et al., 1980, p. 283)

Baer, Wolf, and Risley (1987), writing in the 20th anniversary issue of the *Journal of Applied Behavior Analysis*, emphasized the need to shift from demonstrations of behavior changes—as convincing as they might be—to a more complete analysis and conceptual understanding of the principles that underlie the successful demonstrations.

> Twenty years ago, *analytic* meant a convincing experimental design, and *conceptual* meant relevance to a comprehensive theory about behavior. . . . Now, applied behavior analysis is more often considered an analytic discipline only when it demonstrates convincingly how to make specified behavior changes *and* when its behavior-change methods make systematic, conceptual sense. In the past 20 years, we have sometimes demonstrated convincingly that we had changed behavior as specified, but by methods that did not make systematic, conceptual sense—it was not clear *why* those methods had worked. Such cases let us see that we were sometimes convincingly applied and behavioral, yet even so, not sufficiently analytic. (p. 318)

Morris (1991) expressed concern over the rise of research that "demonstrates the effects of behavioral interventions at the expense of discovering . . . actual controlling relationships" (p. 413). Numerous authors have discussed the importance of focusing on the analysis side of applied behavior analysis as much as the applied side (e.g., Baer, 1991; Birnbrauer, 1979, 1981; Deitz, 1982; Iwata, 1991; Johnston, 1991; see Schlinger, 2017 for a review).

We agree with the need for more sophisticated, thorough analyses of the variables controlling socially important behavior. Fortunately, examination of the recent literature reveals numerous examples of studies featuring component analyses and parametric analyses that are necessary steps to a more complete understanding of behavior—an understanding that is prerequisite to the development of a thoroughly effective technology of behavior change. Several of the studies cited earlier in this chapter as examples of systematic replication incorporated component and parametric analyses.

The extent of a phenomenon's generality is known only when all of the necessary and sufficient conditions for its

reproducibility have been specified. Only when all of the variables influencing a functional relation have been identified and accounted for can an analysis be considered complete. Even then, the notion of a complete analysis is misleading: "Further dissection or elaboration of either variable in a functional relation inevitably reveals fresh variability, and analysis proceeds anew. . . . the analysis of behavior can never be complete" (Pennypacker, 1981, p. 159).

Evaluation of scientific significance takes into consideration such things as the authors' technological description of the experiment as well as their interpretation and discussion of the results. Are the procedures described in sufficient detail so that at least the unique aspects of the study can be replicated?[17]

Readers should consider the level of conceptual integrity displayed in an experimental report. Does the literature review reveal a careful integration of the study with previous research? Does the literature review provide sufficient justification for the study's research questions? Are the authors' conclusions based on the data obtained in the study? Have the authors respected the difference between basic principles of behavior and behavior change tactics? Do the authors speculate beyond the data without making it clear that they are doing so? Do the authors suggest directions for additional research to further analyze the problem studied? Is the study important for reasons other than the results actually obtained? For example, an experiment that demonstrates a new measurement technique, investigates a new dependent or independent variable, or incorporates a novel tactic for controlling a confounding variable can contribute to the scientific advancement of behavior analysis, even though the study failed to achieve experimental control or produce socially significant behavior change.

Numerous criteria and considerations are involved in evaluating the "goodness" of an applied behavior analysis study. Although each criterion is important on one level or another, it is unlikely that any experiment will meet all of the criteria. And, in fact, it is unnecessary for an experiment to do so to be considered worthwhile. Nevertheless, incorporating these considerations into a study enhances its social significance and scientific value.

SUMMARY

Importance of the Individual Subject in Behavior Analysis Research

1. Behavior analysis research methods feature repeated measures of the behavior of individual organisms within and across experimental conditions.
2. By contrast, a between-groups experiment follows a sequence like this:
   - A pool of subjects is selected randomly from the population of interest.
   - The subjects are divided randomly into an experimental group and a control group.
   - A pretest measure of the dependent variable is obtained for all subjects in each group, individual pretest scores for the subjects in each group are combined, and the means and standard deviations are calculated.
   - Subjects in the experimental group are exposed to the independent variable.
   - A posttest measure of the dependent variable is obtained for all subjects, and means and standard deviations are computed for each group.
   - Various statistical tests compare any changes in each group's scores from pretest to posttest, applying to the data that enable inferences regarding the likelihood that any differences between the two groups' performances can be attributed to the independent variable.
3. Knowing that the average performance of a group of subjects changed may not reveal anything about the performance of individual subjects.
4. To be most useful, a treatment must be understood at the level at which people come into contact with it and are affected by it: the individual level.
5. Mean performance of a group of subjects hides intersubject variability in the data. Attempting to cancel out variability through statistical manipulation neither eliminates its presence in the data nor controls the variables responsible for it.
6. When repeated measurement reveals significant variability, the researcher should seek to identify and control the factors responsible for it.
7. The researcher who attributes the effects of unknown or uncontrolled variables to chance is unlikely to identify and analyze important variables.
8. To control the effects of any variable, a researcher must either hold it constant throughout the experiment or manipulate it as an independent variable.
9. Group data may not represent actual behavioral processes.
10. A great strength of within-subject experimental designs is the convincing demonstration of a functional relation made possible by replication within the design itself.
11. The overall performance of a group is socially significant in many situations.
12. When group results do not represent individual performances, researchers should supplement group data with individual results.
13. When the behavior analyst cannot control access to the experimental setting or identify individual subjects, the dependent variable must consist of the responses made by individuals who enter the experimental setting.

Importance of Flexibility in Experimental Design

14. An effective experimental design is any sequence of independent variable manipulations that produces data that effectively and convincingly address the research question(s).

15. No ready-made experimental designs await selection, nor is there a set of rules that must be followed.

16. To investigate the research question(s) of interest, an experimenter must often build an experimental design that employs a combination of analytic tactics.

17. A component analysis is any experiment designed to identify the active elements of a treatment condition, the relative contributions of different components in a treatment package, and/or the necessity and sufficiency of treatment components. Two basic methods are used for conducting component analyses:
    - drop-out component analysis: the investigator presents and assesses the treatment package as a whole, then systematically removes components.
    - add-in component analysis: the investigator presents and assesses components individually or in combination, then presents the complete treatment package.

18. The most effective experimental designs use ongoing evaluation of data from individual subjects as the basis for employing the three elements of baseline logic—prediction, verification, and replication.

Internal Validity: Controlling Potential Sources of Confounding in Experimental Design

19. Experiments that demonstrate a clear functional relation between the independent variable and the target behavior have a high degree of internal validity.

20. An experimental design's strength is determined by the extent to which it (a) demonstrates a reliable effect and (b) eliminates or reduces the likelihood that factors other than the independent variable produced the behavior change.

21. Although the term *experimental control* implies that the researcher controls the subject's behavior, the researcher can control only some aspect of the subject's environment.

22. A confounding variable is an uncontrolled factor known or suspected to have exerted influence on the dependent variable.

23. Confounding variables can be viewed as related primarily to one of four elements of an experiment: subject, setting, measurement of the dependent variable, and independent variable.

24. A placebo control separates effects that may be produced by a subject's expectations of improvement as a result of receiving treatment from the effects actually produced by the treatment.

25. With a double-blind control procedure neither the subject(s) nor the observers know when the independent variable is present or absent.

26. Treatment integrity refers to the extent to which the independent variable is implemented or carried out as planned.

27. Procedural fidelity refers to the extent to which procedures in all conditions of an experiment, including baseline, are correctly implemented.

28. Low treatment integrity invites a major source of confounding into an experiment, making it difficult, if not impossible, to interpret the results with confidence.

29. One threat to treatment integrity, treatment drift, occurs when application of the independent variable during later phases of an experiment differs from the way the treatment was applied at the study's outset.

30. Achieving a high level of treatment integrity begins with a precise operational definition of treatment procedures.

31. Simplifying and standardizing the independent variable and providing criterion-based training and practice for the people responsible for implementing it enhance treatment integrity.

32. Researchers should not assume that a person's general competence or experience in the experimental setting, or that providing the intervention agent with detailed written instructions or a script, will ensure a high degree of treatment integrity.

33. Treatment integrity/procedural fidelity data describe the extent to which the actual implementation of experimental procedures matches their descriptions in the method section of a research report.

34. Treatment integrity/procedural fidelity data are required for a study's inclusion in systematic reviews of literature conducted by professional and government organizations.

Social Validity: Assessing the Applied Value of Behavior Changes and the Treatments That Accomplish Them

35. The social validity of an applied behavior analysis study should be assessed in three ways: the social significance of the behavior change goals, the appropriateness of the intervention, and the social importance of the results.

36. Experts and persons who use the prospective skill in natural environments can help researchers identify socially valid target behaviors.

37. Socially valid goals can be determined empirically by assessing the performance of individuals judged to be highly competent, and experimentally manipulating different levels of performance to determine socially valid outcomes.

38. Several scales and questionnaires for obtaining consumers' opinions of the acceptability of behavioral interventions have been developed.

39. Preference for interventions can be assessed directly by arranging experimental conditions in which practitioners or clients can choose which of multiple treatments to implement or receive.

40. Methods for assessing the social validity of outcomes include: (a) having consumers rate the social validity of participants' performance, (b) asking experts to evaluate participants' performance, (c) comparing participants' performance to that of a normative sample, (d) standardized assessment instruments, and (e) real-world tests of participants' performance.

External Validity: Replicating Experiments to Determine the Generality of Research Findings

41. External validity refers to the degree to which a functional relation found reliable and socially valid in a given experiment operates under different conditions.

42. Group design researchers assume that including many subjects increases the external validity, or generality, of a study's findings to other individuals.

43. The assumption of increased generality violates a fundamental premise of the between-groups method: The proper inferences about the results of a groups design study are from the sample to the population, not from the sample to the individual.

44. A between-groups experiment does not demonstrate a functional relation between the behavior of any subject and some aspect of his or her environment; the external validity of its findings is moot.

45. Although between-groups designs and tests of statistical significance are necessary and effective tools for answering certain types of research questions, they have contributed little to an effective technology of behavior change.

46. The generality of research findings in applied behavior analysis is assessed, established, and specified by replicating experiments.

47. In a direct replication, the researcher makes every effort to duplicate exactly the conditions of an earlier experiment.

48. In a systematic replication, the researcher purposefully varies one or more aspects of an earlier experiment.

49. When a systematic replication successfully reproduces the results of previous research, it not only demonstrates the reliability of the earlier findings but also adds to the generality of the earlier findings by showing that the same effect can be obtained under different conditions.

50. Systematic replications occur in both planned and unplanned ways through the work of many experimenters in a given area, and they result in a body of knowledge with significant scientific integrity and technological value.

Evaluating Applied Behavior Analysis Research

51. The quality and value of an applied behavior analysis study may be evaluated by seeking answers to a sequence of questions related to internal validity, social validity, maintenance and generalization of behavior change, external validity, and scientific and theoretical significance.

52. A Type I error occurs when a researcher concludes that the independent variable had an effect on the dependent variable when it did not. A Type II error occurs when a researcher concludes that the independent variable did not have an effect on the dependent variable when it did.

53. Visual analysis effectively identifies variables that produce strong, large, and reliable effects, which contribute to an effective and robust technology of behavior change. Statistical analysis detects the slightest possible correlations between the independent and dependent variables, which may lead to the identification and inclusion of weak and unreliable variables in the technology.

54. A study can yield significant results from an applied perspective—demonstrate a functional relation between the independent variable and a socially important target behavior—yet contribute little to the advancement of the field.

55. Only when all of the variables influencing a functional relation have been identified and accounted for can an analysis be considered complete.

56. When evaluating the scientific significance of a research report, readers should consider the technological description of the experiment, the interpretation and discussion of the results, and the level of conceptual sense and integrity.

KEY TERMS

add-in component analysis
component analysis
direct replication
double-blind control
drop-out component analysis
placebo control
procedural fidelity
replication
social validity
systematic replication
treatment drift
treatment integrity
treatment package
Type I error
Type II error

MULTIPLE-CHOICE QUESTIONS

1. The most useful level to understand the effect of a treatment is the:
   a. Group level
   b. Individual level
   c. Procedural level
   d. Implementation level
   Hint: (See "Importance of the Individual Subject in Behavior Analysis Research")

2. Applied behavior analysis research has identified effective interventions for socially significant behavior by focusing on the
   a. Behavior of individuals with cognitive delays
   b. Common behavior of groups of individuals
   c. Behavior of individual subjects
   d. Behavior of professionals
   Hint: (See "Importance of the Individual Subject in Behavior Analysis Research")

3. Combining analytic tactics in an experimental design is a good idea when
   a. It allows for a more convincing demonstration of experimental effect
   b. The research question is too broad for a single design
   c. The procedures are quite complex
   d. None of these is a justification for combining tactics
   Hint: (See "Experimental Designs Combining Analytic Tactics")

4. The research tactic for examining two or more elements of a treatment package is called a(n)
   a. Alternating treatment design
   b. Multiple baseline across interventions
   c. Multiple treatments
   d. Component analysis
   Hint: (See "Experimental Designs Combining Analytic Tactics")

5. Experiments that demonstrate a clear functional relationship between the independent variable and the observed behavior are said to have a high degree of
   a. Internal validity
   b. External validity
   c. Social validity
   d. Reliability
   Hint: (See "Internal Validity: Controlling Potential Sources of Confounding in Experimental Design")

6. An uncontrolled factor that is known or suspected to have exerted influence on the dependent variable is called a(n)
   a. Extraneous factor
   b. Confounding variable
   c. Behavioral control
   d. Maintaining event
   Hint: (See "Internal Validity: Controlling Potential Sources of Confounding in Experimental Design")

7. All of the following are methods for assessing the social validity of outcomes except:
   a. Comparing participants' performance to the performance of a normative sample
   b. Using standardized assessment instruments
   c. Asking consumers to rate the social validity of participant outcomes
   d. Asking the researchers to rate the social validity of participant outcomes
   Hint: (See "Social Validity: Assessing the Applied Value of Behavior Changes and the Treatments That Accomplish Them")

8. The ultimate purpose of social validity assessment is to
   a. Guide behavior change program development and application
   b. Improve researchers' chances of publication
   c. Improve the relationship between researchers and clients
   d. Increase the magnitude of behavior change
   Hint: (See "Social Validity: Assessing the Applied Value of Behavior Changes and the Treatments That Accomplish Them")

9. The degree to which a functional relationship can be demonstrated in circumstances that are different from the experimental conditions is called:
   a. Internal validity
   b. Treatment acceptability
   c. Replication
   d. External validity
   Hint: (See "External Validity: Replicating Experiments to Determine the Generality of Research Findings")

10. Which of the following research designs have contributed the least in terms of effective technology for behavior change?
    a. Group comparison designs
    b. Multiple baseline across settings
    c. Reversal designs
    d. Component analyses
    Hint: (See "External Validity: Replicating Experiments to Determine the Generality of Research Findings")

11. Which of the following is a factor not to consider when determining whether or not a functional relation has been demonstrated in an experiment?
    a. The degree to which the researcher controlled potential confounds
    b. An examination of the measurement system
    c. Visual analysis and interpretation of the data
    d. Systematic replication of effects

    Hint: (See "Evaluating Applied Behavior Analysis Research")

12. Which of the following is not a reason that applied behavior analysts favor visual analysis of data over statistical methods?
    a. Statistical significance is not the target outcome for behavior analysts.
    b. Visual analysis is well suited for demonstrating strong effects.
    c. Highly variable data may not be statistically significant.
    d. Predetermined criteria of statistical tests offer less flexibility in experimental design.

    Hint: (See "Evaluating Applied Behavior Analysis Research")

ESSAY-TYPE QUESTIONS

1. Give at least two reasons why knowledge of group performance means is inadequate information for the behavior analyst to evaluate the effectiveness of a treatment.

   Hint: (See "Group Data May Not Represent the Performance of Individual Subjects")

2. Explain two benefits of building an experimental design using a combination of analytic tactics.

   Hint: (See "Experimental Designs Combining Analytic Tactics")

3. Define treatment integrity and explain its importance in applied behavior analysis research.

   Hint: (See "Independent Variable Confounds")

4. Describe the ways that Wolf (1978) suggested that social validity should be assessed in applied behavior analysis.

   Hint: (See "Social Validity: Assessing the Value of Behavior Changes and the Treatments That Accomplish Them")

5. Compare and contrast direct replication with systematic replication. What does each type of replication demonstrate?

   Hint: (See "External Validity and Applied Behavior Analysis")

6. Explain the difference between a Type I and a Type II error in experimental research.

   Hint: (See "Evaluating Applied Behavior Analysis Research")

NOTES

1. Between-groups experimental designs are characterized by few measures of the dependent variable (often just two: pretest and posttest) across many subjects. In contrast, single-case studies require many measures of the dependent variable across a few participants (sometimes just one). Behavioral researchers occasionally employ pretest-treatment-posttest designs, typically reporting the results for each subject as well as group means (e.g., Keintz, Miguel, Kao, & Finn, 2011; Sawyer et al., 2017).
2. This brief sketch of the simplest form of a between-groups design study omits many important details and controls. Readers interested in a thorough explication of group research methods should consult an authoritative text (e.g., Adams & Lawrence, 2019; Campbell and Stanley, 1963; Shaddish Cook, & Campbell, 2001). Blampied (2013), Branch (2014), and Colquhoun (2014, 2016) describe how the decades-long reliance on statistical significance testing, first championed by the agricultural scientist and geneticist R. A. Fisher (1925, 1935), has impaired robust and reliable scientific progress.
3. A complete discussion of the problems posed by commingling data from multiple subjects is beyond the scope of this text. We encourage readers seeking a more complete understanding of these important issues to read Branch and Pennypacker (2013), Johnston and Pennypacker (1980, 1993b, 2009), and Sidman (1960).
4. The posttest data point in the left-hand graph of Figure 10.1 is reminiscent of the man whose bare feet were in a bucket of ice while his head was on fire. Asked how he was feeling, the man replied, "On the average, I feel fine."
5. The analytic tactics presented in Chapters 8 and 9 should not be considered experimental designs in and of themselves for another reason: All experiments incorporate design elements in addition to the type and sequence of independent variable manipulations (e.g., subjects, setting, dependent variable, measurement system).
6. Time-out and differential reinforcement of other behavior (DRO) are described in Chapters 15 and 25, respectively.
7. Treatment integrity can be manipulated as an independent variable to analyze the effects of full versus various levels of fidelity, or types of treatment "mistakes," in implementing an intervention on participants' behavior (e.g., Carroll, Kodak, & Fisher, 2013; DiGennaro Reed, Reed, Baez, & Maguire, 2011; Groskreutz, Groskreutz, & Higbee, 2011; Pence & St. Peter, 2015; St. Peter, Byrd, Pence, & Foreman, 2016 [see discussion of omission errors and commission errors in Chapter 15]; Wilder, Atwell, & Wine, 2006 [see Figure 8.13]).
8. Headsprout Comprehension and Headsprout Early Reading are computer-based reading programs for beginning readers and were developed by behavior analysts (Layng, Twyman, & Stikeleather, 2004; Twyman, Layng, Stikeleather, & Hobbins, 2005).
9. Additional discussions of social validity and procedures for assessing it can be found in Carroll and St. Peter (2014); Common and Lane (2017); Snodgrass, Chung, Meadan, and Halle (2018); and the special section on social validity in the Summer 1991 issue of the *Journal of Applied Behavior Analysis*.

10. Assuming group data describe the behavior of individual participants poses little problem when intersubject differences are negligible or of no particular interest (Blampied, 2013). One kernel of corn is genetically and functionally identical to the millions of other kernels harvested from the same acre of farmland. People are quite another matter.
11. Johnston and Pennypacker (1980) pointed out a distinction between replicating an experiment and reproducing its results. They stated that the quality of the replication should be judged only by "the extent to which equivalent environmental manipulations associated with [the original experiment] are duplicated. . . . Thus, one replicates procedures in an effort to reproduce effects" (pp. 303–304). However, when most researchers report a "failure to replicate," they mean that the results of the replication did not match those obtained in the earlier research (e.g., Ecott, Foate, Taylor, & Critchfield, 1999; Friedling & O'Leary, 1979).
12. Functional communication training (FCT) is described in Chapter 26.
13. Response cards are small cards, signs, or items that students hold up to display their answers to teacher-posed questions or problems.
14. The boy who cried wolf caused both Type I and Type II errors. First everyone believed there was a wolf, when there wasn't. Next everyone believed there was no wolf, when there was. Substitute "effect" for "wolf" and you'll never confuse Type 1 and II errors again (Stafford, 2015).
15. The American Psychological Association (2010) recommends that authors indicate the sex, disability status, socio-economic status, and ethnicity of research participants. Li, Wallace, Ehrhardt, and Poling (2017) found that only 4 of 288 intervention articles published in behavior analysis journals for 2013 through 2015 included information on all four descriptors.
16. It is important to remember that although some research in applied behavior analysis can rightfully be criticized as superficial because it adds little to our conceptual understanding of behavior, studies in which meaningful target behaviors are improved to a socially valid level by the application of a socially valid treatment variable (whether a package or not) are never superficial to the participants and the significant others who share their environment.
17. Ideally, published procedural descriptions should include sufficient detail to allow an experienced investigator to replicate the experiment. However, space limitations of most journals often prohibit such detail. The common and recommended practice in replicating published studies is to request complete experimental protocols from the original investigator(s).

PART 4

Reinforcement

The three chapters in Part 4 are devoted to reinforcement, the most important and widely applied principle of behavior analysis. Reinforcement, a deceptively simple behavior–consequence relation, is the fundamental building block of operant behavior. Chapter 11 presents the operation and defining effect of reinforcement, explains how reinforcers are classified and identified, describes briefly how antecedent stimulus conditions modulate the effects of reinforcement, discusses factors that influence the effectiveness of reinforcement, outlines experimental control techniques for verifying whether a positive reinforcement contingency is responsible for increased responding, and offers guidelines for using reinforcement effectively.

In Chapter 12, Richard Smith and Brian Iwata describe one of the most consistently misunderstood principles of behavior. Smith and Iwata define negative reinforcement, an operant contingency in which responding increases as a result of the termination, reduction, or postponement of a stimulus as a behavioral consequence; compare and contrast it with positive reinforcement and punishment; distinguish between escape and avoidance contingencies; describe events that may serve as negative reinforcers; illustrate how the application of negative reinforcement can be used to strengthen desired behavior; and discuss ethical issues that arise when using negative reinforcement.

One of Skinner's most important discoveries was that reinforcement does not have to follow every response. In fact, under many intermittent schedules of reinforcement—in which reinforcement follows some, but not all, occurrences of the target behavior—responding occurs at higher, more consistent, rates than under a continuous schedule of reinforcement, in which each response is reinforced. Chapter 13 describes how intermittent reinforcement can be scheduled based on various combinations of response and/or temporal requirements and identifies characteristic patterns of responding associated with each schedule. Practitioners who understand how different schedules of reinforcement influence behavior can program reinforcement for more effective and efficient acquisition of new skills and for improved performance and endurance of established skills.

CHAPTER 11

Positive Reinforcement

LEARNING OBJECTIVES

- Define and provide examples of positive reinforcement.
- Define and provide examples of conditioned and unconditioned reinforcement.
- Describe and provide examples of the operant conditioning paradigm (i.e., the three-term and four-term contingencies).
- Identify potential reinforcers.
- Use appropriate parameters and schedules of reinforcement to identify reinforcers.
- Use response-deprivation procedures (e.g., the Premack principle).
- Identify control procedures for positive reinforcement.
- Use positive reinforcement effectively.

In looking back, it seems to me that the most important thing I learned in graduate school was from another student, Burrhus Frederic Skinner (I called him Burrhus, others called him Fred). This man had a box, within which was a smaller box, within which he would place a hungry laboratory rat. When the animal, in its explorations, would depress a lever that projected from one wall, a pellet of food would be discharged into a tray beneath the lever. Under such conditions, the rat would learn, in a matter of minutes, sometimes seconds, how to get its meal by depression of the lever. It would even keep on pressing, sometimes at a rapid rate, when pellets were delivered only now and then; and if the food supply was cut off entirely, the animal would still keep working for awhile.

—Fred Keller (1982, p. 7)

Positive reinforcement is the most important and most widely applied principle of behavior. Although some people continue to believe that the results of laboratory research with animals is not applicable to human learning, by the mid-1960s researchers established the significant role of positive reinforcement in education and treatment. "It is safe to say that without Skinner's detailed laboratory analyses of reinforcement (Skinner, 1938), there would be no field of 'applied behavior analysis' today, least not as we know it" (Vollmer & Hackenberg, 2001, p. 241).

Fittingly, the lead article in the first issue of the *Journal of Applied Behavior Analysis* reported an experiment showing the effects of positive reinforcement on student behavior (Hall, Lund, & Jackson, 1968). Six elementary students who were disruptive or dawdled frequently participated in this classic study. The dependent variable, study behavior, was defined individually for each student, depending on the subject matter being taught, but it generally consisted of the student being seated and oriented toward the appropriate object or person (e.g., looking at course materials or the lecturing teacher) and class participation (e.g., writing the assignment, answering the teacher's question). The independent variable was teacher attention, cued by an observer who held up a small square of colored paper not likely to be noticed by the target student. On this signal, the teacher attended to the child by moving to his desk and making a verbal comment or giving him a pat on the shoulder.

The effects of contingent teacher attention on the behavior of all six students were striking. Figure 11.1 shows the results for Robbie, a third-grader who was "a particularly disruptive student who studied very little" (p. 3). During baseline, Robbie engaged in study behavior for an average of 25% of the observed intervals. The remainder of the time he snapped rubber bands, played with objects in his pocket, talked and laughed with classmates, and played with an empty milk carton from his earlier-served drink. The majority of attention Robbie received followed nonstudy, disruptive behaviors.

Following baseline, the experimenters showed the teacher a graph of Robbie's study behavior, presented the results of previous studies in which contingent adult attention had improved child behavior, and discussed the fundamentals of providing contingent social reinforcement.

The results of contingent reinforcement were as follows: During Reinforcement 1, Robbie's study behavior increased to a mean of 71%. When a reversal to baseline conditions was introduced, his study behavior decreased to a mean of 50%; but when Robbie's teacher again provided contingent attention for study behavior (Reinforcement 2), his study behavior recovered and stabilized at a level ranging between 70% and 80% of the observed intervals. Followup observations over a 14-week period showed that Robbie's study behavior had maintained at 79%. The teacher reported positive behavior changes associated with Robbie's increased study behavior. By the final week of

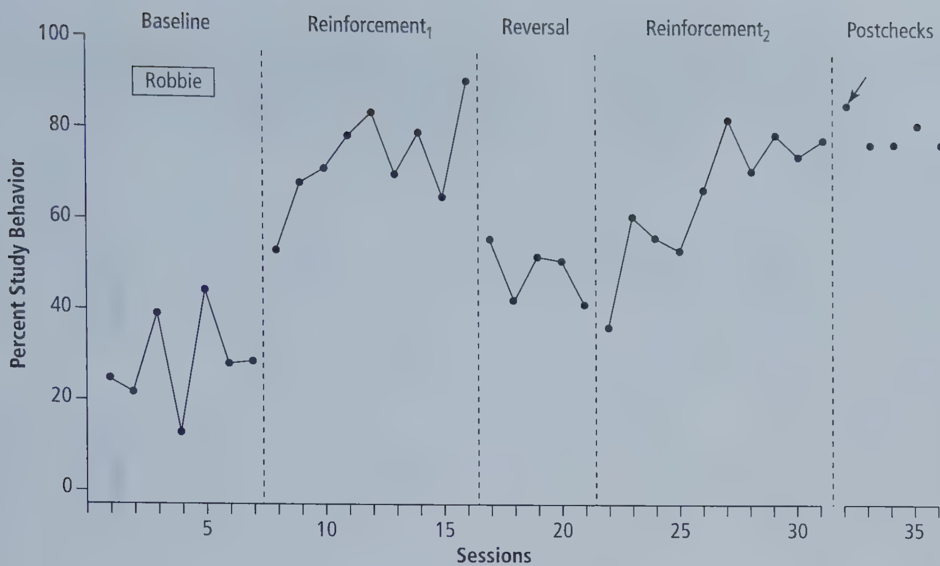

Figure 11.1 Percentage of intervals of study behavior by a third-grade student during baseline and reinforcement conditions. The arrow to the first postcheck data point shows when cueing the teacher to provide attention was discontinued.

Based on "Effects of Teacher Attention on Study Behavior" by R. V. Hall, D. Lund, and D. Jackson, 1968, *Journal of Applied Behavior Analysis, 1*, p. 3. Copyright 1968 by the Society for the Experimental Analysis of Behavior, Inc.

Reinforcement 2, Robbie completed his spelling assignments more consistently, his disruptive behavior had diminished, and he continued to study while drinking his milk and did not play with the carton afterwards. Robbie's intervention was based on the principle of positive reinforcement.

This chapter examines the definition and nature of positive reinforcement, describes methods for identifying potential reinforcers and assessing their effects, outlines experimental control techniques for verifying whether a positive reinforcement contingency is responsible for increased responding, and offers guidelines for using positive reinforcement effectively.

POSITIVE REINFORCEMENT DEFINED

The principle of reinforcement is deceptively simple. "The basic operant functional relation for reinforcement is the following: When a type of behavior (R) is followed by reinforcement (S^R) there will be an increased future frequency of that type of behavior" (Michael, 2004, p. 30).[1] However, as Michael pointed out, three qualifications must be considered regarding the conditions under which the effects of reinforcement will occur: (a) the timing between the end of a given response and the onset of the stimulus change (i.e., the presentation of the reinforcer), (b) the relationship between stimulus conditions present when the response was emitted, and (c) the role of motivation. In this section we examine these qualifications and several other concepts requisite to acquiring a full understanding of reinforcement.

Operation and Defining Effect of Positive Reinforcement

Positive reinforcement occurs when a response is followed immediately by the presentation of a stimulus change that increases the future occurrence of similar responses. Figure 11.2 illustrates the two-term contingency—a response followed closely in time by the presentation of a stimulus—and the increased future responding that defines positive reinforcement. This two-term contingency is the fundamental building block for the selection of all operant behavior.

The stimulus that is presented as a consequence, and that is responsible for the subsequent increase in responding, is called a **positive reinforcer**, or, more simply, a reinforcer. Teacher attention in the form of positive praise was the reinforcer that increased Robbie's study behavior. Cold water flowing into a cup and the sight of a colorful bird are the reinforcers for the two behaviors shown in Figure 11.2.

It is important to remember that a reinforcer does not (and cannot) affect the response that it follows. When making this point, Skinner (1953) reminded us that reinforcement affects the operant response class.

> It is not correct to say the operant reinforcement "strengthens the response which precedes it." The response has already occurred and cannot be changed. What is changed is the future probability of responses in the same class. It is the operant as a class of behavior, rather than the response as a particular instance, which is conditioned. (p. 87)

Skinner (1938, 1966) used rate of responding as the fundamental datum for his research on reinforcement. To strengthen an operant is to make it occur more often.[2] However, rate is not the only dimension of behavior selected, shaped, and maintained by reinforcement. Reinforcement can also alter the duration, latency, interresponse time, magnitude, and/or topography of behavior. For example, if reinforcement follows only responses that fall within a range of magnitude—that is, above a minimum force but below a maximum force—responses within that range will occur more frequently. Reinforcement contingent on responses meeting multiple criteria will alter the response class meeting those criteria (e.g., responses by a golfer practicing 10-foot putts must fall within a narrow range of force and form to be successful).

Immediacy of Reinforcement

The direct effects of reinforcement involve "temporal relations between behavior and its consequences that are on the order of a few seconds" (Michael, 2004, p. 161). Although research with nonhuman animals suggests that as much as 30 seconds can elapse without critical loss of effect (e.g., Bradley & Poling,

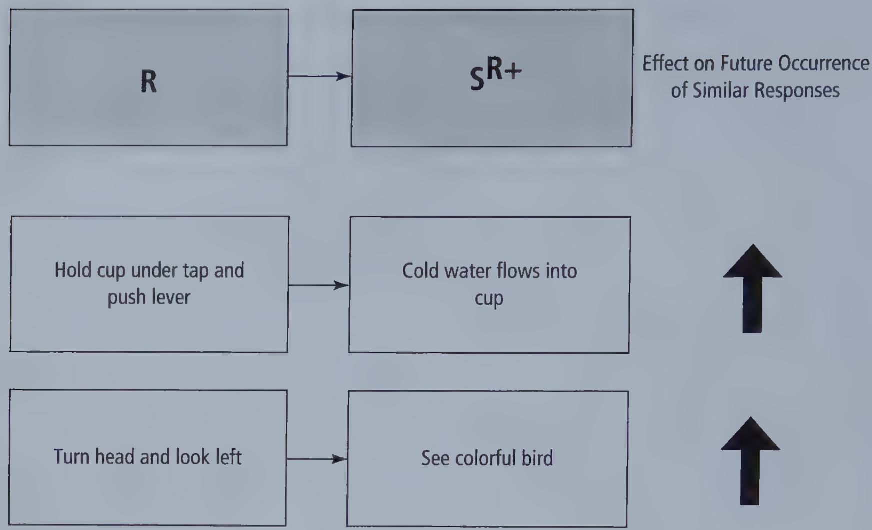

Figure 11.2 Two-term contingency illustrating positive reinforcement: A response (R) is followed closely in time by a stimulus change (S^{R+}) that results in an increased occurrence of similar responses in the future. Used with the permission of Skinner, B. F. (1953). Science and human behavior. New York: Macmillan.

2010; Byrne, LeSage, & Poling, 1997; Critchfield & Lattal, 1993; Lattal & Gleason, 1990; Wilkenfeld, Nickel, Blakely, & Poling, 1992), a response-to-reinforcement delay of as little as 1 second will be less effective than a reinforcer delivered immediately. This is because behaviors other than the target behavior can occur during the delay; the behavior temporally closest to the presentation of the reinforcer will be strengthened by its presentation. As Sidman (1960) described, "If the reinforcer does not immediately follow the response that was required for its production, then it will follow some other behavior. Its major effect will then be upon the behavior that bears, adventitiously to be sure, the closest prior temporal relationship to the reinforcement" (p. 371).

Malott and Shane (2014) discussed the importance of a brief response-to-reinforcement delay, as follows:

> [I]f you're trying to reinforce a response, don't push that 60-second limit, push the other end—the 0-second end. The direct effect of reinforcement drops off quickly as you increase the delay, even to 3 or 4 seconds. And even a 1-second delay may reinforce the wrong behavior. If you ask a young child to look at you and deliver the reinforcer 1 second after the response, you're liable to reinforce looking in the wrong direction. So, one problem with delayed reinforcement is that it reinforces the wrong response—the one that occurred just before the delivery of the reinforcer. (p. 4)

A common misconception is that delayed consequences can reinforce behavior, even when the consequences occur days, weeks, or even years after the responses occurred. "When human behavior is apparently affected by long-delayed consequences, the change is accomplished by virtue of the human's complex social and verbal history, and should not be thought of as an instance of the simple strengthening of behavior by reinforcement" (Michael, 2004, p. 36).

For example, suppose that a piano student practiced dutifully every day for several months in preparation for a statewide competition, at which she received a first-place award for her solo piano performance. Although some might believe that the award reinforced her persistent daily practice, they would be mistaken. Delayed consequences do not reinforce behavior directly. Delayed consequences can, when combined with language, *influence* future behavior through instructional control and rule following. A *rule* is a verbal description of a behavioral contingency (e.g., "Turnip seeds planted by August 15 will yield a crop before a killing freeze."). Learning to follow rules is one way that a person's behavior can come under the control of consequences that are too delayed to influence behavior directly. A statement by the piano teacher such as "If you practice your assignments every day for one hour between now and the competition, you could win first place" could have functioned as a rule that influenced the piano student's daily practice. The student's daily practice was evidence of rule-governed behavior if daily practice occurred because of her teacher's rule.[3] In other words, **rule-governed behavior** is behavior controlled by a rule (i.e., a verbal statement of an antecedent-behavior-consequence contingency) that enables human behavior to come under the indirect control of temporarily remote or improbable but potentially significant consequences. The following conditions provide strong indicators that behavior is the result of instructional control or is rule-governed behavior rather than a direct effect of reinforcement (Malott, 1988; Michael, 2004).

- No immediate consequence for the behavior is apparent.
- The response–consequence delay is greater than 30 seconds.
- Behavior changes without reinforcement.
- A large increase in the occurrence of the behavior occurs following one instance of reinforcement.
- No consequence for the behavior exists, including no automatic reinforcement, but the rule exists.

Reinforcement Is Not a Circular Concept

Another common misconception is that reinforcement is the product of circular reasoning and therefore contributes nothing to our understanding of behavior. Not so. Circular reasoning is a form of faulty logic in which the name used to describe an observed effect is mistaken as the cause for the effect. This confusion of cause and effect is circular because the observed effect is the sole basis for identifying the presumed cause.

In circular reasoning, the suspected cause is not independent of its effect—they are one and the same.

Here is an example of circular reasoning that occurs often in education. A student's persistent difficulties learning to read (effect) leads to a formal diagnosis of a learning disability, which is then offered as an explanation for the student's struggles with reading: "Yoshi's reading problem is due to his learning disability." How do you know Yoshi has a learning disability? Because he hasn't learned to read. Why hasn't Yoshi learned to read? Because his learning disability has prevented him from learning to read. And around and around it goes.

Similarly, it would be circular reasoning if we said that teacher attention increased Robbie's study behavior *because* it is a reinforcer. Instead, it is correct to say that because Robbie's study behavior increased when (and only when) it was followed immediately by teacher attention, teacher attention is a reinforcer. The difference is more than the direction of the relation, or some semantic sleight-of-hand. In circular reasoning, the suspected cause is not manipulated as an independent variable to see whether it affects the behavior. In circular reasoning, such experimental manipulation is impossible because the cause and effect are the same. Yoshi's learning disability cannot be manipulated as an independent variable because, as we used the concept in this example, it is nothing more than another name for the dependent variable (effect).

Reinforcement is not a circular concept because the two components of the response–consequence relation can be separated, allowing the delivery of a consequence to be manipulated to determine whether it increases the occurrence of the behavior it follows. Epstein (1982) described it as follows:

> If we can show that a response increases in frequency because (and only because) it is followed by a particular stimulus, we call that stimulus a *reinforcer* and its presentation, *reinforcement*. Note the lack of circularity. *Reinforcement* is a term we invoke when we observe certain relations between events in the world. . . . [However,] if we say, for example, that a particular stimulus strengthens a response behavior *because* it is a reinforcer, we are using the term *reinforcer* in a circular fashion. It is *because* it strengthens behavior that we call the stimulus a *reinforcer*. (p. 4)

Epstein (1982) went on to explain the difference between using an empirically demonstrated principle such as reinforcement in a theoretical account of behavior and using a circular argument.

> In some of his writings, Skinner speculates that certain behavior (for example, verbal behavior) has come about through reinforcement. He may suggest, for example, that certain behavior is strong *because* it was reinforced. This use of the concept is not circular, only speculative or interpretive. Using the language of reinforcement in this way is reasonable when you have accumulated a large data base. . . . When Skinner attributes some everyday behavior to past reinforcers, he is making a plausible guess based on a large data base and principles of behavior established under controlled conditions. (p. 4)

Used properly, *reinforcement* describes an empirically demonstrated (or speculative, in a theoretical or conceptual analysis) functional relation between a stimulus change (consequence) immediately following a response and an increase in the future occurrence of similar responses. Table 11.1 shows restrictions and examples of appropriate use of the terms *reinforcer, reinforcing, reinforcement*, and *to reinforce*, as suggested by Catania (2013). Box 11.1 describes four mistakes commonly made when speaking and writing about reinforcement.

Relationship Between Reinforcement and Antecedent Stimulus Conditions

Reinforcement does more than increase the future occurrence of behavior; it also changes the function of stimuli that immediately precede the reinforced behavior. By virtue of being

TABLE 11.1 The Vocabulary of Reinforcement*

Term	Restrictions	Examples
reinforcer (noun)	A stimulus	Food pellets were used as reinforcers for the rat's lever presses.
reinforcing (adjective)	A property of a stimulus	The reinforcing stimulus was produced more often than the other, nonreinforcing stimuli.
reinforcement (noun)	As an operation, the delivery of consequences when a response occurs	The fixed-ratio schedule of reinforcement delivered food after every 10th key peck.
	As a process, the increase in responding that results from the reinforcement	The experiment with monkeys demonstrated reinforcement produced by social consequences.
to reinforce (verb)	As an operation, to deliver consequences when a response occurs; responses are reinforced and not organisms	When a period of free play was used to reinforce the child's completion of school work, the child's grades improved.
	As a process, to increase responding through the reinforcement operation	The experiment was designed to find out whether gold stars would reinforce cooperative play among first-graders.

*This vocabulary is appropriate if and only if three conditions exist: (1) A response produces consequences; (2) that type of response occurs more often when it produces those consequences than when it does not produce them; and (3) the increased responding occurs *because* the response has those consequences. A parallel vocabulary is appropriate to punishment (including *punisher* as a stimulus and *punish* as a verb), with the difference being that a punishing consequence reduces the likelihood of future responding.

BOX 11.1

Common Mistakes in Talking and Writing About Reinforcement

A standard set of technical terms is prerequisite to the meaningful description of any scientific activity. Effectively communicating the design, implementation, and outcome of an applied behavior analysis depends on the accurate use of the discipline's technical language. The language of reinforcement includes some of the most important elements of the behavior analyst's vocabulary.

In this box we identify four mistakes made frequently by students of applied behavior analysis when describing reinforcement-based interventions. Perhaps the most common mistake—confusing negative reinforcement with punishment—is not discussed here. That terminology error was introduced in Chapter 2 and receives additional attention in Chapter 12.

Reinforcing the Person

Although it is proper to speak of presenting a *reinforcer* to a learner (e.g., "The teacher delivered a token to Bobby each time he asked a question"), statements such as "The teacher reinforced Bobby when he asked a question" and "Chloe was reinforced with praise each time she spelled a word correctly" are incorrect. *Behaviors* are reinforced, not people. Bobby's teacher reinforced question asking, not Bobby. Of course, reinforcement acts on and affects the overall person, in that it strengthens behaviors within the person's repertoire. However, the procedural focus and the primary effect of reinforcement are on the behaviors that it follows.

Practice as Reinforcement for a Skill

Educators will sometimes say that students should practice a skill because "practicing reinforces the skill." The phrase poses no problem if the speaker is describing a common outcome of practice with the everyday language connotation of *reinforce*, as in "to make something stronger" (e.g., to reinforce concrete by embedding steel rods in it). Well-designed drill and practice on a skill usually yields stronger performance in the form of better retention, reduced latency, higher response rates, and/or increased endurance (e.g., Johnson & Layng, 1994; Swanson & Sachse-Lee, 2000). Unfortunately, a phrase such as "practicing reinforces the skill" is often misused and misinterpreted as technical usage of the language of operant conditioning.

Although a skill that has been practiced is often stronger as a result of the practice, the practice itself could not be a *reinforcer* for the behavior practiced. Practice refers to the form and manner in which the target skill is emitted (e.g., answering as many math problems as you can in 1 minute). Practicing is a behavior that could be reinforced with various consequences, such as a preferred activity (e.g., "Practice solving these math problems; then you can have 10 minutes of free time"). Depending on a learner's history and preferences, the opportunity to practice a certain skill may function as a reinforcer for practicing another skill (e.g., "Finish your math problems; then you'll get to do 10 minutes of repeated reading practice").

Artificial Reinforcement

A distinction between natural and artificial reinforcers is made sometimes, as in this statement: "As the students' success rates improved, we gradually stopped using artificial reinforcers, such as stickers and trinkets, and increased the use of natural reinforcers." Some authors have suggested that applications of the principles of behavior result in "artificial control" (e.g., Smith, 1992). A behavior–consequence contingency may be effective or ineffective as reinforcement, but none of its elements (the behavior, the consequence, or the resultant behavior change) is, or can be, artificial.

The reinforcement contingencies and stimuli used as reinforcers in any behavior change program are always contrived—otherwise, there would be no need for the program—but they are never artificial (Skinner, 1982). The meaningful distinction when talking about reinforcement contingencies is not between the natural and the artificial, but between contingencies that already exist in a given setting prior to a behavior change program and contingencies that are contrived as part of the program (Kimball & Heward, 1993). Although the ultimate effectiveness of a behavior change program may depend on shifting control from contrived to naturally occurring contingencies, there is no such thing as artificial reinforcement.

Reinforcement and Feedback as Synonyms

Some speakers and writers mistakenly use *reinforcement* and *feedback* interchangeably. The two terms refer to different operations and outcomes, though some of each term encompasses parts of the other term's meaning. *Feedback* is information a person receives about a particular aspect of his or her behavior following its completion (e.g., "Very good, Kathy. Two quarters equal 50 cents."). Feedback is most often provided in the form of verbal descriptions of performance, but it can also be provided by other means, such as vibration or lights (e.g., Greene, Bailey, & Barber, 1981). Because feedback is a consequence that often results in the increased future occurrence of behavior, it sometimes leads to the faulty assumption that reinforcement must involve feedback or that *reinforcement* is just a behaviorist's term for *feedback*.

Reinforcement always increases the future frequency of responding. Feedback may result in (a) an increase in the future occurrence of the student's performance as a reinforcement effect and/or as a prompt or instruction on how to respond next time (e.g. "Your handwriting is improving, Jason, but don't forget to cross your T's") and/or (b) a reduction in the occurrence of some aspect of the learner's performance as a function of punishment or instruction (e.g., "You dropped your elbow on that pitch. Don't do that."). Feedback may have multiple effects, increasing one aspect of performance and decreasing another. Feedback may also have no effect on future responding whatsoever.

Reinforcement is defined functionally by its effect on future responding; feedback is defined by its formal characteristics (information about some aspect of performance). The operation of either concept is neither necessary nor sufficient for the other. That is, reinforcement may occur in the absence of feedback, and feedback may occur without a reinforcement effect.

Sometimes Commonsense Language Is Better

The technical language of behavior analysis is complex, and mastering it is no simple matter. Beginning students of behavior analysis are not the only ones who commit terminology errors. Well-trained practitioners, established researchers, and experienced authors also make mistakes now and then when speaking and writing about behavior analysis. Using behavioral concepts and principles—such as positive reinforcement—to confidently explain complex situations involving multiple processes and uncontrolled and unknown variables is a mistake that catches the most attentive and conscientious of behavior analysts at times.

Instead of invoking the terminology and concepts of reinforcement to explain the influence of temporally distant consequences on behavior, it is probably wiser to follow Jack Michael's (2004) advice and simply use everyday descriptive language and commonsense relations.

> Incorrectly used technical language is worse than common sense language because it suggests that the situation is well understood, and it may displace serious attempts at further analysis. Until we are able to provide an accurate analysis of the various processes relevant to indirect effects [of reinforcement], we are better off using ordinary descriptive language. Thus, say "the successful grant application is *likely to encourage* future efforts in the same direction," but don't say it as though you had the science of behavior behind you. Stop referring to successful settlements of a labor dispute as reinforcement for striking, and successful election of a political candidate as reinforcement for political activity. . . . Don't talk about good grades as reinforcement for effective study behavior, although they are no doubt responsible for maintaining it in some cases. Just say that they're responsible for maintaining it. Restraint of this sort will deprive some of us of an opportunity to (incorrectly) display our technical knowledge, but so much the better. (p. 165, emphasis in original)

temporally paired with the response–reinforcer contingency, antecedent events acquire the ability to evoke (make more likely) instances of the reinforced response class. As introduced in Chapter 2, a *discriminative stimulus* (S^D, pronounced "ess-dee") is an antecedent stimulus correlated with the availability of reinforcement for a particular response class. Responding in the presence of the S^D produces reinforcement; responding in the absence of the S^D (a condition called *stimulus delta* (S^Δ, pronounced "ess-delta") does not. As a result of this history of reinforcement, a person learns to make more responses in the presence of the S^D than in its absence. The behavior is then considered to be under *stimulus control* (see Chapter 17).

With the addition of the S^D, the two-term contingency for reinforcement becomes the three-term contingency of the *discriminated operant*. Figure 11.3 shows examples of three-term contingencies for positive reinforcement. Assuming that cold water is currently reinforcing and the person has a history of obtaining cold water only under blue taps, he is more likely to hold his cup under the blue tap on the cooler (than, say, a red tap). Similarly, assuming that seeing a colorful bird is currently reinforcing and a person has a history of seeing birds more often when looking toward chirping sounds (than, say, other sounds or silence), turning one's head and looking to the left will occur more often when chirping is heard to the left.

The Role of Motivation

The phrase *assuming that cold water is currently reinforcing* in the previous paragraph holds another key to understanding reinforcement. Although reinforcement is commonly thought of as a way to motivate people—and it can be—the momentary effectiveness of any stimulus change as reinforcement depends on an existing level of motivation with respect to the stimulus change in question. As introduced in Chapter 2, *motivating operations* alter the current effectiveness of stimulus changes as reinforcement.

> Motivating operations (MOs) are environmental variables that have two effects on behavior: (1) They alter the operant reinforcing effectiveness of some specific stimuli, objects, or events (the value-altering effect); and (2) They alter the momentary frequency of all behavior that has been reinforced by those stimuli, objects, or events (the behavior-altering effect). The value-altering effect, like response-reinforcement delay, is relevant to the effectiveness of the reinforcer at the time of conditioning, and stating that the consequence is a form of reinforcement implies that a relevant MO is in effect and at sufficient strength. (Michael 2004, p. 31)

In other words, for a stimulus change to "work" as reinforcement at any given time, the learner must already *want* it. This is a critical qualification in terms of the environmental conditions under which the effects of reinforcement will be seen. Michael (2004) explained this qualification as follows:

> The behavior-altering effect is relevant to the increased future frequency of the reinforced behavior, and must be added as a third qualification to the operant reinforcement relation: In a given stimulus situation (S) when a type of behavior (R) is followed immediately by reinforcement (S^R) there will be an increase in the future frequency of that type of behavior in the same or similar stimulus conditions, *but the increased frequency will only be seen when the MO relevant to the reinforcement that was used is again in effect.* (p. 31, emphasis in original)

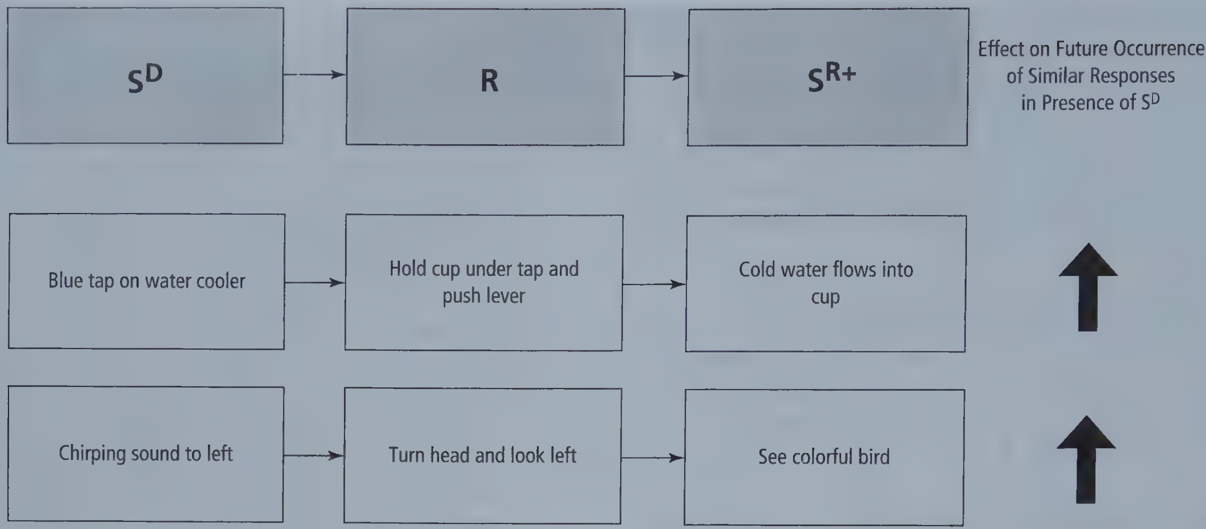

Figure 11.3 Three-term contingency illustrating positive reinforcement of a discriminated operant: A response (R) emitted in the presence of a discriminative stimulus (S^D) is followed closely in time by a stimulus change (S^{R+}) and results in an increased occurrence of similar responses in the future when the S^D is present. A discriminated operant is the product of a conditioning history in which responses in the presence of the S^D produced reinforcement, and responses in the absence of the S^D (a condition called stimulus delta [S^{Δ}]) were not reinforced (or resulted in a reduced amount or quality of reinforcement than in the S^D condition).

Motivating operations take two forms. An MO that increases the current effectiveness of a reinforcer is called an *establishing operation (EO)* (e.g., food deprivation makes food more effective as a reinforcer); an MO that decreases the current effectiveness of a reinforcer is an *abolishing operation (AO)* (e.g., food ingestion reduces the effectiveness of food as a reinforcer).[4]

Adding the *establishing operation (EO)* to a discriminated operant results in a four-term contingency, as shown in Figure 11.4. Spending several hours in a hot and stuffy room without water is an EO that (a) makes water more effective as a reinforcer and (b) increases the momentary frequency of all behaviors that have produced water in the past. Similarly, a park ranger stating prior to a hike that any hiker who describes the coloring of the bird that makes a certain chirping sound will receive a $5 token for the gift shop is an EO that will (a) make seeing a bird that makes the chirping sound effective as reinforcement and (b) increase the frequency of all behaviors (e.g., turning one's head to look around, stepping quietly) that have produced similar consequences (in this case, seeing the source of sounds) in the past.

In simpler terms, establishing operations (EOs) determine what an individual *wants* at any particular moment. EOs are dynamic, always changing. Reinforcer effectiveness

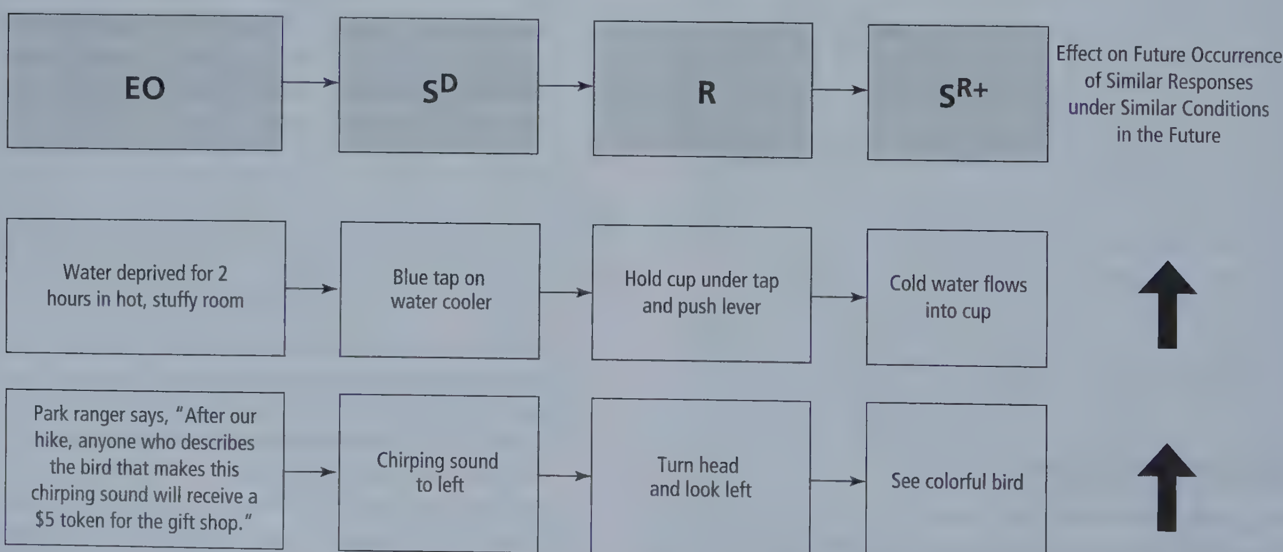

Figure 11.4 Four-term contingency illustrating positive reinforcement of a discriminated operant made current by a motivating operation: An establishing operation (EO) increases the momentary effectiveness of a stimulus change as a reinforcer, which in turn makes the S^D more likely to evoke behavior that has been reinforced by that stimulus change in the past.

(the want) goes up with increasing levels of deprivation and goes down with levels of satiation. Vollmer and Iwata (1991) demonstrated how the reinforcing effectiveness of three classes of stimuli—food, music, and social attention—varied under conditions of deprivation and satiation. Participants were five adults with developmental disabilities, and the dependent variable was the number of responses per minute on two motor tasks—pressing a switch or picking up small blocks from a container and putting them through the hole in the top of another container. All sessions lasted 10 minutes and began with the experimenter saying, "Do this, [participant's name]," and modeling the response. During baseline, participants' responses received no programmed consequences. During the deprivation and satiation conditions, responses were followed by presentation of food, music, or social attention. Initially each response was followed by the programmed consequence; this gradually shifted to every third, fifth, or tenth response being followed by the consequence.

Different procedures were used to create deprivation and satiation conditions for each stimulus class. With food, for example, baseline and deprivation condition sessions were conducted 30 minutes prior to a participant's scheduled lunchtime; sessions during the satiation condition were conducted within 15 minutes after the participant had eaten lunch. For social attention, baseline and deprivation condition sessions were conducted immediately following a 15-minute period in which the participant had either been alone or been observed to have had no social interaction with another person. Immediately prior to each session in the satiation condition, the experimenter provided continuous social interaction (e.g., played a simple game, conversation) with the participant for 15 minutes.

All five participants responded at higher rates under the deprivation conditions than during the satiation conditions. Figure 11.5 shows the effects of deprivation and satiation of social attention on the effectiveness of social attention as a reinforcer for two of the study's participants, Donny and Sam. Other researchers have reported similar findings concerning the effects of deprivation and satiation of various stimuli and events as motivating operations that affect the relative effectiveness of reinforcement (e.g., Hanley, Iwata, & Roscoe, 2006; Klatt, Sherman, & Sheldon, 2000; North & Iwata, 2005; Zhou, Iwata, & Shore, 2002).

Automaticity of Reinforcement

> *A reinforcing connection need not be obvious to the individual reinforced.*
>
> —B. F. Skinner (1953, p. 75)

The fact that a person does not have to understand or verbalize the relation between his or her actions and a reinforcing consequence, or for that matter even be aware that a consequence has occurred, for reinforcement to occur is known as the *automaticity of reinforcement*. Skinner (1983) provided an interesting example of automaticity in the third and final volume of his autobiography, *A Matter of Consequences*. He described an incident that took place at a meeting of distinguished scholars who had been invited to discuss the role of intention in political activity. At one point during the meeting, the psychologist Erich Fromm began to argue that "people were not pigeons," perhaps

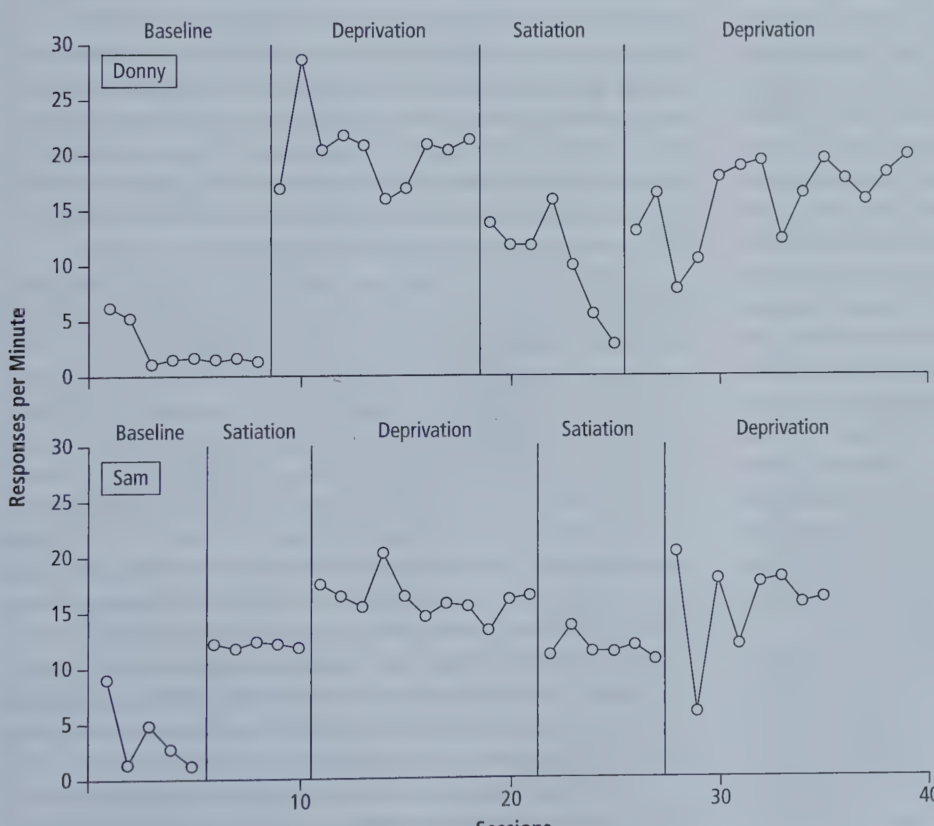

Figure 11.5 Responses per minute by two students during baseline and when social attention was used as reinforcement under deprivation and satiation conditions for social attention.

From "Establishing Operations and Reinforcement Effects," by T. R. Vollmer and B. A. Iwata, 1997, *Journal of Applied Behavior Analysis*, *24*, p. 288. Copyright 1991 by the Society for the Experimental Analysis of Behavior, Inc. Reprinted by permission.

implying that an operant analysis based on positive reinforcement could not explain human behavior, which Fromm believed is the product of thought and free will. Skinner recounted what happened next:

> I decided that something had to be done. On a scrap of paper I wrote, "Watch Fromm's left hand. I am going to shape [reinforce by successive approximations] a chopping motion" and passed it down the table to Halleck [a member of the group]. Fromm was sitting directly across the table and speaking mainly to me. I turned my chair slightly so that I could see him out of the corner of my eye. He gesticulated a great deal as he talked, and whenever his left hand came up, I looked straight at him. If he brought the hand down, I nodded and smiled. Within five minutes he was chopping the air so vigorously that his wristwatch kept slipping out over his hand. (pp. 150–151, words in brackets added)

Arbitrariness of the Behavior Selected

> *So far as the organism is concerned, the only important property of the contingency is temporal.*
>
> —B. F. Skinner (1953, p. 85)

Reinforcement occurs independent of a logical or adaptive connection between behavior and a reinforcing consequence. In other words, reinforcement strengthens any behavior that immediately precedes it. This arbitrary nature of the behavior selected is critical to understanding reinforcement. All other relations (e.g., what's logical, desirable, useful, appropriate) must compete with the temporal relation between behavior and consequence. "To say that reinforcement is contingent upon a response may mean nothing more than that it followed the response . . . conditioning takes place presumably because of the temporal relation only, expressed in terms of the order and proximity of response and reinforcement" (Skinner, 1948, p. 168).

Skinner (1948) demonstrated the arbitrary nature of the behaviors selected by reinforcement in one of his most famous experimental papers, "Superstition in the Pigeon." He gave pigeons a small amount of food every 15 seconds, "with no reference whatsoever to the bird's behavior" (p. 168). The fact that reinforcement will strengthen whatever behavior it immediately follows was soon evident. Six of the eight birds developed idiosyncratic behaviors "so clearly defined, that two observers could agree perfectly in counting instances" (p. 168). One bird walked counterclockwise around the cage; another repeatedly thrust its head into one of the upper corners of the cage. Two birds acquired a "pendulum motion of the head and body, in which the head was extended forward and swung from right to left with a sharp movement followed by a somewhat slower return" (p. 169). The pigeons had exhibited none of those behaviors at "any noticeable strength" during adaptation to the cage or before the food was periodically presented.

Whatever behavior the pigeons happened to be doing when the food hopper appeared tended to be repeated, which made it more likely to be occurring when food appeared the next time. Reinforcement was not contingent (in the sense of, dependent) on the behavior; it was only a coincidence that reinforcement sometimes followed the behavior. Such accidentally reinforced behavior is called "superstitious" because it has no influence on whether reinforcement follows. Humans engage in many superstitious behaviors. Sports provide countless examples: A basketball player tugs on his shorts before shooting a foul shot, a golfer carries his lucky ball marker, a batter goes through the same sequence of adjusting his wristbands before each pitch, a college football fan wears a goofy-looking necklace made of inedible nuts to bring good luck to his team.[5]

The importance of understanding the arbitrariness of reinforcement goes far beyond providing a possible explanation for the development of harmless superstitious and idiosyncratic behaviors. The arbitrary nature of selection by reinforcement may explain the acquisition and maintenance of many maladaptive and challenging behaviors. For example, a caregiver's well-meaning social attention provided in an attempt to console or divert a person who is hurting himself may help shape and maintain the very behavior the caregiver is trying to prevent or eliminate. Kahng, Iwata, Thompson, and Hanley (2000) documented with a functional analysis that social reinforcement maintained the self-injurious behavior (SIB) and aggression of three adults with developmental disabilities. Kahng and colleagues' data support the hypothesis that aberrant behaviors may be selected and maintained by social attention because of the arbitrariness of reinforcement.

Automatic Reinforcement

Kennedy (1994) noted that applied behavior analysts use two meanings to define the term *automatic reinforcement*. In the first instance, automatic reinforcement is determined by the absence of social mediation (Vollmer, 1994, 2006). In this context, **automatic reinforcement** refers to the behavior–stimulus change relation that occurs without the presentation of consequences by other people (Vaughan & Michael, 1982; Vollmer, 1994, 2006). In short, automatic reinforcement occurs independent of social mediation of others. Response products that function as automatic reinforcement are often in the form of a naturally produced sensory consequence that "sounds good, looks good, tastes good, smells good, feels good to the touch, or the movement itself is good" (Rincover, 1981, p. 1). Scratching an insect bite to relieve or attenuate the itch is a common example of automatic reinforcement.

In the second instance, *automatic reinforcement* is assumed when a behavior persists in the absence of any known reinforcer (Hagopian, Rooker, & Yenokyan, 2018). In these "default" situations, automatic reinforcement is assumed to be the controlling variable (Fisher, Lindauer, Alterson, & Thompson, 1998; Ringdahl, Vollmer, Marcus, & Roane, 1997; Roscoe, Iwata, & Goh, 1998). Persistent, seemingly nonpurposeful, repetitive, self-stimulatory behaviors (e.g., flipping fingers, head rolling, body rocking, toe walking, hair pulling, fondling body parts) may produce sensory stimuli that function as automatic reinforcement. Such "self-stimulation" is thought to be a factor maintaining self-injurious behavior (Iwata, Dorsey, Slifer, Bauman, & Richman, 1994), stereotypic repetitive movements, hair pulling (Rapp, Miltenberger, Galensky, Ellingson, & Long, 1999), nail biting, chewing on the mouth or lips, and twirling objects or fondling jewelry (Miltenberger, Fuqua, & Woods, 1998).

Determining that a behavior may be maintained by automatic reinforcement, and when possible isolating or substituting the source of that reinforcement (see Figure 8.5; Shore,

Iwata, DeLeon, Kahng, & Smith, 1997), has important implications for designing interventions to either capitalize on the automatic reinforcing nature of the behavior or counteract it. As Vollmer (1994) stated ". . . one clear goal of research should be to develop procedures designed to identify specific sources of automatic reinforcement. Effective assessment might allow for the development of treatments that involve reversing or eliminating the contingencies maintaining a behavior" (p. 191). Assuming that such assessment provides important clues for intervention, Vollmer further proposed five interventions to reduce or eliminate behaviors maintained by automatic reinforcement.

1. Eliminate or minimize medically based establishing operations. For example, a child whacking his ear or scratching his arm repeatedly might be treated by an antibiotic or medicated lotion to reduce or eliminate aversive stimulation produced by an earache or allergy-based itch that established whacking or scratching responses as a negative reinforcement.
2. Try a sensory extinction procedure, thus eliminating, or reducing, sources of visual, auditory, or proprioceptive stimulation. Wearing gloves, shielded clothes, helmets, and so forth serve as examples.
3. Implement differential reinforcement of alternative behavior (DRA) interventions, thus providing a "choice" with an alternative source of reinforcement contingent on appropriate behavior. A course of action would provide a different source of visual, auditory, or proprioceptive stimulation that would compete with the automatically reinforced behavior. Teaching the person to turn on an electric vibrator, television, or musical carousel to obtain alternative stimulation serve as examples.
4. Consider punishment to override current maintaining contingencies, and thus capitalize on the fact that (a) punishment does not require the knowledge of the specific controlling variables, and (b) exigent circumstances do not allow for prolonged detective work to determine the existing reinforcement contingencies.
5. Implement a "package" program. "It is unlikely that any given intervention derived from establishing operations, sensory extinction, differential reinforcement, or punishment would be used in isolation from other procedures. Package treatment approaches are common both in research and in clinical settings. In the case of automatic reinforcement, it is possible that a package approach would be highly suitable". (Vollmer, 1994, p. 203)

Each of these recommendations has advantages and disadvantages, and none is a "silver bullet" that will instantly address automatic reinforcement's effect on behavior. As Vollmer (1994) notes, "When reinforcers maintaining a behavior are not within the control of the therapist or experimenter (i.e., the social environment), behavior is especially difficult to assess and treat" (p. 188). Still, these five recommendations provide a direction for analysts to determine their efficacy in individual instances.

Responses may produce unconditioned or conditioned automatic reinforcement. Sundberg, Michael, Partington, and Sundberg (1996) described a two-stage conditioning history that may account for conditioned automatic reinforcement.

> For example, a person may persist in singing or humming a song while coming home from a movie despite no obvious direct reinforcement for singing. In order for this behavior to occur as automatically reinforced behavior, a special two-stage conditioning history is necessary. In stage one, some stimulus (e.g., a song) must be paired with an existing form of conditioned or unconditioned reinforcement (e.g., an enjoyable movie, popcorn, relaxation). As a result, the new stimulus can become a form of conditioned reinforcement (e.g., hearing the song may now be a new form of conditioned reinforcement). In stage two, the emission of a response (for whatever reason) produces a response product (i.e., the auditory stimuli produced by singing the song) that has topographical similarity to that previously neutral stimulus (e.g., the song), and may now have self-strengthening properties. (pp. 22–23)

Several theorists have suggested that automatic reinforcement may help to explain the extensive babbling of infants and how babbling shifts naturally, without apparent intervention from others, from undifferentiated vocalizations to the speech sounds of their native language (e.g., Bijou & Baer, 1965; Mowrer, 1950; Skinner, 1957; Staats & Staats, 1963; Vaughan & Michael, 1982). Caregivers frequently talk and sing while holding, feeding, and bathing a baby. As a result of repeated pairing with various reinforcers (e.g., food, warmth), the caregiver's voice may become a conditioned reinforcer for the baby. The baby's babbling is automatically reinforced when it produces sounds that match or closely approximate the caregiver's. At that point, "The young child alone in the nursery may automatically reinforce his own exploratory vocal behavior when he produces sounds that he has heard in the speech of others" (Skinner, 1957, p. 58).

Although the idea that automatic reinforcement is a factor in early language acquisition has been proposed repeatedly, few experimental analyses of the phenomenon have appeared in the literature (e.g., Miguel, Carr, & Michael, 2002; Sundberg, Michael, Partington, & Sundberg, 1996; Yoon & Bennett, 2000). Sundberg and colleagues (1996) reported the first study showing the effects of a stimulus–stimulus pairing procedure on the rate with which children emitted new vocal sounds without direct reinforcement or prompts to respond. Five children, ages 2 to 4 and representing a broad range of language abilities, served as subjects. During the prepairing (baseline) condition, the parents and in-home trainers sat a few feet away from the child and recorded each word or vocal sound emitted by the child as he played with a train set and several toys. Data were collected in consecutive 1-minute intervals. The adults did not interact with the subject during the prepairing baseline. The stimulus–stimulus pairing procedure consisted of a familiar adult approaching the child, emitting a target vocal sound, word, or phrase, and then immediately delivering a stimulus that had been established previously as a form of reinforcement for the child (e.g., tickles, praise, bouncing in a parachute held by adults). This stimulus–stimulus pairing procedure was repeated 15 times per minute for 1 or 2 minutes. The adult used a variety

of pitches and intonations when voicing the target sound, word, or phrase. During the postpairing condition, which began immediately after the stimulus–stimulus pairings, the adult moved away from the child and conditions were the same as during the prepairing condition.

The stimulus–stimulus pairing of a vocal sound, word, or phrase with an established reinforcer was followed by an increased frequency of the targeted word during the postpairing condition for all five children. Figure 11.6 shows the results of a representative sample of one of three pairings conducted with Subject 2, a 4-year-old boy with autism. Subject 2 had a verbal repertoire of more than 200 mands, tacts, and intraverbals, but rarely emitted spontaneous vocalizations or engaged in vocal play.[6] During the prepairing condition, the child did not say the target word and emitted four other vocalizations at a mean rate of 0.5 per minute. The stimulus– stimulus pairing procedure consisted of pairing the word *apple* with tickles approximately 15 times in 60 seconds. Immediately after the pairing, the subject said "apple" 17 times in 4 minutes, a rate of 4.25 responses per minute. In addition, the child said "tickle" four times within the first minute of the postpairing condition. Sundberg and colleagues' results provide evidence that the children's vocal response products may have functioned as automatic conditioned reinforcement after being paired with other forms of reinforcement.

In summing up the uses and limitations of automatic reinforcement as a concept, Vollmer (2006) suggested that:

- Practitioners should recognize that not all reinforcement is planned or socially mediated.
- Some behaviors maintained by automatic reinforcement (e.g., self-stimulation, stereotypy) may not be reduced or eliminated with timeout, planned ignoring, or extinction.
- Affixing the label *automatic reinforcement* to an observed phenomenon too quickly may limit our analysis and effectiveness by precluding further efforts to identify the actual reinforcer-maintaining behavior.
- When socially mediated contingencies are difficult to arrange or simply not available, practitioners might consider automatic reinforcement as a potential aim.

CLASSIFYING REINFORCERS

In this section we review the technical classification of reinforcers by their origin as well as several practical categories by which practitioners and researchers often describe and classify reinforcers by their formal characteristics. Regardless of type or classification, all reinforcers share their most important and defining characteristic: All reinforcers increase the future occurrence of behavior that immediately precedes them.

Classification of Reinforcers by Origin

As introduced in Chapter 2, there are two basic types of reinforcers—a reinforcer that is the product of the evolution of the species (an unconditioned reinforcer) or a reinforcer that is the result of the learning history of the individual (a conditioned reinforcer).

Unconditioned Reinforcers

An **unconditioned reinforcer** is a stimulus change that functions as reinforcement even though the learner has had no particular learning history with it. (The terms *primary reinforcer* and

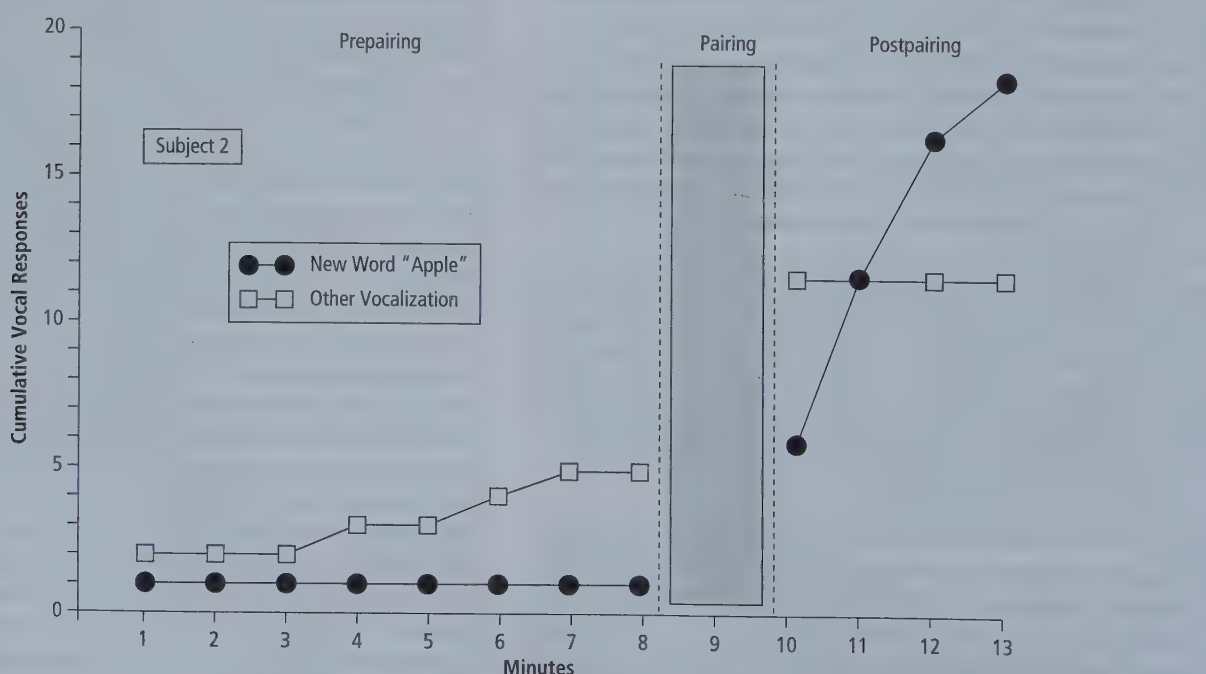

Figure 11.6 Cumulative number of times a 4-year-old child with autism vocalized "apple" before and after "apple" had been paired repeatedly with an established form of reinforcement. Automatic reinforcement may explain the increased frequency of the child's vocalizing "apple" after pairing.

From "The Role of Automatic Reinforcement in Early Language Acquisition," by M. L. Sundberg, J. Michael, J. W. Partington, and C. A. Sundberg, 1996, *The Analysis of Verbal Behavior*, *13*, p. 27. Copyright 1996 by the Association for Behavior Analysis, Inc. Used by permission.

unlearned reinforcer are synonyms for unconditioned reinforcer.) Because unconditioned reinforcers are the product of the evolutionary history of a species (phylogeny), all biologically intact members of a species are more or less susceptible to reinforcement by the same unconditioned reinforcers. For example, food, water, oxygen, warmth, and sexual stimulation are examples of stimuli that do not have to undergo a learning history to function as reinforcers. Food will function as an unconditioned reinforcer for a human deprived of sustenance; water will function as an unconditioned reinforcer for a person deprived of liquid, and so forth.

Human touch may also be an unconditioned reinforcer (Gewirtz & Pelaez-Nogueras, 2000). Pelaez-Nogueras and colleagues (1996) found that infants preferred face-to-face interactions that included touch stimulation. Two conditioning treatments were implemented in alternated counterbalanced order. Under the touch condition, infants' eye-contact responses were followed immediately by adult attention (eye contact), smiling, cooing, and rubbing the infants' legs and feet. Eye-contact responses during the no-touch condition were followed by eye contact, smiles, and coos from the adult, but no touching. All of the babies in the study emitted eye contact for longer durations, smiled and vocalized at higher rates, and spent less time crying and protesting in the contingent condition that included touch. From these results and several related studies, Pelaez-Nogueras and colleagues concluded that "these results suggest that . . . touch stimulation can function as a primary reinforcer for infant behavior" (p. 199).

Conditioned Reinforcers

A **conditioned reinforcer** (sometimes called a *secondary reinforcer* or *learned reinforcer*) is a previously neutral stimulus change that has acquired the capability to function as a reinforcer through stimulus–stimulus pairing with one or more unconditioned reinforcers or conditioned reinforcers. Through repeated pairings, the previously neutral stimulus acquires the reinforcement capability of the reinforcer(s) with which it has been paired.[7] For example, after a tone has been paired repeatedly with food, when food is delivered as a reinforcer, the tone will function as a reinforcer when an EO has made food a currently effective reinforcer.

Neutral stimuli can also become conditioned reinforcers for humans without direct physical pairing with another reinforcer through a pairing process Alessi (1992) called *verbal analog conditioning*.

> For example, a class of preschool children who have been receiving M&M candies for good school work might be shown pieces of cut up yellow construction paper and told, "These pieces of yellow paper are what big kids work for" (Engelmann, 1975, pp. 98–100). Many children in the group immediately refuse M&Ms, and work extra hard, but accept only pieces of yellow paper as their rewards.
>
> We might say that the pieces of yellow paper act as "learned reinforcers." Laboratory research tells us that neutral stimuli become reinforcers only through direct pairing with primary reinforcers (or other "learned reinforcers"). Yellow paper was not paired with any reinforcer and certainly not with the primary (M&Ms) reinforcers. Yellow paper acquired reinforcing properties even more powerful than the primary M&Ms reinforcers, as demonstrated by the children's refusal to accept M&Ms, demanding instead pieces of yellow paper. (For the sake of this example, assume that the children had not been satiated with M&Ms just before the session.) (p. 1368)

It is sometimes thought that the "power" of a conditioned reinforcer is determined by the number of times it has been paired with other reinforcers. However, a statement such as, "The more often the tone is paired with food, the more reinforcing the tone will become" is not completely accurate. Although numerous pairings will increase the likelihood that the tone will function as a conditioned reinforcer in the first place (though a single pairing is sometimes sufficient), the momentary effectiveness of the tone as a reinforcer will be a function of the relevant EO for the reinforcer(s) with which the conditioned reinforcer has been paired. A tone that has been paired only with food will function as an effective reinforcer for a food-deprived learner, but the tone will have little effect as a reinforcer if the learner has just consumed a lot of food, regardless of the number of times it has been paired with food.

A **generalized conditioned reinforcer** is a conditioned reinforcer that as a result of having been paired with many unconditioned and conditioned reinforcers does not depend on a current EO for any particular form of reinforcement for its effectiveness. For example, social attention (proximity, eye contact, praise) is a generalized conditioned reinforcer for many people because it has occurred simultaneously with many reinforcers. The more reinforcers with which a generalized conditioned reinforcer has been paired, the greater the likelihood that it will be effective at any given time. Because it can be exchanged for a nearly limitless variety of backup reinforcers, money is a generalized conditioned reinforcer whose effectiveness is usually independent of current establishing operations.

It is sometimes thought that a conditioned reinforcer is called a generalized conditioned reinforcer because it can function as reinforcement across a wide range of behaviors. This, however, is not so. Any reinforcer is capable of strengthening the future occurrence of any similar behavior that immediately precedes its occurrence. A conditioned reinforcer is called a generalized conditioned reinforcer because it is effective as reinforcement across a wide range of EO conditions. Because of their versatility across EO conditions, generalized conditioned reinforcers offer great advantages for practitioners, who often have limited control of the EOs for particular reinforcers.

Generalized conditioned reinforcers provide the basis for implementing a *token economy*, a reinforcement-based system capable of improving multiple behaviors of multiple participants (Alstot, 2015; Campbell & Anderson, 2011; Hirst, Dozier, & Payne, 2016). In a token economy, participants receive tokens (e.g., points, checkmarks, poker chips) contingent on a variety of target behaviors. Participants accumulate the tokens and exchange them at specific times for their choices from a menu of backup reinforcers (e.g., free time, computer time, snacks). Token economy systems and guidelines for designing and implementing them are described in Chapter 28.

Classification of Reinforcers by Formal Properties

When applied behavior analysts describe reinforcers by their physical properties—a practice that can enhance communication among researchers, practitioners, and the agencies and people they serve—reinforcers are typically classified as edible, sensory, tangible, activity, or social.

Edible Reinforcers

Researchers and practitioners have used bites of preferred foods, snacks, candy, and sips of drinks as reinforcers. One interesting and important use of edibles as reinforcers is in the treatment of chronic food refusal in children. For example, Riordan, Iwata, Finney, Wohl, and Stanley (1984) used "highly preferred food items" as reinforcers to increase the food intake of four children at a hospital treatment facility. The treatment program consisted of dispensing the high-preference food items (e.g., cereal, yogurt, canned fruit, ice cream) contingent on the consumption of a target food item (e.g., vegetables, bread, eggs).

Kelley, Piazza, Fisher, and Oberdorff (2003) used edible reinforcers to increase cup drinking by Al, a 3-year-old boy who had been admitted to a day treatment program for food refusal and bottle dependency. The researchers measured the percentage of trials in which Al consumed 7.5 ml of three different liquids from the cup. During baseline, when Al was praised if he consumed the drink, his consumption averaged 0%, 44.6%, and 12.5% of trials for orange juice, water, and a chocolate drink, respectively. During the positive reinforcement component of the cup-drinking intervention, each time Al consumed the drink, the therapist praised him (as was done in baseline) and delivered a level spoon of peaches (a preferred food) to his mouth. Al consumed all three beverages on 100% of the trials during the positive reinforcement condition.

Fahmie, Iwata, and Jann (2015) found that 12 individuals diagnosed with intellectual disabilities or autism and ranging in age from 5 to 22 years preferred 15-sec access to a single edible reinforcer (e.g., M&M, raisin, pretzel) to 15-sec access to a leisure item (e.g., music box, plush bear, maraca) and that edible reinforcers maintained responding somewhat longer than leisure-item reinforcers. Regarding the implications of these results for effective practice, Fahmie and colleagues noted:

> These advantages provide evidence in favor of including edible items in preliminary preference assessments. One additional advantage of edible reinforcers is that they are delivered more easily and efficiently, which may have an overall beneficial effect on training in the long run. Nevertheless, researchers (e.g., Ferrari & Harris, 1981; Rincover & Newsom, 1985) have emphasized the relative benefits of leisure stimuli during training, stating that leisure stimuli are more natural, are less deleterious to health (see also Behavior Analysis Certification Board, 2014, Guideline 4.10), and promote more active engagement. Of course, behavior analysts also are responsible for providing the most effective treatment (Behavior Analyst Certification Board, 2014, Guideline 2.09). This study provides some additional evidence to help balance these goals. (p. 342, BACB citations updated to most recent version).

Sensory Reinforcers

Various forms of sensory stimulation such as vibration (e.g., massager), tactile stimulation (e.g., tickles, strokes with a feather boa), flashing or sparkling lights, and music have been used effectively as reinforcers (e.g., Bailey & Meyerson, 1969; Ferrari & Harris, 1981; Gast et al., 2000; Hume & Crossman, 1992; Rincover & Newsom, 1985; Vollmer & Iwata, 1991).

Tangible Reinforcers

Items such as stickers, trinkets, school materials, trading cards, and small toys often serve as tangible reinforcers. An object's intrinsic worth is irrelevant to its ultimate effectiveness as a positive reinforcer. Virtually any tangible item can serve as a reinforcer. Remember Engelmann's (1975) kindergarten students who worked for yellow slips of paper!

Activity Reinforcers

When the opportunity to engage in a certain behavior functions as reinforcement, that behavior is an activity reinforcer. Activity reinforcers may be everyday activities (e.g., playing a board game, leisure reading, listening to music), privileges (e.g., lunch with the teacher, shooting baskets, first in line), or special events (e.g., a trip to the zoo).

McEvoy and Brady (1988) evaluated the effects of contingent access to play materials on the completion of math worksheets by three students with autism and behavior disorders. During baseline, the teacher told the students to complete the problems as best that they could and to either complete other unfinished assignments or "find something else to do" if they finished the worksheets before a 6-minute timing elapsed. No other prompts or instructions were given for completing the worksheets. The teacher praised the completion of the worksheets.

On the first day of intervention for each student, he was taken to another room and shown a variety of toys and play materials. The teacher told the student he would have approximately 6 minutes to play with the materials if he met a daily criterion for completing math problems. Figure 11.7 shows the results. During baseline, the rate at which all three students correctly completed problems was either low (Dicky) or highly variable (Ken and Jimmy). When contingent access to the play activities was introduced, each student's completion rate increased and eventually exceeded criterion levels.

Premack (1959) hypothesized that activity reinforcers can be identified by looking at the relative distribution of behaviors in a free operant situation. Premack believed that behaviors themselves could be used as reinforcers and that the relative frequency of behavior was an important factor in determining how effective a given behavior might be as a reinforcer if the opportunity to engage in the behavior is contingent on another behavior. The **Premack principle** states that making the opportunity to engage in a behavior that occurs at a relatively high free operant (or baseline) rate contingent on the occurrence of low-frequency behavior will function as reinforcement for the low-occurrence behavior. For a student who typically spends much more time watching TV than doing homework, a contingency based on the Premack principle (informally known as

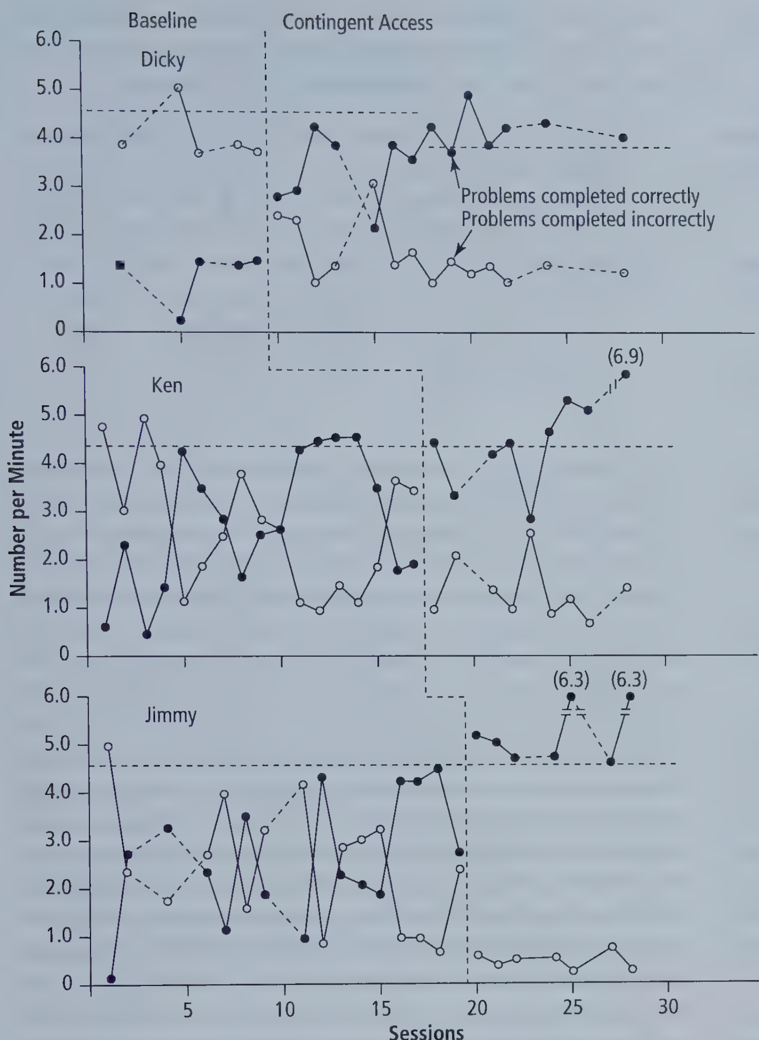

Figure 11.7 Number of math problems completed correctly and incorrectly per minute by three special education students during baseline and contingent access to play materials. Dashed horizontal lines indicate criteria.

From "Contingent Access to Play Materials as an Academic Motivator for Autistic and Behavior Disordered Children," by M. A. McEvoy and M. P. Brady, 1988, *Education and Treatment of Children, 11*, p. 15. Copyright 1998 by the Editorial Review Board of *Education and Treatment of Children*. Used by permission.

"Grandma's Law") might be, "When you have finished your homework, you can watch TV."

Building on Premack's concept, Timberlake and Allison (1974) proposed the **response-deprivation hypothesis** as a model for predicting whether access to one behavior (the contingent behavior) will function as reinforcement for another behavior (the instrumental response) based on the relative baseline rates at which each behavior occurs and whether access to the contingent behavior represents a restriction compared to the baseline level of engagement. Restricting access to a behavior presumably acts as a form of deprivation that serves as an EO, thus making the opportunity to engage in the restricted behavior an effective form of reinforcement (Allison, 1993; Iwata & Michael, 1994).

Iwata and Michael (1994) cited a series of three studies by Konarski and colleagues as demonstrating the veracity and applied implications of the response-deprivation hypothesis. In the first study, when students were given access to coloring (a high-probability behavior contingent on completing math problems (a low-probability behavior), they spent more time doing math, but only if the reinforcement schedule represented a restriction of the amount of time spent coloring compared to baseline (Konarski, Johnson, Crowell, & Whitman, 1980). The researchers found that a contingency in which students could earn *more time* coloring than they did in baseline for completing math problems was ineffective. These basic findings were reproduced in a subsequent study in which access to reading (or math, depending on the subject) was contingent on math (or reading) (Konarski, Crowell, Johnson, & Whitman, 1982). In the third study, Konarski, Crowell, and Duggan (1985) took the response-deprivation hypothesis a step further by examining the "reversibility of reinforcement" within subjects; that is, engaging in either of two activities—reading or math—could serve as reinforcement for increased performance in the other activity, in a response-deprivation condition for the contingent activity. Response deprivation for reading as the contingent response resulted in increases in math (instrumental response); conversely, response deprivation for math as the contingent response produced increases in reading. In all three studies, response restriction was the key factor in determining whether access to the contingent response would be reinforcing.

Iwata and Michael (1994) concluded that the collective results of Konarski and colleagues' studies illustrate each of three predictions based on the response-deprivation hypothesis

(assume the ratio of baseline rates of doing homework to watching TV is 1:2 in the following examples):

- Reinforcement of a low-rate target behavior when access to a high-rate contingent behavior is restricted below baseline levels (e.g., 30 minutes of homework gets access to 30 minutes of TV).
- Nonreinforcement of a low-rate behavior when access to a high-rate contingent behavior is not restricted below baseline levels (e.g., 30 minutes of homework gets access to 90 minutes of TV).
- Reinforcement of a high-rate target behavior when access to the low-rate behavior is restricted below baseline levels (e.g., 30 minutes of TV yields 5 minutes of homework).

Although recognizing that practitioners seldom design reinforcement programs to increase the rate of behaviors such as TV watching that already occur at high rates, Iwata and Michael (1994) noted that:

> There are a number of instances in which one may wish to produce highly accelerated performance (e.g., as in superlative academic or athletic performance that is good to begin with). In such cases, one need not find another activity that occurs at a higher rate to serve as reinforcement if one could arrange a suitable deprivation schedule with an activity that occurs at a relatively low rate. (p. 186)

As with all other descriptive categories of reinforcers, there is no a priori list that reveals what activities will or will not function as reinforcers. An activity that serves as effective reinforcement for one learner might have quite another effect on the behavior of another learner. For example, in Konarski, Crowell, and colleagues' (1982) study, access to math functioned as reinforcement for doing more reading for three students, whereas getting to read was the reinforcer for completing math problems for a fourth student. Many years ago, a classic cartoon brought home this crucial point very well. The cartoon showed two students dutifully cleaning the chalkboard and erasers after school. One student said to the other, "You're cleaning erasers for punishment!? I get to clean erasers as a reward for completing my homework."

Social Reinforcers

Physical contact (e.g., hugs, pats on the back), proximity (e.g., approaching, standing, or sitting near a person), attention, and praise are examples of events that often serve as social reinforcers. Adult attention is one of the most powerful and generally effective forms of reinforcement for children. The nearly universal effects of contingent social attention as reinforcement has led some behavior analysts to speculate that some aspects of social attention may entail unconditioned reinforcement (e.g., Gewirtz & Pelaez-Nogueras, 2000; Vollmer & Hackenberg, 2001).

The original experimental demonstrations and discovery of the power of adults' social attention as reinforcement for children's behavior took place in a series of four studies designed by Montrose Wolf and carried out by the preschool teachers at the Institute of Child Development at the University of Washington in the early 1960s (Allen, Hart, Buell, Harris, & Wolf, 1964; Harris, Johnston, Kelly, & Wolf, 1964; Hart, Allen, Buell, Harris, & Wolf, 1964; Johnston, Kelly, Harris, & Wolf, 1966). Describing those early studies, Risley (2005) wrote:

> We had never seen such power! The speed and magnitude of the effects on children's behavior in the real world of simple adjustments of something so ubiquitous as adult attention was astounding. Forty years later, social reinforcement (positive attention, praise, "catching them being good") has become the core of most American advice and training for parents and teachers—making this arguably the most influential discovery of modern psychology. (p. 280)

Because of the profound importance of this long-known but underused phenomenon, we describe a second study showing the effects of contingent attention as reinforcement for children's behavior. The first volume of the *Journal of Applied Behavior Analysis* included no fewer than seven studies building on and extending Wolf and colleagues' pioneering research on social reinforcement.[8] R. Vance Hall and colleagues conducted two of those studies. Like the Hall, Lund, and Jackson (1968) study, which introduced this chapter and from which we selected the example of a teacher's use of positive reinforcement with Robbie, the three experiments reported by Hall, Panyan, Rabon, and Broden (1968) continue to serve as powerful demonstrations of the effects of teacher attention as social reinforcement.

Participating in one of the experiments was a first-year teacher whose class of 30 sixth-graders exhibited such high rates of disruptive and off-task behaviors that the school principal described the class as "completely out of control." Throughout the study, Hall, Panyan, Rabon, and Broden (1968) measured teacher attention and student behavior during a continuous 30-minute observation period in the first hour of the school day. The researchers used a 10-second partial-interval observation and recording procedure to measure study behavior (e.g., writing the assignment, looking in the book, answering the teacher's question) and nonstudy behavior (e.g., talking out, being out of seat, looking out the window, fighting or poking a classmate). The observers also recorded the occurrence of teacher attention in each interval. Each instance of teacher verbal attention, defined as a comment directed to a student or group of students, was recorded with a "+" if it followed appropriate study behavior and with a "−" if it followed nonstudy behavior.

During baseline the class had a mean percentage of intervals of study behavior of 44%, and the teacher made an average of 1.4 comments following study behavior per session (see Figure 11.8). "Almost without exception those [comments] that followed study behavior were approving and those that followed nonstudy behavior were in the form of a verbal reprimand" (Hall, Panyan, Rabon, & Broden, 1968, p. 316). The level of study behavior by the class was 90% on one day when the helping teacher presented a demonstration lesson (see data points marked by solid arrows). On three occasions during baseline (data points marked by open arrows), the principal met with the teacher to discuss his organizational procedures in an effort to improve the students' behavior. These counseling sessions

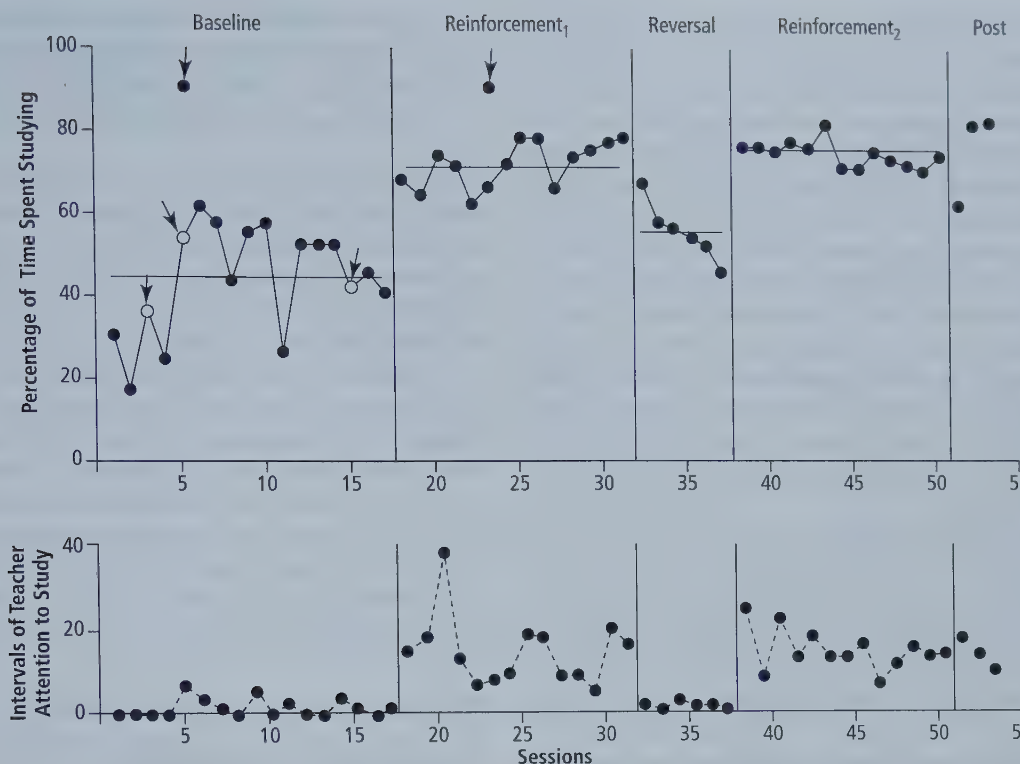

Figure 11.8 A record of class study behavior and teacher attention for study behavior during reading period in a sixth-grade classroom. Baseline = before experimental procedures; Reinforcement 1 = increased teacher attention for study; Reversal = removal of teacher attention for study; Reinforcement 2 = return to increased teacher attention for study. Post-follow up checks occurred up to 20 weeks after termination of the experimental procedures.

From "Instructing Beginning Teachers in Reinforcement Procedures Which Improve Classroom Control," by R. V. Hall, M. Panyan, D. Rabon, and M. Broden, 1968, *Journal of Applied Behavior Analysis*, *1*, p. 317. Copyright by the Society for the Experimental Analysis of Behavior, Inc. Reprinted by permission.

resulted in the teacher writing all assignments on the board (after the first meeting) and changing the seating chart (after the third meeting). Those changes had no apparent effect on the students' behavior.

Prior to the first day of the reinforcement condition, the teacher was shown baseline data on the class study behavior and the frequency of teacher attention following study behavior. The teacher was instructed to increase the frequency of positive comments to students when they were engaged in study behavior. After each session during this condition, the teacher was shown data on the level of class study behavior and the frequency of his comments that followed study behavior. During the first reinforcement phase, teacher comments following study behavior increased to a mean frequency of 14.6, and the mean level of study behavior was 72%. The teacher, principal, and data collectors reported that the class was under better control and that noise had decreased significantly.

During a brief return of baseline conditions, the teacher provided "almost no reinforcement for study behavior," and a sharp downward trend in class study behavior was observed. The teacher, principal, and data collectors all reported that disruptive behavior and high noise levels had returned. The reinforcement conditions were then reinstated, which resulted in a mean frequency of 14 teacher comments following study behavior, and a mean level of 76% of intervals of study behavior.

IDENTIFYING POTENTIAL REINFORCERS

> *In the laboratory, we had learned to use a simple test: Place a candy in the palm of our hand, show it to the child, close our fist fairly tightly around the candy, and see if the child will try to pull away our fingers to get at the candy. If he or she will do that, even against increasingly tightly held fingers, the candy is obviously a reinforcer.*
>
> —Murray Sidman (2000, p. 18)

The ultimate success of many behavior change programs requires an effective reinforcer that the practitioner or researcher can deliver to increase future occurrences of the desired behavior targeted for improving. Fortunately, identifying effective and accessible reinforcers for most learners is relatively easy. Sidman (2000) described a quick and simple method for determining whether candy would likely function as a reinforcer. However, every stimulus, event, or activity that might function as a reinforcer cannot be held in the palm of the hand.

Identifying robust and reliable reinforcers for learners with severe and/or multiple disabilities may pose a major challenge. Although many common events (e.g., praise, music, free time, tokens) serve as effective reinforcers for most people, these stimuli do not function as reinforcers for all learners. Time, energy, and resources would be lost if planned interventions

were to fail because a practitioner used a presumed, instead of an actual, reinforcer.

Also, reinforcer preferences shift, and the transitory and idiosyncratic nature of preference has been reported repeatedly in the literature (Bishop & Kenzer, 2012; Carr, Nicholson, & Higbee, 2000; DeLeon et al., 2001; Ortiz & Carr, 2000; Shapiro, Kazemi, Pgosjana, Rios, & Mendoza, 2016). Preferences may change with the person's age, interest level, time of day, social interactions, deprivation and satiation levels, and the presence of establishing operations (EOs) (Gottschalk, Libby, & Graff, 2000; Whitehouse, Vollmer, & Colbert, 2014). What a teacher asks in September to determine preferences may have to be repeated a month later or a day later. Likewise, a therapist who asks a client what is reinforcing during a morning session may find that this stimulus is not preferred in an afternoon session (Bishop & Kenzer, 2012).

After reviewing 13 published studies that evaluated preferences and reinforcers for people with profound multiple disabilities, Logan and Gast (2001) concluded that preferred stimuli do not always function as reinforcers, and preferred stimuli at one point in time changed later. Additionally, individuals with behavioral or severe to profound developmental disabilities may engage in activities for such a limited time, or shift preferences within teaching sessions, that it is difficult to clearly determine whether a stimulus change is a reinforcer (Bishop & Kenzer, 2012).

To meet the challenge of identifying effective reinforcers, researchers and practitioners have developed a variety of procedures that fall under the twin headings of stimulus preference assessment and reinforcer assessment. Stimulus preference assessment and reinforcer assessment are often conducted in tandem to determine if a stimulus identified as a reinforcer actually functions as one (Kang et al., 2013; Lee, Yu, Martin & Martin, 2010; Piazza, Fisher, Hagopian, Bowman, & Toole, 1996; Whitehouse et al., 2014). Piazza et al. (1996) state:

> During preference assessments, a relatively large number of stimuli are evaluated to identify preferred stimuli. The reinforcing effects of a small subset of stimuli (i.e., the highly preferred stimuli) are then evaluated during reinforcer assessment. Although the preference assessment is an efficient procedure identifying potential reinforcers from a large number of stimuli, it does not evaluate the reinforcing effects of the stimuli. (pp. 1–2)

Stimulus preference assessment identifies stimuli that are likely highly preferred and thus likely to serve as reinforcers. As Kelley, Shillingsburg, and Bowen (2016) state, "The value of preference assessments is grounded in the extent to which the identified stimuli ultimately function as reinforcers for socially important behaviors" (p. 394).

Reinforcer assessment, in contrast, puts the highly preferred, potential reinforcers to a direct test by presenting them contingent on occurrences of a behavior and measuring performance effects (Fisher, Piazza, Bowman, & Amari, 1996). In this section we describe a variety of techniques developed by researchers and practitioners for conducting stimulus preference assessments and reinforcer assessment (see Figures 11.9 and 11.10). These methods form a continuum of approaches ranging from simple and quick to more complex and time-consuming.

Stimulus Preference Assessment

Stimulus preference assessment (SPA) refers to a variety of procedures used to determine (a) the stimuli that the person differentially selects, (b) the relative hierarchical preference value of those stimuli (high preference to low preference), (c) the conditions under which those preference values change when task demands, deprivation states, or schedules of reinforcement are modified, and (d) whether highly preferred items ultimately serve as effective reinforcers. Generally speaking, stimulus preference assessment is conducted using a three-step process: (1) A large pool of stimuli that might serve as reinforcers is gathered, (2) those stimuli are presented to the target person systematically to identify preference, and (3) high- and sometimes low-preference items are "tested" experimentally to determine the conditions under which they serve as reinforcers (Livingston & Graff, 2018). It is essential for practitioners to narrow the initial field of possible preferred stimuli to those that have good

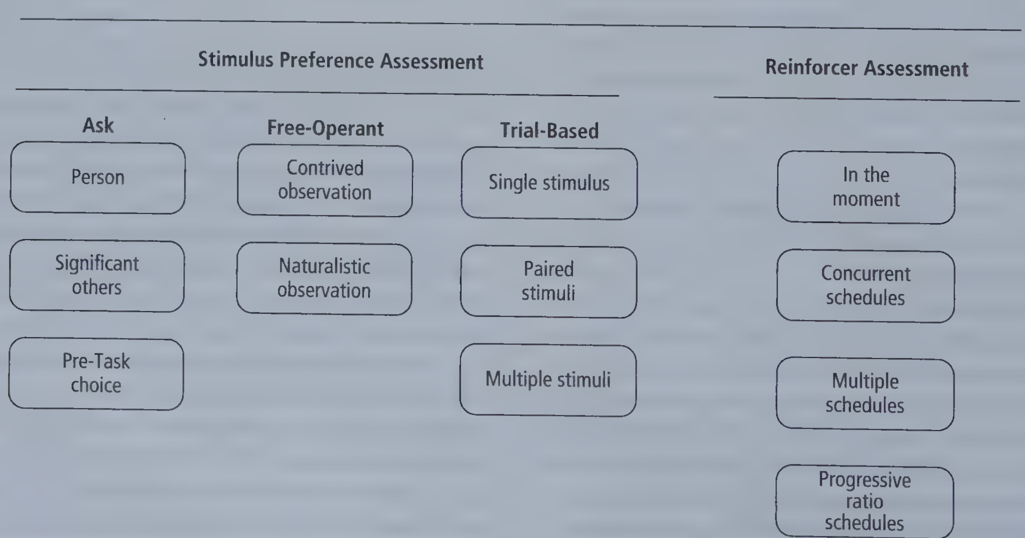

Figure 11.9 Stimulus preference assessment and reinforcer assessment methods for identifying potential reinforcers.

Figure 11.10 Commonly used stimulus preference assessments.

Name of Assessment (Citation)	Description of Assessment
Single-stimulus (SS) (Pace et al., 1985)	Across a series of trials, stimuli are presented one at a time. Approach responses (e.g., moving hand or body toward the item) are recorded. Preference hierarchies are established by calculating the percentage of approach responses per stimulus.
Paired-stimulus (PS) (Fisher et al., 1992)	Across a series of trials, stimuli are presented two at a time; individuals can approach (i.e., select) only one item on a trial. Approach responses are recorded. Preference hierarchies are established by calculating the percentage of approach responses per stimulus.
Multiple-stimulus-without-replacement (MSWO) (DeLeon & Iwata, 1996)	At the start of each session, multiple stimuli are placed in front of the individual, who can select one. Approach responses are recorded. The selected item is not replaced, and the positions of the remaining stimuli are changed. Then, the individual selects from the remaining items. Continue in this manner until all items have been selected or the individual stops selecting items. Typically, several sessions are conducted. Preference hierarchies are established by calculating the percentage of approach responses per stimulus across all sessions.
Brief Free Operant (FO) (Roane et al., 1998)	Multiple stimuli are placed on a tabletop, and participants are free to engage with any of the items for 5 min. Duration of engagement with each object (e.g., manipulating objects) is measured. Preference hierarchies are established by ranking items according to the duration of object manipulation for each stimulus.

From "Assessing Preferences of Individuals with Developmental Disabilities: A Survey of Current Practices," by R. B. Graff and A. M. Karsten, 2012a, *Behavior Analysis in Practice 5*(2), p. 38. Used with permission.

odds of functioning as reinforcers; otherwise, the assessment process will be protracted and intervention delayed.

Methodologically, SPA can be conducted using at least five forms: single-stimulus (SS), paired-stimulus (PS), free operant (FO), multiple-stimulus with item replacement (MSW), and multiple-stimulus without item replacement (MSWO). Each SPA method has advantages or disadvantages with respect to bias, assessment time required, likelihood of identifying reinforcers, and the chance that the assessment activity itself may evoke problem behavior (see Figure 11.11) (Karsten, Carr, & Lepper, 2011).

As illustrated in Figure 11.9 these five methodological variations can be clustered into three categories: (1) ask the person (or significant others) to identify preferred stimuli; (2) employ a free operant procedure by observing the person approaching, interacting, or engaging with various stimuli; and (3) measure responses to trial-based pairs or multiply presented stimuli by replacing or not replacing the stimulus after preference selection.

In choosing which method to use, practitioners must balance three competing perspectives: (a) gaining the maximum amount of preference assessment data within the least amount of time, but with false positives (i.e., believing a stimulus is preferred when it is not); (b) conducting a more extensive and time- and labor-intensive assessment that will delay intervention, but may yield more conclusive results; and (c) assessing the skill level of colleagues conducting the stimulus preference assessment and any initial or recurrent training needs they have

Figure 11.11 Assets and barriers associated with stimulus preference assessments.

Method	Assets	Potential barriers
MSWO	Likely to identify multiple reinforcers in minimal time	Positional bias, limited to smaller tabletop items and fewer items; requires more time than FO assessment
PS	Likely to identify multiple reinforcers, accommodates larger tabletop items and a greater number of items	Positional bias, requires more time than MSWO and FO assessments
SS	Likely to identify multiple reinforcers, accommodates larger items and activities	False positive results, less likely to identify relative preferences than MSWO and PS methods except when duration of engagement is also measured
FO	Less likely to evoke problem behavior, requires minimal time, accommodates larger items and activities	Less likely to identify multiple reinforcers than other methods except when assessment is repeated without most preferred item

Note: MSWO = multipe stimulus without replacement; PS = paired stimulus; SS = single stimulus; FO = free operant.

From "Description of a Practitioner Model for Identifying Preferred Stimuli with Individuals with Autism Spectrum Disorders," by A. M. Karsten, J. E. Carr, and T. L. Lepper, 2011, *Behavior Modification, 35*(4), p. 350. Copyright by Sage Publication. Reprinted by permission.

(Leaf et al., 2015). To assist analysts and practitioners with deciding which of the five methodological variations to employ, Karsten et al. (2011) proposed a three-step model that progresses from (a) choosing the SPA that is likely to yield an accurate hierarchy of high-preference stimuli, (b) modifying that SPA approach based on actual data collected during the SPA, and (c) verifying that the high-preference stimuli function as reinforcers.

Still, a practical roadblock may affect the implementation of the best of intended SPA models. Graff and Karsten (2012a) stated that upwards of one half of the respondents to their SPA questionnaire reported that they had little to no experience with conducting SPAs. Given that conducting some level of a SPA has become the gold standard of best practice for identifying highly preferred stimuli and ultimately reinforcers (Leaf et al., 2018), it seems important that training programs at the pre- and in-service levels address this shortcoming. Deliperi, Vladescu, Reeve, Reeve, and DeBar (2015) state the issue succinctly:

> Due to the reliance on reinforcement in interventions for consumers with disabilities, assessing the preferences of these individuals is an important part of effective programming. The failure to identify stimuli that function as reinforcers may compromise skill acquisition and behavior reduction programs. Therefore, identifying and implementing effective training procedures are essential to increasing the likelihood that staff will conduct preference assessments and use data from these assessments to guide their selection of consequences during subsequent programming. (p. 324)

Box 11.2 discusses a number of questions associated with training practitioners to conduct stimulus preference assessments.

BOX 11.2

Training Practitioners to Conduct Stimulus Preference Assessments (SPA)

Identifying reinforcers is key to a successful behavior change program. But busy, inexperienced, and inadequately trained preservice or in-service practitioners, who now also lack time and resources, are not likely to engage in conducting stimulus preference assessments without training from an experienced analyst (Graff & Karsten, 2012a). Although not intended to be exhaustive, the following frequently asked questions may provide a starting point to address stimulus preference assessment training issues for inexperienced, novice, or poorly trained preservice practitioners within either an individual or group-training context.

For SPAs to Be Conducted, What Skills Must Be Taught?

There appears to be consensus in the literature that practitioners need three main skills: (1) identifying stimulus items for the assessment; (2) conducting the SPA with a confederate or actual consumer; and (3) scoring and interpreting the results of the assessment to determine high- and low-preference stimuli. (Source: Deliperi et al., 2015)

Can Inexperienced Practitioners Learn the Skills Necessary to Conduct Reliable, Accurate, and Worthwhile Stimulus Preference Assessments?

Yes. Although the methods might vary and depend on local available resources, broadband Internet connectivity, and skill level of the trainer, it is quite possible—even desirable—to train (or retrain) inexperienced practitioners to use SPA. Doing so will give the teacher, parent, or caregiver direction for using those assessment data to further determine actual reinforcers that will affect future occurrences of target behaviors for the persons in their care. (Source: Ringdahl et al., 1997)

How Long Does It Take to Train an Inexperienced Person to Conduct a SPA?

The good news is that within several training sessions trainees can gain sufficient skill to conduct an SPA, especially if the training provides combinations of video models, scripts, voice-overs, practice, feedback, and supervision. (Sources: Bovi, Vladescu, DeBar, Carroll, & Sarokoff, 2017; Deliperi et al., 2015; Weldy, Rapp, & Capocosa, 2014)

Will Warranty Work Be Required? Does the Training Stick?

Whether future "booster" or "refresher" sessions will be required to maintain skills depends on a number of variables. For example, if novice practitioners only use SPA a few times per year, you can expect loss of initial skill acquisition. If, however, they use SPA regularly, it is more likely that initial training will be maintained, especially if they receive follow-up feedback and have access to review materials (prior training videos, embedded directions, etc.). In these cases, as the behavior analyst trainer, you would have more confidence that initial skills would be maintained. (Source: Deliperi et al., 2015)

Does SPA Training Only Work for "Ask" or "Free Operant" Categories of SPA?

No. A number of researchers have shown that analysts can train inexperienced practitioners to use *ask, free operant*, and *trial-based* variations of SPA. The complexity of the SPA methodology is not a determining or self-limiting factor in training. Inexperienced participants can learn a variety of SPA methods. (Sources: DeLeon & Iwata, 1996; Fisher et al., 1992; Hanley, Iwata, Roscoe, 2006; Pace, Ivancic, Edwards, Iwata, & Page, 1985)

Will Brief Written Instructions Alone—Like Those Found in a Method Section of a Journal Article—Be Sufficient for Training?

Probably not. Simply providing an opportunity for inexperienced practitioners to read the *method section* of a journal article on SPA is not likely to be successful. A number of researchers have demonstrated that written instructions alone are not robust enough to bring inexperienced practitioners up to a standard whereby they can conduct an SPA without supervision. Additional and supplementary materials are needed to "enhance" written instructions. These enhancements might include providing pictures, video models, role playing, voiceovers, feedback, and so on. (Sources: Graff & Karsten, 2012b; Lavie and Sturmey, 2002; Ramon, Yu, Martin, & Martin, 2015; Roscoe & Fisher, 2008; Shapiro et al., 2016).

If I Develop a Self-instruction Manual, Will That Work?

It depends. Although self-instruction manuals can be an improvement over brief, written methodological synopses excerpted from journals, the scope and sequence of the manual would be of primary importance. Otherwise, your trainee might be left with the equivalent of "written instructions alone," which has not been shown to be effective. Using a self-instruction manual alone in this manner would be tantamount to a "train and hope" process. However, if the manual provides introductory content, step-by-step directions, a procedural checklist, exercises, an answer key, and methods for recording, summarizing, and interpreting SPA data, the manual's utility is enhanced considerably. If the trainer uses feedback from the trainees as a way to improve the accuracy and completeness of the manual, the manual would evolve over time into a more effective document. (Source: Ramon et al., 2015)

Can I Use Video, Multimedia, or a Smartphone App to Teach SPA?

Yes. Video methods have been shown to be effective, especially when combined as a "package approach," including feedback, embedded text, rehearsal, and supervision. Also, trainers can use smartphone apps (e.g., Plickers.com) to conduct basic SPA formative assessments with groups of students. (Sources: Hansard & Kazemi, 2018; Lavie & Sturmey, 2002; Radley, Dart, Battaglia, & Ford, 2018)

I Have a Number of Practitioners to Teach. Can I Teach Within a Group Context?

Yes. Teaching practitioners within a small-group context can increase training efficiency, without loss of effect. (Source: Weldy et al., 2014)

I Live in a Rural/Remote Area. Can I Use Distance Learning with My Staff?

Yes. One of the remarkable benefits of high-speed, broadband Internet connections is that telecommunication links can be established and operated remotely. Training staff in distant locations appears to be at least as comparable to in-person training with respect to initial skill acquisition and maintenance, even without in-person contact or on-site trainers. (Source: Higgins, Luczynski, Carroll, Fisher, & Mudford, 2017)

Choosing a method to teach inexperienced practitioners rests with the trainer's assessment of current staff resources (e.g., time, physical facilities, exigent circumstances, location) and consumer needs. Although a number of methods can be effective, depending on individual or group instruction, trainers would be advised to follow a "model-lead-test" sequence to ensure initial training to mastery. If necessary, be prepared to provide follow-up "booster" sessions to ensure maintenance and retention. Do not assume that "once taught is forever learned," especially if the practitioner has few opportunities to implement SPA after initial training.

Asking About Stimulus Preferences

A person's preference for various stimuli might be determined by merely asking what she likes. Asking can greatly reduce the time needed for more intrusive stimulus preference assessment, and it often yields information that can be integrated within an intervention program. Several variations of asking exist: asking the target person, asking significant others in the person's life, or offering a pretask choice assessment.

Asking the Target Person. A straightforward method for determining stimulus preference is to ask the target person what she likes. Typical variations include asking open-ended questions, providing the person with a list of choices or asking her to rank-order a list of choices.

- ***Open-ended questions.*** Depending on the learner's language abilities, an open-ended assessment of stimulus preference can be done orally or in writing. The person may be asked to name preferences among general categories of reinforcers—for example, "What do you like to do in your free time?" "What are your favorite foods and drinks?" "Are there any types of music or performers whose music you like?" An open-ended assessment can be accomplished simply by asking the learner to list as many favorite activities or items as possible. She should list not only everyday favorite things and activities but also special items and activities. Figure 28.15 is simply a sheet with numbered lines on which family members identify potential rewards they would like to earn by completing tasks on contingency contracts.

- ***Choice format.*** This format could include asking questions such as the following: "Which would you do a lot of hard work to get?" "Would you rather get things to eat, like chips, cookies, or popcorn, or get to do things like art projects, play computer games, or go to the library?" (Northup, George, Jones, Broussard, & Vollmer, 1996, p. 204)
- ***Rank-ordering.*** The learner can be given a list of items or stimuli and instructed to rank-order them from most to least preferred.

For learners with limited language skills, pictures of items, icons, or, preferably, the actual stimuli can be presented (Clevenger & Graff, 2005). For example, a teacher, while pointing to an icon, might ask a student, "Do you like to drink juice, use the computer, ride the bus, or watch TV?" Students simply nod yes or no.

Surveys have been developed to assess students' preferences. For example, elementary school teachers might use the *Child Reinforcement Survey*, which includes 36 rewards in four categories: edible items (e.g., fruit, popcorn), tangible items (e.g., stickers), activities (e.g., art projects, computer games), and social attention (e.g., a teacher or friend saying, "I like that") (Fantuzzo, Rohrbeck, Hightower, & Work, 1991). Other surveys are the *School Reinforcement Survey Schedule* for students in grades 4 through 12 (Holmes, Cautela, Simpson, Motes, & Gold, 1998) and the *Reinforcement Assessment for Individuals with Severe Disabilities* (Fisher et al., 1996).

Although asking for personal preferences is relatively uncomplicated, the procedure is not entirely foolproof with respect to confirming that a preferred choice will later serve as a reinforcer (Whitehouse et al., 2014). "Poor correspondence between verbal self-reports and subsequent behavior has been long noted and often demonstrated" (Northup, 2000, p. 335). Although a child might identify watching cartoons as a preferred event, watching cartoons may function as a reinforcer only when the child is at home on Saturday mornings, but not at Grandma's house on Sunday night.

Further, surveys may not differentiate accurately between what children claim to be high-preference and low-preference items for reinforcers. Northup (2000) found that preferences of children with attention-deficit hyperactivity disorder (ADHD) did not rise beyond chance levels when survey results were later compared to reinforcer functions. "The relatively high number of false positives and low number of false negatives again suggest that surveys may more accurately identify stimuli that are not reinforcers than those that are" (p. 337). Merely asking children their preferences once might lead to false positives (i.e., children may choose an event or stimulus as a reinforcer, but it may not be reinforcing).

Asking Significant Others. A pool of potential reinforcers can be obtained by asking parents, siblings, friends, or caregivers to identify the activities, items, foods, hobbies, or toys that they believe the learner prefers. For example, the *Reinforcer Assessment for Individuals with Severe Disabilities (RAISD)* is an interview protocol that asks caregivers to identify preferred stimuli across visual, auditory, olfactory, edible, tactile, and social domains (Fisher et al., 1996). Significant others then rank-order the selected preferences based on likely high-versus low-preference items. Finally, significant others are asked to identify the conditions under which they predict that specific items might function as reinforcers (e.g., cookies with milk versus just cookies alone). As a cautionary note, however, analysts should be aware that stimuli identified as highly preferred by a significant other's opinion *alone* may not always function as an effective reinforcer. Fisher et al. (1996) remind us: "Caregiver opinion alone is insufficient for accurate reinforcer identification" (p.14). However, when caregiver opinion is combined with a structured interview that provides prompts, cues, and a broader array of potential reinforcers for the significant other to consider, the caregiver report can be a helpful supplement to other methods.

Offering a Pretask Choice. In this method, the practitioner asks the participant to choose what he wants to earn for doing a task. The participant then chooses one item from two or three options presented (Piazza et al., 1996). All of the stimuli presented as pretask choices will have been identified as preferred stimuli by other assessment procedures. For instance, a teacher might make the following statement: "Robyn, when you finish your math problems, you may have 10 minutes to play *Battleship* with Martin, read quietly, or help Ms. Obutu prepare the social studies poster. Which activity do you want to work for?" A learner's choice of a consequence will not necessarily be a more effective reinforcer than one selected by the researcher or practitioner (Smith, Iwata, & Shore, 1995).

Free Operant Observation

The activities that a person engages in most often when able to choose freely from among behaviors will often serve as effective reinforcers when made contingent on engaging in low-probability behaviors. Observing and recording what activities the target person engages in when she can choose during a period of unrestricted access to numerous activities is called *free operant observation.* A total duration measure of the time the person engages with each stimulus item or activity is recorded. The longer the person engages with an item, the stronger the inference that the item is preferred.

Procedurally, the person has unconstrained and simultaneous access to a predetermined set of items or activities or to the materials and activities that are naturally available in the environment. There are no response requirements, and all stimulus items are available and within the person's sight and reach. An item is never removed after engagement or selection. According to Ortiz and Carr (2000) and Karsten et al. (2011), free operant responding is less likely to produce problem behavior during the assessment that might otherwise be observed if a stimulus is removed. Free operant observations can be contrived or conducted in naturalistic settings.

Contrived Free Operant Observation. Practitioners use contrived observation to determine whether, when, how, and the extent to which the person engages with each of a predetermined set of activities and materials. The observation is contrived because the researcher or practitioner "salts" the environment with a variety of items that may be of interest to the learner.

Figure 11.12 Number of minutes Mike spent engaged in activities during 2 hours of free time after school.

Activity	Mon	Tue	Wed	Thus	Fri	Total
Leisure reading	—	10	—	10	—	20
Watch TV	35	50	60	30	30	205
Phone with friends	15	15	10	20	10	70
Play video games	70	45	40	60	80	295
Play with constuction toy	—	—	10	—	—	10
Minutes observed	**120**	**120**	**120**	**120**	**120**	**600**

Free operant assessment presupposes that the person has had sufficient time to move about and explore the environment and has had the chance to experience each of the stimuli, materials, or activities. Just prior to the free operant observation period, the learner is provided brief noncontingent exposure to each item. All of the items are then placed within view and easy access to the learner, who then has the opportunity to sample and choose among them freely. Observers record the total duration of time that the learner engages with each stimulus item or activity.

Naturalistic Free Operant Observation. Naturalistic observations of free operant responding are conducted in the learner's everyday environment (e.g., playground, classroom, home). As unobtrusively as possible, the observer notes how the learner allocates his time and records the number of minutes the learner devotes to each activity. For instance, Figure 11.12 shows how a teenager, Mike, distributed his time during 2 hours of free time each day after school. Mike's parents collected these data by keeping a chart of the total number of minutes their son was engaged in each activity. The summary chart for the week shows that Mike played computer video games, watched television, and talked on the phone to his friends every day. On two different days Mike spent 10 minutes reading a library book, and he played with a new construction toy for a brief time on Wednesday. Two activities—watching television and playing video games—occurred the most often and for the longest duration. If Mike's parents wanted to apply the Premack principle introduced earlier in this chapter to increase the amount of time he spends reading for pleasure or playing with the construction toy (i.e., low-probability behaviors), they might make watching television or playing video games (i.e., high-probability behaviors) contingent on a certain amount of time spent leisure reading or playing with the construction toy.

Trial-based Methods

In trial-based methods of stimulus preference assessment, stimuli are presented to the learner in a series of tests, and the learner's responses to the stimuli are measured as an index or hierarchy of preference. One or more of three measures of the learner's behavior are recorded in trial-based stimulus preference assessment: approach, contact (DeLeon & Iwata, 1996), and engagement with the stimulus (DeLeon, Iwata, Conners, & Wallace, 1999; Hagopian, Rush, Lewin, & Long, 2001; Roane, et al., 1998). *Approach* responses typically include any detectable movement by the person toward the stimulus (e.g., eye gaze, head turn, body lean, hand reach), a *contact* is tallied each time the person touches or holds the stimulus, and *engagement* is a measure of the total time or percentage of observed intervals in which the person interacts with the stimulus (e.g., in which the person held a massager against her leg). An assumption is made that the more frequently the person approaches, touches or holds, or engages with a stimulus, the more likely the stimulus is preferred. As DeLeon and colleagues (1999) stated, "duration of item contact is a valid index of reinforcer value" (p. 114).

Preferred stimuli are typically labeled along a hierarchy from high-preference (HP) to low-preference (LP) stimuli based on predetermined criteria (e.g., stimuli chosen 80% or more of the time are HP) (Carr et al., 2000; Northup, 2000; Pace et al., 1985; Piazza et al., 1996). Implicit, but testable, assumptions are that a highly preferred stimulus will serve as a reinforcer and that preference stability is necessary before treatment can begin. Although these assumptions do not always hold (Higbee, Carr, & Harrison, 2000; Verriden & Roscoe, 2016), they have proven to be efficient and workable assumptions with which to begin.

The many variations of trial-based stimulus preference assessment can be grouped by presentation method as single stimulus (successive choice), paired stimuli (forced choice), and multiple stimuli with or without replacement.[9]

Single Stimulus. A single-stimulus presentation method, also called a *successive choice* or *single-stimulus engagement preference* method, represents the most basic assessment available for determining preference. Simply stated, a stimulus is presented by a trained clinician or teacher, and the person's reaction to, or engagement with, the stimulus is noted. Engagement behaviors include touching, playing with, looking at, or holding the stimulus for a predetermined time. Presenting one stimulus at a time "may be well suited for individuals who have difficulty selecting among two or more stimuli" (Hagopian et al., 2001, p. 477).

To conduct a single-stimulus assessment, target stimuli across all sensory systems (i.e., visual, auditory, vestibular, tactile, olfactory, gustatory, and multisensory) are made available to the participant for a brief period. The participant is allowed to sample the stimuli one at a time, engage with it briefly, and, if a toy, see how it works, before the formal assessment protocol begins. Next, the stimuli are presented one at a time in random order, and the person's reaction to and/or engagement with

each stimulus is recorded (Logan et al., 2001; Pace et al., 1985). Approach, avoidance, or rejection responses are recorded in terms of occurrence (yes or no), count (e.g., number of touches per minute), or duration (i.e., time spent engaged with an item). Each item in the array of proposed stimuli is presented sequentially. For example, a mirror might be presented to determine the duration of time the participant gazes into it, touches it, or rejects the mirror altogether (i.e., pushes it away). Each item is presented several times, and the order of presentation should be varied. Once all stimuli have been presented, a graphical hierarchy is constructed with the stimuli listed on the *x*-axis and the percentage of engagement on the *y*-axis. By analyzing the data with a bar graph, stimuli that are ranked the highest are presumed to be the preferred reinforcers.[10]

Boutot and DiGangi (2018) used a single-stimulus assessment procedure to identify preferred and nonpreferred toys by Dominic, a 5-month-old infant with Down syndrome. If Dominic looked at the adult-activated toy for longer than 5 seconds, changed facial expressions while looking at the object (e.g., smiled), or produced a marked bodily movement (kicked his legs or waved his arms), the toy was deemed preferred. Using this method, the researchers ultimately identified three toys and later employed them as reinforcers to increase the percentage of time Dominic sustained his head in an elevated position during tummy time over a "No Toy" condition (See Figure 11.13). Boutet and DiGangi (2018) concluded that the single-stimulus assessment procedure could be used in an efficient, probe-like manner to identify preferred stimuli and that those stimuli could be used by researchers and parents to improve important muscular skills for an infant with Down syndrome.

Paired Stimuli. Each trial in the paired-stimuli presentation method, also sometimes called the "forced choice" method, consists of the simultaneous presentation of two stimuli. The observer records which of the two stimuli the learner chooses. To conduct a paired-stimuli assessment, each stimulus is matched randomly with all other stimuli in the proposed group of stimuli to be compared (Fisher et al., 1992). The number in the group is at the discretion of the analyst. For example, Piazza and colleagues (1996) used 66 to 120 paired-stimuli trials to determine reinforcer preference. Data from a paired-stimuli assessment show how many times each stimulus is chosen. The stimuli are then rank-ordered from high to low preference. Items that received engagement, play, manipulation, or selection over 80% of the pairings are deemed high-preference items. Low-preference items were selected at the 50% level. Pace and colleagues (1985) found that paired-stimuli presentations yielded more accurate distinctions between high- and low-preference items than did single-stimulus presentations. Paired-stimulus preference assessment has the advantage of arranging all stimuli sequentially, thereby providing choices that otherwise would not be possible during a single-stimulus presentation format. Thus,

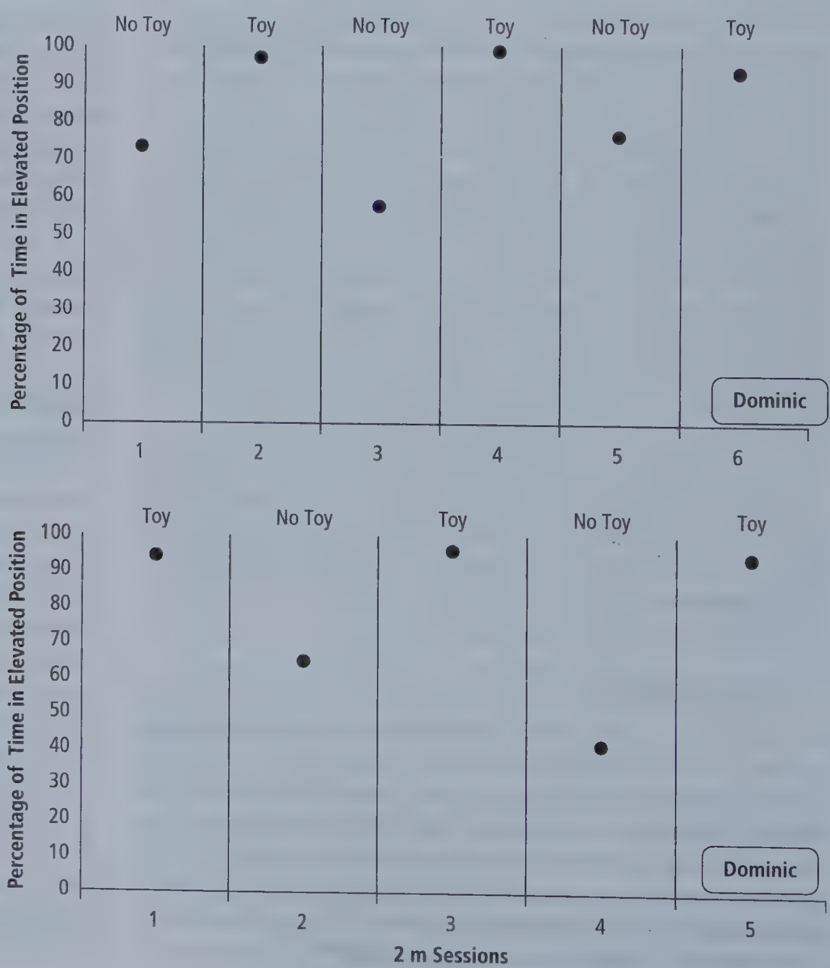

Figure 11.13 Percentage of each 2-minute session in which Dominic elevated his head above a 45° angle when the researcher (top panel) or parent (bottom panel) activated a preferred toy during tummy time or when no toy was present.

From "Effects of Activation of Preferred Stimulus on Tummy Time Behavior of an Infant with Down Syndrome and Associated Hypotonia," by E. A. Boutot and S. A. DiGangi, 2018, *Behavior Analysis in Practice*, *11*, p. 146. Copyright by the Association for Behavior Analysis International. Reprinted by permission.

the likelihood of ultimately identifying reinforcers is higher (Paclawskyj & Vollmer, 1995).

Because every possible pair of stimuli must be presented, paired-stimuli assessing is likely to take more time than the simultaneous presentation of a series of multiple stimuli. However, DeLeon and Iwata (1996) argued that ultimately the paired-stimuli method may be more time efficient because "the more consistent results produced by the PS method may indicate that stable preferences can be determined in fewer, or even single, sessions" (p. 520)[11].

Multiple Stimuli. The multiple-stimuli presentation method is an extension of the paired-stimuli procedure developed by Fisher and colleagues (1992). The participant to be assessed chooses a preferred stimulus from an array of three or more stimuli (Windsor, Piche, & Locke, 1994). By presenting multiple stimuli together, assessment time is reduced. For example, instead of presenting a series of trials consisting of all possible pairs of stimuli from a group of six stimuli and continuing until all pairs have been presented, all six stimuli are presented simultaneously.

The two major variations of the multiple-stimuli preference assessment are multiple stimuli with replacement (MSWI) and multiple stimuli without replacement (MSWO). The difference between the two lies in which stimuli are removed or replaced in preparation for the next trial after the participant indicates a preference among the displayed items. In the multiple stimuli with replacement procedure, the item chosen by the learner remains in the array and items that were not selected are replaced with new items. In the multiple stimuli without replacement procedure, the chosen item is removed from the array, the order or placement of the remaining items is structurally rearranged, and the next trial begins with a reduced number of items in the array (Brodhead, Al-Dubayan, Mates, Abel, & Brouwers, 2016).[12]

In any case, each trial begins by asking the person, "Which one do you want the most?" (Higbee et al., 2000), or instructing the person to "Choose one" (Ciccone, Graff, & Ahearn, 2005) and then continues until all items from the original array, or the gradually reducing array, have been selected. The entire sequence is usually repeated several times, although a single round of trials may identify stimuli that function as reinforcers (Carr et al., 2000).

The stimuli presented in each trial might be tangible objects themselves, pictures of the items, or verbal descriptions. Comparisons between conducting stimulus preference assessments with tangible objects themselves versus pictures of those objects have been mixed. Whereas Brodhead et al. (2016) have shown that video MSWO may be a suitable complement to tangible MSWI, Higbee, Carr, and Harrison (1999) found that the tangible objects produced greater variation and distribution of preferences than the picture objects did. Cohen-Almeida, Graff, and Ahearn (2000) found that the tangible object assessment was about as effective as a verbal preference assessment, but the clients completed the verbal preference assessment in less time.

In sum, MSWO assessment may identify stimuli that function as reinforcers, may require fewer sessions or less time to complete than other variations of preference assessments, yields a hierarchy of student preference, and appears to be suitable for a wide range of students due to fast administration and accuracy in identifying potential reinforcers (Brodhead et al., 2016).

DeLeon and Iwata (1996) used an adaptation of the multiple-stimuli and paired-stimuli presentations they described as a *brief stimulus assessment* to reduce the time needed to determine stimulus preference. Basically, in the brief stimulus assessment, once a particular stimulus item is chosen, that item is *not* returned to the array. Subsequent trials present a reduced number of items from which to choose (Carr et al., 2000; DeLeon et al., 2001; Roane et al., 1998). DeLeon and Iwata (1996) found that multiple stimuli without replacement identified preferred items in approximately half the time that a paired-stimulus comparison procedure did. According to Higbee and colleagues (2000), "With a brief stimulus preference procedure, practitioners have a method for reinforcer identification that is both efficient and accurate" (pp. 72–73).

Guidelines for Selecting and Using Stimulus Preference Assessments

Practitioners can combine assessment procedures to compare single versus paired, paired versus multiple, or free operant versus trial-based methods (Ortiz & Carr, 2000).[13] In day-to-day practice, brief stimulus presentations using comparative approaches might facilitate reinforcer identification, thereby speeding up interventions using those reinforcers. For teaching purposes and to launch instruction as soon as possible, Karsten et al. (2011) recommend using FO and/or MSWO options, as they are efficient and likely to provide sufficient information on a reinforcer hierarchy. Tung, Donaldson, and Kang (2017) also state that the FO procedure may be the method of choice when problem behavior is anticipated when tangible stimuli are removed during the assessment process.

In summary, an important goal of stimulus preference assessments is to identify stimuli that are most highly preferred and thus likely to function as reinforcers (Kelly, Roscoe, Hanley, & Schlichenmeyer, 2014). Each method for assessing preference has advantages and limitations with respect to identifying preferences (Karsten et al., 2011; Roane et al., 1998). Practitioners may find the following guidelines helpful when conducting stimulus preference assessments (DeLeon & Iwata, 1996; Gottschalk et al., 2000; Higbee et al., 2000; Ortiz & Carr, 2000; Roane et al., 1998; Roscoe, Iwata, & Kahng, 1999):

- Monitor the learner's activities during the time before the stimulus preference assessment session to be aware of EOs that may affect the results.
- Use stimulus preference assessment options that balance the cost–benefit of brief assessments (but the possible occurrence of false positives) with more prolonged assessments, which, while they may ultimately identify more highly preferred stimuli (and reinforcers), delay intervention.
- Balance using a stimulus preference method that may yield a ranking of preferred stimuli against an assessment method that occurs without rankings, but occurs more frequently, to counteract shifts in preference.
- Conduct a brief stimulus preference assessment with fewer items in an array (i.e., 3 instead of 5 or more) when assessment time is limited.
- Combine data from multiple assessment methods and sources of stimulus preference (e.g., asking the learner

and significant others, free operant observation, and trial-based methods).

- Verify that stimuli identified by any efficient SPA method ultimately serve that function as a reinforcer.
- Recognize that whereas stimulus preference may be stable for individuals over time (Kelley et al., 2016), the possibility exists that stimulus preference will shift, and further SPAs may be necessary.
- To facilitate SPA assessment with respect to time, consider using categories of stimuli. Edible categories might include chocolate, gummy treats, crunchy snacks, and so forth. Toy categories might include, for example, trucks, cars, and fire engines. It's likely that if SPA shows a preference for one item within a category, other unassessed items within that category might also serve as reinforcers, even if they are not initially formally assessed.

Reinforcer Assessment

The only way to tell whether or not a given event is reinforcing to a given organism under given conditions is to make a direct test.

—B. F. Skinner (1953, pp. 72–73)

Highly preferred stimuli may not always function as reinforcers (Higbee et al., 2000); even the candy that a child pried out of Sidman's hand may not have functioned as reinforcer under certain conditions. Conversely, least preferred stimuli might serve as reinforcers under some conditions (Gottschalk et al., 2000). The only way to know for sure whether a given stimulus serves as a reinforcer is to present it immediately following the occurrence of a behavior and note its effects on responding.

Reinforcer assessment refers to a variety of direct, data-based methods used to present one or more stimuli contingent on a target response and then measuring the future effects on the rate of responding. Researchers and practitioners have developed reinforcer assessment methods to determine the relative effects of a given stimulus as reinforcement under different and changing conditions and to assess the comparative effectiveness of multiple stimuli as reinforcers for a given behavior under specific conditions. Reinforcer assessment or analysis is often accomplished by presenting stimuli suspected of being reinforcers either "in the moment" or contingent on responding within concurrent, multiple, or progressive-ratio reinforcement schedules.[14]

In-the-Moment Reinforcer Analysis

In-the-moment reinforcer analysis is conducted by practitioners when a learner's response is followed immediately by the presentation of a stimulus change—in this case, a stimulus presumed to be a reinforcer—and the effect is noted on increases in the future occurrence of similar responses (Leaf et al., 2018). In practical applications, the analyst, with immediate access to numerous presumed reinforcers, makes an instantaneous judgment about which of those "reinforcers" is likely to function as such, and delivers that reinforcer to the learner. When deciding which reinforcer to deliver, the analyst considers the learner's current affect (smiling, frowning), previous interactions with that stimulus item (approaching, engaging, contacting), past data showing the effectiveness of that stimulus with respect to performance (improved or decreased), interactions with similar items in the past (furry dog, fleece-covered cat), and other past observational preferences (Leaf et al., 2012).

Leaf et al. (2018) compared formal paired-stimulus preference assessments with "in-the-moment reinforcer analysis" used to determine rates of learning a simple picture-labeling task by two preschool boys with autism. Procedurally, the teachers conducted a paired-stimulus preference assessment to determine the top three preferred items. During teaching, if the boys answered a question correctly, they received access to one of the top three items for 10 seconds. If they answered incorrectly, they received feedback that their response was incorrect. During the in-the-moment condition, the identical pool of paired-stimulus condition items was available, but the teachers had complete discretion about which item to deliver contingent on a correct response. They could deliver the same reinforcer during all learning trials or change the reinforcer after each trial. The determining factor was their moment-to-moment judgment based on the factors cited above.

The results of Leaf et al. showed no clear difference in skill acquisition for the boys—they learned equally well in both conditions, but the in-the-moment procedure was far more efficient with respect to the division of time spent in assessment versus teaching conditions. Leaf and colleagues concluded by stating: "When teaching individuals with learning difficulties, any incremental gain in speed of acquisition through formal preference assessments must be weighed against the reduced teaching time that remains after completing the assessments, which is a point that seems to be too often overlooked" (p. 23).

Concurrent Schedule Reinforcer Assessment

When two or more contingencies of reinforcement operate independently and simultaneously for two or more behaviors, a *concurrent schedule of reinforcement* is in effect. When used as a vehicle for reinforcer assessment, a concurrent schedule arrangement essentially pits two stimuli against each other to see which will produce the larger increase in responding when presented as a consequence for responding. If a learner allocates a greater proportion of responses to one component of the concurrent schedule over the other, the stimulus used as a contingent consequence for that component is the more effective reinforcer. Using a concurrent schedule in this way shows the relative effectiveness of high-preference (HP) and low-preference (LP) stimuli as reinforcers (Koehler, Iwata, Roscoe, Rolider, & O'Steen, 2005; Piazza et al., 1996).

Concurrent schedules may also be used to determine differences between *relative* and *absolute* reinforcement effects of stimuli. That is, will an LP stimulus now presented contingently in the absence of the HP stimulus serve as a reinforcer? Roscoe and colleagues (1999) used concurrent schedules to compare the effects of HP and LP stimuli as reinforcers for eight adults with developmental disabilities. Following the preference assessments, a concurrent schedule of reinforcement was established using the high-preference and low-preference stimuli. The target response was pressing either of two micro switch panels. Each panel was a different color. Pressing a panel would illuminate

a small light in the center of the panel. A training condition took place prior to baseline to establish panel pressing in the subjects' repertoires and to expose them to the consequences of responding. During baseline, pressing either panel resulted in no programmed consequences. During the reinforcement phase, an HP stimulus was placed on a plate behind one of the panels, and an LP stimulus was placed on a plate behind another panel. All responses to either panel resulted in the participant immediately receiving the item on the plate behind the respective panel (i.e., an FR 1 schedule of reinforcement).

Under the concurrent schedule of reinforcement that enabled participants to choose reinforcers on the same FR 1 schedule, the majority of participants allocated most of their responding to the panel that produced the HP stimulus as reinforcement (e.g., see results for Sean, Peter, Matt, and Mike on Figure 11.14). However, these same participants, when later presented with the opportunity to obtain LP stimuli as reinforcers on a single-schedule contingency (i.e., only one panel to push), showed increased levels of responding over baseline, similar to those obtained with the HP stimuli in the concurrent schedule. The study by Roscoe and colleagues (1999) demonstrated how concurrent schedules may be used to identify the relative effects of stimuli as reinforcers. The study also showed that the potential effects of a stimulus as a reinforcer may be masked or overshadowed when that stimulus is pitted against another stimulus on a concurrent schedule. In such cases, a potentially reinforcing stimulus might be abandoned prematurely.

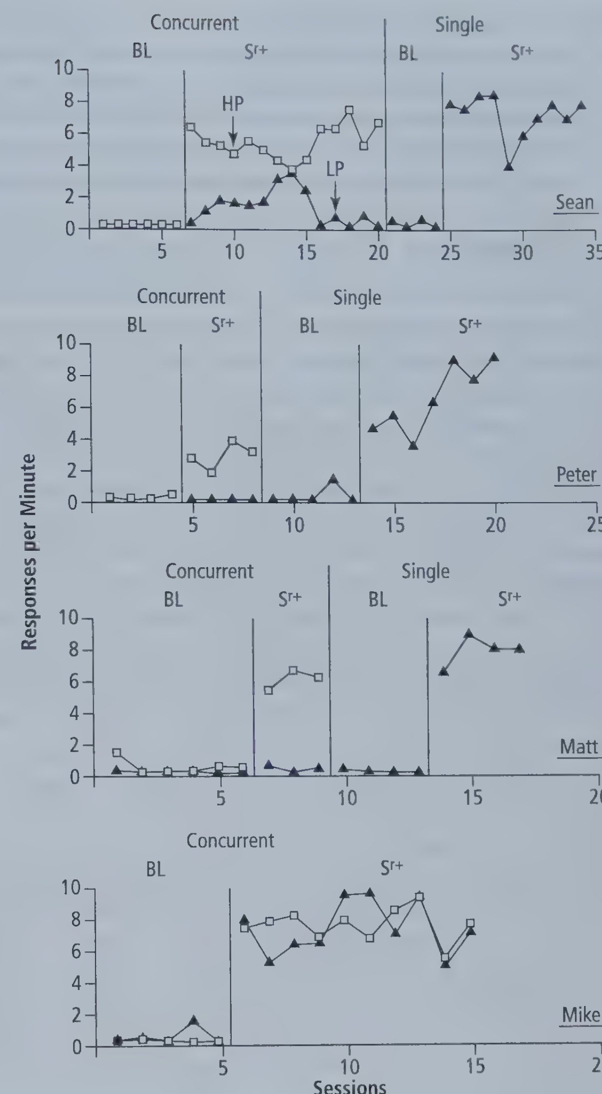

Figure 11.14 Responses per minute during concurrent-schedule and single-schedule baseline and reinforcement conditions for four adults with intellectual disabilities.

"Relative Versus Absolute Reinforcement Effects: Implications for Preference Assessments" by E. M. Roscoe, B. A. Iwata, and S. Kahng, 1999, *Journal of Applied Behavior Analysis*, *32*, p. 489. Copyright 1999 by the Society for the Experimental Analysis of Behavior, Inc.

Multiple Schedule Reinforcer Assessment

A *multiple schedule of reinforcement* consists of two or more component schedules of reinforcement for a single response with only one component schedule in effect at any given time. A discriminative stimulus (S^D) signals the presence of each component schedule, and that stimulus is present as long as the schedule is in effect. One way that a multiple schedule could be used for reinforcer assessment would be to present the same stimulus event contingent (i.e., response dependent) on each occurrence of the target behavior in one component of the multiple schedule and on a fixed-time schedule (i.e., response independent) in the other component. For example, if a practitioner wanted to use a multiple schedule to assess whether social attention functioned as a reinforcer, she would provide social attention contingent on occurrences of cooperative play when one component of the multiple schedule is in effect, and during the other component the practitioner would present the same amount and kind of social attention except on a fixed-time schedule, independent of cooperative play (i.e., noncontingent reinforcement). The teacher could apply the response-dependent schedule during the morning play period, and the response-independent schedule during the afternoon play period. If social attention functioned as reinforcement, cooperative play would likely increase over its baseline rate in the morning periods, and because of no relationship with cooperative play, attention would likely have no effect in the afternoon period. This situation follows a multiple schedule because there is one class of behavior (i.e., cooperative play), a discriminative stimulus for each contingency in effect (i.e., morning and afternoon play periods), and different conditions for reinforcement (i.e., response dependent and response independent).

Progressive-Ratio Schedule Reinforcer Assessment

Stimulus preference assessments with low response requirements (e.g., FR 1) may not predict the effectiveness of the stimulus as a reinforcer when presented with higher response requirements (e.g., on an FR 10 schedule, a student must complete 10 problems to obtain reinforcement). As DeLeon, Iwata, Goh, and Worsdell (1997) stated:

> Current assessment methods may make inaccurate predictions about reinforcer efficacy when the task used in training regimens requires either more responses or more effort

> before the delivery of reinforcement . . . for some classes of reinforcers, simultaneous increases in schedule requirements may magnify small differences in preferences that are undetected when requirements are low. In such cases, a stimulus preference assessment involving low response requirements (FR1) schedules does not accurately predict the relative potency of reinforcers under increased response requirements. (pp. 440, 446)

Progressive-ratio schedules provide a framework for assessing the relative effectiveness of a stimulus as a reinforcer as response requirements increase. In a *progressive-ratio schedule of reinforcement*, the response requirements for reinforcement are increased systematically over time independent of the participant's behavior. In a progressive-ratio schedule, the practitioner gradually requires more responses per presentation of the preferred stimulus until a breaking point is reached and the response rate declines (Roane, Lerman, & Vorndran, 2001). For example, initially each response produces reinforcement (FR 1), and then reinforcement is delivered after every 2nd response (FR 2), then perhaps after every 5th, 10th, and 20th response (FR 5, FR 10, and FR 20). At some point, a preferred stimulus may no longer function as a reinforcer (Tustin, 1994).

DeLeon and colleagues (1997) used a progressive ratio within a concurrent schedule to test the relative effectiveness of two similarly preferred stimuli (e.g., cookie and cracker) and two dissimilar stimuli (e.g., drink and balloon) as reinforcers for micro switch panel pressing for Elaine and Rick, two adults with intellectual disabilities. One panel was blue and one was yellow. The experimenters placed two reinforcers on separate plates, and put one plate behind each of the panels. Each trial (24 per session for Rick; 14 per session for Elaine) consisted of the subject pushing either one of the panels and immediately receiving the item on the plate behind that panel. During the first phase, an FR 1 schedule was used (i.e., each response produced the item on the plate). Later, the response requirement for obtaining the items was gradually increased (FR 2, FR 5, FR 10, and FR 20).

Elaine and Rick made responses that produced the two dissimilar items at roughly the same rates during the FR 1 phase (see the top two tiers in Figure 11.15). As response requirements for receiving the dissimilar stimuli increased, Elaine and Rick continued to evenly allocate responding between the two panels. However, when initially equivalent and similar reinforcers (food in FR 1) were compared under increasing schedule requirements, the differences in responses rates on the two panels revealed clear

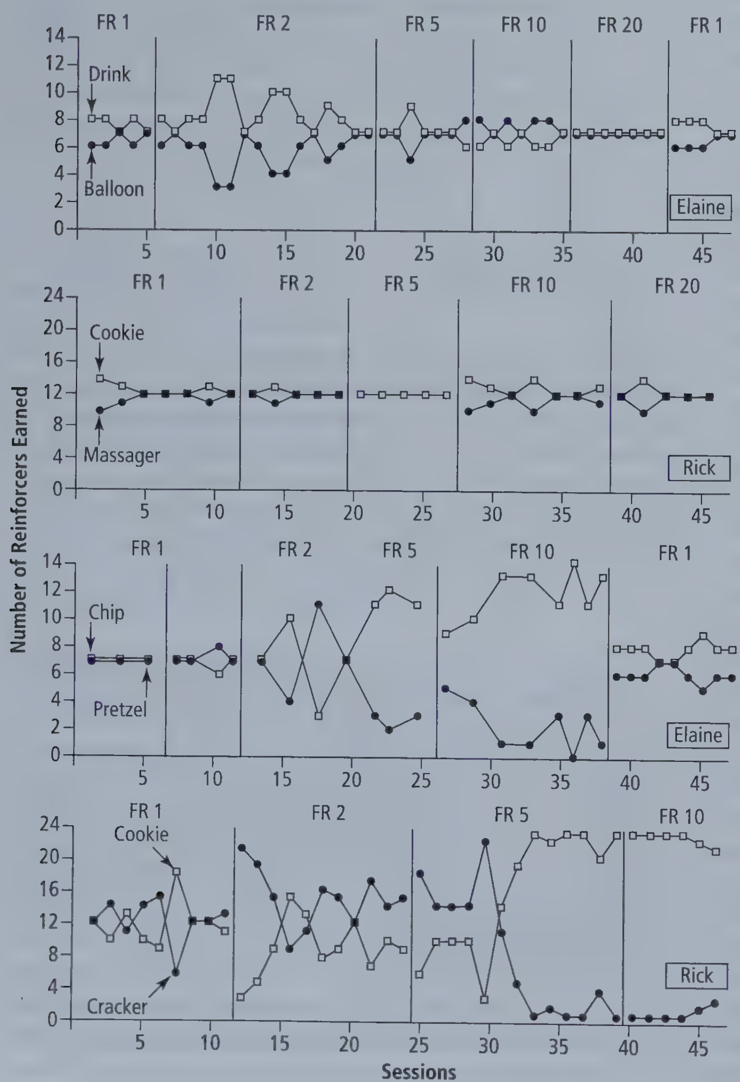

Figure 11.15 Responses per minute during concurrent-schedule and single-schedule baseline and reinforcement conditions for two adults with intellectual disabilities.

From "Emergence of Reinforcer Preference as a Function of Schedule Requirements and Stimulus Similarity," by I. G. DeLeon, B. A. Iwata, H. Goh, and A. S. Worsdell, 1997, *Journal of Applied Behavior Analysis, 30*, p. 444. Copyright 1997 by the Society for the Experimental Analysis of Behavior, Inc. Used by permission.

and consistent preferences (see the bottom two tiers in Figure 11.15). For example, when Elaine needed to work more to receive food, she allocated the majority of her responses to the panel that produced chips rather than the one that produced pretzels. In the same way, as the number of responses required to receive reinforcement increased, Rick showed a clear preference for cookies over crackers. These results suggest that "for some classes of reinforcers, simultaneous increases in schedule requirements may magnify small differences in preference that are undetected when requirements are low" (DeLeon et al., 1997, p. 446).

Increasing response requirements within a concurrent schedule may reflect the effects of increasing response requirements on the choice between reinforcers and also may reveal whether and under what conditions two reinforcers are substitutable for each other. If two reinforcers serve the same function (i.e., are made effective by the same establishing operation), an increase in the price (i.e., response requirement) for one of the reinforcers will lead to a decreased consumption of that item if a substitutable reinforcer is available (Green & Freed, 1993). DeLeon and colleagues (1997) used a hypothetical person with a slight preference for Coke over Pepsi as an analogy to explain the results shown in Figure 11.15.

> Assuming that Coke and Pepsi are both available for $1.00 per serving and that a person has only a slight preference for Coke, the individual may allocate choices rather evenly, perhaps as a function of periodic satiation for the preferred item, but with slightly more overall selections of Coke. Now assume that the cost of each is increased to $5.00 per serving. At this price, the preference for Coke is likely to be expressed. By contrast, a similar arrangement involving Coke and bus tokens may produce different results. Again, at $1.00 per item, roughly equal selection between the two options would not be surprising, assuming that the establishing operation for each dictates that both are momentarily equally valuable. However, these items serve distinctly different functions and are not substitutable; that is, the person is not free to trade one for the other and to continue to receive functionally similar reinforcement at the same rate. The person is more likely to continue choosing equally, even when the price for both reinforcers increases substantially.
>
> The same might be said for the results obtained in the present study. When choices involved two substitutable items, such as a cookie and a cracker, concurrent increases in the cost of each may have "forced" the expression of slight preference for one of the items. However, when reinforcers that were unlikely to be substitutes, such as a cookie and a massager, were concurrently available and equally preferred, increases in cost had little effect on preference. (pp. 446–447)

Although Stimulus X and Stimulus Y may each function as reinforcers when task demands are low, or when the reinforcement schedule is dense, when the task demands increase or when the schedule becomes leaner (i.e., more responses required per reinforcement), participants may choose only Stimulus Y. DeLeon and colleagues (1997) pointed out that practitioners who are alert to these relationships might be more skeptical in believing that original preferences will be sustained under changing environmental conditions, and judicious in how they plan reinforcement delivery relative to task assignment once intervention is under way. That is, it might be better to save some types of preferred stimuli for when task demands are high rather than substituting them for other equally preferred stimuli when task demands are low.

CONTROL PROCEDURES FOR POSITIVE REINFORCEMENT

Positive reinforcement control procedures are used to manipulate the contingent presentation of a potential reinforcer and observe any effects on the future frequency of behavior. *Control*, as the term is used here, requires an experimental demonstration that the presentation of a stimulus contingent on the occurrence of a target response functions as positive reinforcement. Control is demonstrated by comparing response rates in the absence and presence of a contingency, and then showing that with the absence and presence of the contingency the behavior can be turned on and off, or up and down (Baer, Wolf, & Risley, 1968). Historically, researchers and practitioners have used the reversal technique as the major control technique for positive reinforcement. Briefly, the reversal technique includes two conditions and a minimum of four phases (i.e., *ABAB*). In the *A* condition, the behavior is measured over time until it achieves stability in the absence of the reinforcement contingency. The absence of the contingency is the *control* condition. In the *B* condition, the reinforcement contingency is presented; the same target behavior continues to be measured to assess the effects of the stimulus change. The presence of the reinforcement contingency is the *experimental* condition. If the rate of responding increases in the presence of the contingency, the analyst then withdraws the reinforcement contingency and returns to the *A* and *B* conditions to learn whether the absence and presence of the contingency will turn the target behavior down and up.

However, using extinction as the control condition during the reversal phase presents practical and conceptual problems. First, withdrawing reinforcement may result in extinction-produced side effects (e.g., an initial increase in response rate, emotional responses, aggression—see Chapter 24) that affect the demonstration of control. Second, in some situations it may be impossible to withdraw the reinforcement contingency completely. For example, it is unlikely that a teacher could completely remove teacher attention during the *A* condition. In addition to these problems, Thompson and Iwata (2005) noted that, although

> extinction has often been successful in reversing the behavioral effects of positive reinforcement, its use as a control procedure presents interpretive difficulties. Essentially, extinction does not adequately isolate the reinforcement *contingency* as the variable controlling the target response, because mere stimulus presentation cannot be ruled out as an equally viable explanation. (p. 261, emphasis added)

According to Thompson and Iwata (2005), "the ideal control procedure for positive reinforcement eliminates the contingent relation between the occurrence of the target response and the presentation of the stimulus while controlling for the effects of the mere stimulus presentation" (p. 259). They reviewed the effectiveness of

three variations of the reversal technique as control procedures for determining reinforcement: noncontingent reinforcement (NCR), differential reinforcement of other behavior (DRO), and differential reinforcement of alternative behavior (DRA).[15]

Noncontingent Reinforcement

Noncontingent reinforcement (NCR) is the presentation of a potential reinforcer on a fixed-time (FT) or variable-time (VT) schedule independent of the occurrence of the target behavior. The response-independent presentation of the potential reinforcer eliminates the contingent relation between the target behavior and the stimulus presentation, while allowing any effects of the stimulus presentation alone to be detected. Thus, NCR meets Thompson and Iwata's (2005) criteria for an ideal control procedure for positive reinforcement.

The NCR reversal technique entails a minimum of five phases (*ABCBC*): *A* is a baseline condition; *B* is an NCR condition, where the potential reinforcer is presented on a fixed- or variable-interval schedule independent of the target behavior; and *C* is a condition in which the potential reinforcer is presented contingent on the occurrence of the target behavior. The *B* and *C* conditions are then repeated to learn whether the level of responding decreases and increases as a function of the absence and presence of the response-consequence contingency. The quality, amount, and rate of reinforcement should be approximately the same during the contingent and noncontingent *B* and *C* conditions of the analysis.

NCR often produces persistent responding, perhaps because of accidental reinforcement that sometimes occurs with a response-independent schedule, or because similar EOs and antecedent stimulus conditions evoke the persistent responding. Whatever the cause, persistent responding is a limitation of the NCR control procedure because it makes achieving a reversal effect (reduced responding) more time-consuming than the reversal technique with extinction. Achieving the effect may require lengthy contact with the NCR schedule.

Differential Reinforcement of Other Behavior

A practitioner using *differential reinforcement of other behavior (DRO)* delivers a potential reinforcer whenever the target behavior has not occurred during a set time interval or at a specific point in time. The DRO reversal technique includes a minimum of five phases (*ABCBC*): *A* is a baseline condition; *B* is a reinforcement condition, in which the potential reinforcer is presented contingent on the occurrence of the target behavior; and *C* is the DRO control condition in which the potential reinforcer is presented contingent on the absence of the target behavior. The analyst then repeats the *B* and *C* conditions to determine whether the level of responding decreases and increases as a function of the absence and presence of the response-consequence contingency.

The DRO schedule allows for the continued presentation of the reinforcement contingency during the reversal phases of the control procedure. In one condition, the contingency is active with occurrences of the target behavior. In another condition, the contingency is active for the omission of the target behavior. The DRO control procedure may produce the reversal effect in less time than the NCR schedule, perhaps because of the elimination of accidental reinforcement of the target behaviors.

Differential Reinforcement of Alternative Behavior

When *differential reinforcement of an alternative behavior (DRA)* is used as a control condition, the potential reinforcer is presented contingent on occurrences of a desirable alternative to the target behavior.[16] The DRA reversal technique includes a minimum of five phases (*ABCBC*): *A* is a baseline condition; *B* is a reinforcement condition, in which the potential reinforcer is presented contingent on the occurrence of the target behavior; and *C* is a condition in which the potential reinforcer is presented contingent on the occurrence of an alternative behavior (i.e., DRA). The analyst will then repeat phases *B* and *C* to ascertain whether the level of responding decreases and increases as a function of the absence and presence of the response–consequence contingency.

Thompson and Iwata (2005) summarized the limitations of using DRO and DRA as control conditions procedures to test for positive reinforcement:

> [DRO and DRA] introduce a new contingency that was not present in the original experimental arrangement. As a result, reductions in the target response under a contingency reversal might be attributed to either (a) termination of the contingency between the target response and the reinforcer or (b) introduction of reinforcement for the absence of the target response or for the occurrence of a competing response. In addition, given that reinforcement is provided contingent on some characteristic of responding during the contingency reversal, it may be difficult to control for the rate of stimulus presentation across experimental and control conditions. If responding is not quickly reduced (DRO) or reallocated toward responses that produce reinforcement (DRA), the rate of reinforcement in the control condition may be low relative to the rate of reinforcement in the experimental conditions. When this occurs, the contingency-reversal strategy is functionally similar to the conventional extinction procedure. (p. 267)

Given the considerations for the reversal technique with extinction, and its three variations, Thompson and Iwata (2005) concluded that NCR offers the most thorough and unconfounded demonstration of the effects of positive reinforcement.

USING REINFORCEMENT EFFECTIVELY

We offer practitioners nine guidelines for applying positive reinforcement effectively. These guidelines come from three main sources: the research literatures of the experimental analysis of behavior, applied behavior analysis, and our personal experiences.

Set an Easily Achieved Initial Criterion for Reinforcement

A common mistake in applications of reinforcement is setting the initial criterion for reinforcement too high, which prohibits the learner's behavior from contacting the contingency. To

use reinforcement effectively, practitioners should establish an initial criterion so that the participant's first responses produce reinforcement, and then increase the criterion for reinforcement gradually as performance improves. Heward (1980) suggested the following method for establishing initial criteria for reinforcement based on the learner's level of responding during baseline (see Figure 11.16).

> For a behavior you wish to increase, set the initial criterion higher than the child's average baseline performance and lower than or equal to his best performance during baseline. For a behavior you want to decrease in frequency, the initial criterion for reinforcement should be set below the child's average performance during baseline and greater than or equal to his lowest baseline performance. (p. 7)

Use High-Quality Reinforcers of Sufficient Magnitude

Reinforcers that maintain responding on simple tasks may not have the potency to produce similar levels of responding on more difficult or longer tasks. Practitioners will likely need to use a reinforcer of higher quality for behaviors that require more effort or endurance. A highly preferred stimulus chosen during preference assessments sometimes functions as a high-quality reinforcer. Neef, Mace, Shea, and Shade (1992), for example, found that behaviors that received a lower reinforcer rate but a higher quality reinforcer increased in occurrence, whereas behaviors that received a higher reinforcer rate with a lower quality reinforcer decreased in occurrence. Reinforcer quality is relative also to other consequences for responding currently available to the learner.

Applied behavior analysts define the magnitude (or amount) of a reinforcer as (a) the duration of time for access to the reinforcer, (b) the number of reinforcers per unit of time (i.e., *reinforcer rate*), or (c) the intensity of the reinforcer. Increases in reinforcer magnitude may correlate with an increased effectiveness of the behavior-reinforcer relation. However, the effects of reinforcer magnitude are not well understood because "few applied studies have examined the effects of magnitude on responding in a single-operant arrangement" (Lerman, Kelly, Vorndran, Kuhn, & LaRue, 2002, p. 30). Consideration of how much reinforcement to use should follow the maxim "Reinforce abundantly, but don't give away the store." We suggest that the amount of reinforcement be proportional to the quality of the reinforcer and the effort required to emit the target response.

Use Varied Reinforcers to Maintain Potent Establishing Operations

Reinforcers often decrease in effectiveness with frequent use. Presenting an overabundance of a specific reinforcer is likely to diminish the momentary effectiveness of the reinforcer due to satiation. Practitioners can minimize satiation effects by using a variety of reinforcers. If reading a specific book on sports functions as a reinforcer and the teacher relies solely on this reinforcer,

Figure 11.16 Using data from learners' baseline performance to set initial criteria for reinforcement.

The criterion-setting formulas are

For increasing behavior:

baseline average < initial criterion ≤ highest performance during baseline

For decreasing behavior:

baseline average > initial criterion ≥ lowest performance during baseline

Examples

Target Behavior	Performance Goal	Lowest	Highest	Baseline Average	Range for Initial Criterion
Playing alone	Increase	2 min.	14 min.	6 min.	7–14 min.
Identifying letters of the alphabet	Increase	4 letters	9 letters	5 letters	6–9 letters
Number of leg exercises completed	Increase	0	22	8	9–22
Percentage of math problems correctly solved	Increase	25%	60%	34%	40–60%
Number of typing errors in one letter	Decrease	16	28	22	16–21
Number of calories consumed per day	Decrease	2,260	3,980	2,950	2,260–2,900

From: "A Formula for Individualizing Initial Criteria for Reinforcement," by W. L. Heward, 1980, *Exceptional Teacher, 1*(9), p. 8. Used by permission.

ultimately reading that book may no longer produce reinforcement. Conversely, known reinforcers that are not always available may have increased effectiveness when they are reintroduced. If a teacher has demonstrated that "being first in line" is a reinforcer, but uses this reinforcer only once per week, the reinforcement effect will be greater than if "being first in line" is used frequently.

Varying reinforcers may enable less preferred stimuli to function as reinforcers. For example, Bowman, Piazza, Fisher, Hagopian, and Kogan (1997) found that some learners responded better to a variety of less preferred stimuli as compared to a continuous access to a single, more highly preferred stimulus. Also, using a variety of reinforcers may keep the potency of any one particular reinforcer higher. For example, Egel (1981) found that students' correct responding and on-task behavior were higher when the students had access to one of three randomly selected reinforcers across trials versus a constant reinforcement condition in which one of the stimuli was presented following each successful trial. Even within a session, teachers could let students select a variety of consequences from a menu. Similarly, varying a property of a reinforcer may keep its reinforcing potency for a longer time. If comic books are used as reinforcers, having several different genres of comic books available is likely to maintain their potency.

Use Direct Rather Than Indirect Reinforcement Contingencies When Possible

With a direct reinforcement contingency, emitting the target response produces direct access to the reinforcer; the contingency does not require any intervening steps. With an indirect reinforcement contingency, the response does not produce reinforcement directly. The practitioner presents the reinforcer. Research suggests that direct reinforcement contingencies may enhance performance (Koegel & Williams, 1980; Williams, Koegel, & Egel, 1981). Thompson and Iwata (2000), for example, linked the definitions of direct and indirect contingencies to the difference between automatic reinforcement (i.e., direct) and **socially mediated contingencies** (i.e., indirect) and summarized their research on response acquisition under direct and indirect contingencies of reinforcement this way:

> Under both contingencies, completion of identical tasks (opening one of several types of containers) produced access to identical reinforcers. Under the direct contingency, the reinforcer was placed inside the container to be opened; under the indirect contingency, the therapist held the reinforcer and delivered it to the participant upon task completion. One participant immediately performed the task at 100% accuracy under both contingencies. Three participants showed either more immediate or larger improvements in performance under the direct contingency. The remaining two participants showed improved performance only under the direct reinforcement contingency. Data taken on the occurrence of "irrelevant" behaviors under the indirect contingency (e.g., reaching for the reinforcer instead of performing the task) provided some evidence that these behaviors may have interfered with task performance and that their occurrence was a function of differential stimulus control. (p. 1)

Whenever possible, practitioners should use direct reinforcement contingency, especially with learners having limited behavioral repertoires.

Combine Response Prompts and Reinforcement

Response prompts are supplementary antecedent stimuli used to occasion a correct response in the presence of an S^D that will eventually control the behavior. Applied behavior analysts give response prompts before or during the performance of a target behavior. The three major forms of response prompts are instructions, modeling, and physical guidance.

Instructions describing the contingency may function as a motivating operation for learners with verbal skills, making it more likely they will contact the reinforcer more quickly. For example, Mayfield and Chase (2002) told college students who were learning five basic algebra rules that they would earn money for correct answers and not be penalized for incorrect answers.

Bourret, Vollmer, and Rapp (2004) used verbal response prompts during an assessment of the vocal verbal mand repertoires of three participants with autism.

> Each vocalization assessment session consisted of 10 trials, each 1 min in duration. A nonspecific prompt [describing the contingency] was delivered (e.g., "If you want this, ask me for it") 10 s after the onset of the trial. A prompt including a model of the complete targeted utterance (e.g., "If you want this, say 'chip' ") was delivered 20 s into the trial. The participant was prompted to say just the first phoneme of the targeted response (e.g., "If you want this, say 'ch' ") 30 s after the initiation of the trial. (pp. 131–132)

Chapter 17 provides further discussion of response prompts, including specific procedures for combining response prompts with reinforcement, and additional examples of using verbal instruction, modeling, and physical guidance response prompts.

Initially Reinforce Each Occurrence of the Behavior Initially

Provide reinforcement for each occurrence of the target behavior (i.e., continuous reinforcement) to strengthen behavior, primarily during the initial stages of learning a new behavior. After the behavior is established, gradually thin the rate of reinforcement so that some, but not all, occurrences of the behavior are reinforced (i.e., intermittent reinforcement). For example, a teacher might initially reinforce each correct response to sight words printed on flash cards and then use a ratio schedule to thin reinforcement. To firm the responses after the initial learning, provide reinforcement following two correct responses for a few trials, then following each set of four correct responses, and so on. Hanley and colleagues (2001) gradually shifted from a very dense fixed interval (FI) 1-sec schedule of reinforcement (on an FI schedule, the first target response following the end of the interval produces reinforcement) to thinner schedules with the following increments of intervals: 2 sec, 4 sec, 8 sec, 16 sec, 25 sec, 35 sec, 46 sec, and finally to an FI 58-sec schedule. Chapter 13 provides more information on using continuous and intermittent reinforcement.

Provide Contingent Attention and Descriptive Praise

As discussed earlier in this chapter, social attention and praise are powerful reinforcers for most people. However, behavioral improvements following praise often involve something more, or altogether different from, the direct effects of reinforcement. Michael (2004) discussed the common conceptual mistake of assuming that increased responding following praise and attention is a function of reinforcement.

> Consider the common use of *descriptive praise*, providing some general sign of social approval (a smile plus some comment such as "Good work!") *and, in addition*, a brief description of the behavior that is responsible for the approval ("I like the way you're . . . !"). When such praise is provided to a normally verbal person over 5 or 6 years of age, it probably functions as a form of instruction or as a rule, much as if the praiser had said, "If you want my continued approval you have to . . . " For example, a factory supervisor walks up to an employee who is cleaning up an oil spill on the factory floor, smiles broadly, and says, "George, I really like the way you're cleaning up that spill before anyone steps in it. That's very considerate of you." Now suppose that George cleans up spills from that time forward—a rather large change in behavior considering that it was followed by only a single instance of reinforcement. We might suspect that the praise functioned not simply as reinforcement but rather as a form of rule or instruction, and that George, for various reasons, provided himself with similar instruction every time another spill occurred. (pp. 164–165, emphasis in original)

A study by Goetz and Baer (1973) investigating the effects of teacher praise on preschool children's creative play with building blocks used descriptive praise in one condition of the study. "The teacher remarked with interest, enthusiasm, and delight every time that the child placed and/or rearranged the blocks so as to create a form that had not appeared previously in that session's construction(s). . . . 'Oh, that's very nice—that's different'!)" (p. 212). The three 4-year-old girls increased the construction of block form diversity during each phase of contingent descriptive praise. Goetz and Baer did not conduct a component analysis to determine how much of the girls' improved performance could be attributed to reinforcement in the form of positive attention ("That's very nice!") or to the feedback they received ("That's different!"), which enabled them to create a rule to follow ("Building *different things* with the blocks gets the teacher's attention."). The authors surmised that

> for some children, either [reinforcing attention or descriptive praise] will be sufficient without the other, but that for other children, the mix of the two will be more effective than either alone. If so, then for applied purposes a package of positive attention and descriptive praise is probably the best technique to apply to children in general. (p. 216, words in brackets added)

We recommend that, in the absence of data showing that attention and praise have produced counter-therapeutic effects for a given learner, practitioners incorporate contingent praise and attention into any intervention entailing positive reinforcement.

Gradually Increase the Response-to-Reinforcement Delay

We recommended in a previous guideline that practitioners reinforce each occurrence of the target behavior during the initial stages of learning, and then thin the delivery of reinforcers by switching to an intermittent schedule of reinforcement. Because the consequences that maintain responding in natural environments are often delayed, Stromer, McComas, and Rehfeldt (2000) reminded us that using continuous and intermittent schedules of reinforcement might be just the first steps of programming consequences for everyday situations. "Establishing the initial instances of a behavioral repertoire typically requires the use of programmed consequences that occur immediately after the target response occurs. However, the job of the applied behavior analyst also involves the strategic use of delayed reinforcement. Behaviors that yield delayed reinforcement are highly adaptive in everyday life, but they may be difficult to establish and maintain" (p. 359).[17]

Examples of tactics that applied behavior analysts have used to help people learn to respond effectively for delayed consequences include (a) a delay-to-reinforcement time interval that begins with a short delay that is gradually increased (Dixon, Rehfeldt, & Randich, 2003; Schweitzer & Sulzer-Azaroff, 1988); (b) a gradual increase in work requirements during the delay (Dixon & Holcomb, 2000); (c) an activity during the delay to "bridge the gap" between the behavior and reinforcer (Mischel, Ebbesen, & Zeiss, 1972); and, importantly, (d) verbal instruction in the form of an assurance that the reinforcer will be available following a delay (e.g., "The calculator will show the amount of money to be placed in a savings account for you. You will be given all the nickels in your savings account on [day]") (Neef, Mace, & Shade, 1993, p. 39). We present more on using delayed consequences to promote generalization and maintenance of behavior changes in Chapter 30.

Gradually Shift from Contrived to Naturally Occurring Reinforcers

We end this chapter with an extract from Murray Sidman's (2000) insightful and thought-provoking account of what he learned in the "early days" of applying behavioral principles to human behavior. In describing a project from 1965 to 1975 that emphasized the use of positive reinforcement with boys between the ages of 6 and 20 years who were diagnosed with intellectual disabilities and living in a state institution, Sidman recollected how introducing tokens as generalized conditioned reinforcers eventually led to praise from the project staff, and later to learning itself, becoming powerful reinforcers for the boys.

> We began with tokens, which had the advantage of being visible and easily handled. Later, after the boys had learned to save tokens and to understand numbers, we were able to introduce points. For some, points led eventually to money. As the boys saw how pleased we were when they earned the tokens and points that brought them other reinforcers,

our pleasure also became important to them, and we became able to use praise as a reinforcer. As they learned more and more, many of the boys found that what they learned permitted them to deal more effectively with their gradually enlarging world. For them, learning itself became reinforcing. (p. 19)

Success in manipulating the environment may be the ultimate naturally occurring reinforcer. As Skinner (1989) pointed out, this powerful reinforcer "does not need to be contrived for instructional purposes; it is unrelated to any particular kind of behavior and hence always available. We call it *success*." (p. 91)

SUMMARY

Positive Reinforcement Defined

1. Positive reinforcement occurs when a response is followed immediately by the presentation of a stimulus change that increases the future occurrence of similar responses.
2. The stimulus that is presented as a consequence, and that is responsible for the subsequent increase in responding, is called a positive reinforcer, or, more simply, a reinforcer.
3. The importance of the immediacy of reinforcement must be emphasized; a response-to-reinforcement delay of as little as 1 second will be less effective than a reinforcer delivered immediately.
4. The effects of long-delayed consequences on human behavior should not be attributed to reinforcement, as these effects drop off quickly as the delay is increased.
5. A misconception held by some is that reinforcement is a circular concept. Circular reasoning is a form of faulty logic in which cause and effect are confused and not independent of each other. Reinforcement is not a circular concept because the two components of the response–consequence relation can be separated and the consequence manipulated to determine whether it increases the frequency of the behavior it follows.
6. Reinforcement does more than increase the future occurrence of similar behavior; it also changes the function of stimuli that immediately precede the reinforced behavior. By virtue of being temporally paired with the response–reinforcer contingency, antecedent events acquire the ability to evoke (make more likely) instances of the reinforced response class. An antecedent stimulus that evokes behavior because it has been correlated with the availability of reinforcement is called a discriminative stimulus (S^D).
7. A discriminated operant is defined by a three-term contingency of $S^D \rightarrow R \rightarrow S^{R+}$.
8. The momentary effectiveness of any stimulus change as reinforcement depends on an existing level of motivation with respect to that stimulus change. An establishing operation (EO) (e.g., deprivation) increases the current effectiveness of a reinforcer; an abolishing operation (AO) (e.g., satiation) decreases the current effectiveness of a reinforcer.
9. A complete description of reinforcement of a discriminated operant entails a four-term contingency: $EO \rightarrow S^D \rightarrow R \rightarrow S^{R+}$.
10. Automaticity of reinforcement refers to the fact that a person does not have to understand or verbalize the relation between his or her actions and a reinforcing consequence, or for that matter even be aware that a consequence has occurred, for reinforcement to happen.
11. Reinforcement strengthens any behavior that immediately precedes it; no logical or adaptive connection between behavior and the reinforcing consequence is necessary.
12. The importance of understanding the arbitrariness of reinforcement goes far beyond providing a possible explanation for the development of harmless superstitious and idiosyncratic behaviors. The arbitrary nature of selection by reinforcement may explain the acquisition and maintenance of many maladaptive and challenging behaviors.
13. Automatic reinforcement refers to the behavior–stimulus change relation that occurs without the presentation of consequences by other people, or is assumed when a behavior persists in the absence of any known reinforcer.

Classifying Reinforcers

14. An unconditioned reinforcer is a stimulus change that functions as reinforcement even though the learner has had no particular learning history with it. (The terms *primary reinforcer* and *unlearned reinforcer* are synonyms for unconditioned reinforcer.)
15. A conditioned reinforcer (sometimes called a *secondary reinforcer* or *learned reinforcer*) is a previously neutral stimulus change that has acquired the capability to function as a reinforcer through stimulus–stimulus pairing with one or more unconditioned reinforcers or conditioned reinforcers.
16. A generalized conditioned reinforcer is a conditioned reinforcer that, as a result of having been paired with many unconditioned and conditioned reinforcers, does not depend on a current EO for any particular form of reinforcement for its effectiveness.
17. When reinforcers are described by their physical properties, they are typically classified as edible, sensory, tangible, activity, or social reinforcers.
18. The Premack principle states that making the opportunity to engage in a behavior that occurs at a relatively high free operant (or baseline) rate contingent on the occurrence of low-frequency behavior will function as reinforcement for the low-occurrence behavior.
19. The response-deprivation hypothesis is a model for predicting whether access to one behavior (the contingent behavior) will function as reinforcement for another

behavior (the instrumental response) based on the relative baseline rates at which each behavior occurs and whether access to the contingent behavior represents a restriction compared to the baseline level of engagement.

Identifying Potential Reinforcers

20. Stimulus preference assessment refers to a variety of procedures used to determine (a) the stimuli that the person differentially selects; (b) the relative hierarchical preference value of those stimuli (high preference to low preference); (c) the conditions under which those preference values change when task demands, deprivation states, or schedules of reinforcement are modified; and (d) whether highly preferred items ultimately serve as effective reinforcers.

21. Stimulus preference assessment can be conducted using at least five forms: the single-stimulus (SS), paired-stimulus (PS), free operant (FO), multiple-stimulus with item replacement (MSWI), multiple-stimulus without item replacement (MSWO). These five forms can be clustered into three categories: ask the target person and/or significant others, conduct free operant observations, and conduct trial-based assessments.

22. Preferred stimuli do not always function as reinforcers, and stimulus preferences often change over time.

23. Reinforcer assessment refers to a variety of direct, data-based methods for determining the relative effects of a given stimulus as reinforcement under different and changing conditions or the comparative effectiveness of multiple stimuli as reinforcers for a given behavior under specific conditions. Reinforcer assessment is often conducted with in-the-moment procedures, concurrent schedules of reinforcement, multiple schedules of reinforcement, and progressive reinforcement schedules.

Control Procedures for Positive Reinforcement

24. Positive reinforcement control procedures are used to manipulate the contingent presentation of a potential reinforcer and observe any effects on the future frequency of behavior. *Control*, as the term is used here, requires an experimental demonstration that the presentation of a stimulus contingent on the occurrence of a target response functions as positive reinforcement. Control is demonstrated by comparing response rates in the absence and presence of a contingency, and then showing that with the absence and presence of the contingency the behavior can be turned on and off, or up and down.

25. In addition to a reversal design using the withdrawal of the reinforcement contingency (i.e., extinction) as the control condition, noncontingent reinforcement (NCR), differential reinforcement of other behavior (DRO), and differential reinforcement of alternative behavior (DRA) can be used as control conditions for reinforcement.

Using Reinforcement Effectively

26. Guidelines for increasing the effectiveness of positive reinforcement interventions include:

- Set an easily achieved initial criterion for reinforcement.
- Use high-quality reinforcers of sufficient magnitude.
- Use varied reinforcers to maintain potent establishing operations.
- Use direct rather than indirect reinforcement contingencies when possible.
- Combine response prompts and reinforcement.
- Initially reinforce each occurrence of the behavior.
- Provide contingent attention and descriptive praise.
- Gradually increase the response-to-reinforcement delay.
- Gradually shift from contrived to naturally occurring reinforcers.

KEY TERMS

automatic reinforcement
conditioned reinforcer
generalized conditioned reinforcer
positive reinforcement
positive reinforcer
Premack principle
reinforcer assessment
response-deprivation hypothesis
rule-governed behavior
socially mediated contingencies
stimulus preference assessment
unconditioned reinforcer

MULTIPLE-CHOICE QUESTIONS

1. A teacher wants to deliver a sticker to Johnny every time he says "Please." This would be considered positive reinforcement if:

a. The behavior of saying "Please" increases over time.
b. The behavior of saying "Please" decreases over time.
c. The behavior of saying "Please" does not change over time.
d. The behavior of sticker giving decreases over time.

Hint: (See "Positive Reinforcement Defined")

2. The qualifications to be considered when utilizing positive reinforcement are:

a. Delay between response and consequence
b. Stimulus conditions when response was emitted
c. Strength of motivation
d. All of these

Hint: (See "Using Reinforcement Effectively")

3. An example of unconditioned reinforcer(s) is:
   a. Food
   b. Water
   c. Oxygen
   d. Warmth
   e. Sexual stimulation
   f. All of these

   Hint: (See "Classifying Reinforcers")
4. A neutral stimulus can be made into a reinforcer by:
   a. Pairing it with an unconditioned stimulus
   b. Pairing it with an unconditioned response
   c. Presenting it individually after a response multiple times
   d. A neutral stimulus cannot be utilized as a reinforcer

   Hint: (See "Classifying Reinforcers")
5. Heather hears a phone ring, then picks up the phone. Her husband talks with her over the phone. What is the behavior in this three-term contingency?
   a. Husband talking
   b. Heather picks up the phone
   c. Phone ringing
   d. None of these

   Hint: (See "Positive Reinforcement Defined")
6. An example of a motivating operation is:
   a. Hunger
   b. Hay fever
   c. Argument with significant other
   d. All of these
   e. None of these

   Hint: (See "Positive Reinforcement Defined")
7. Which of the following is not an appropriate way to identify potential reinforcers?
   a. Pick a stimulus that is reinforcing for someone else
   b. Ask the person or significant other what is reinforcing
   c. Observe the person
   d. Measure the person's responses to trial-based tests

   Hint: (See "Identifying Potential Reinforcers")
8. Stimulus preference assessment refers to a variety of procedures to determine:
   a. The stimulus a person prefers
   b. The relative preference values of those stimuli
   c. The conditions under which those preference values hold
   d. All of these

   Hint: (See "Identifying Potential Reinforcers")
9. What information does a concurrent schedule reinforcer assessment provide?
   a. A rank order of preference for a variety of stimuli
   b. How often children will select one stimulus versus another to indicate preference
   c. Whether or not a stimulus functions as a reinforcer and how effective that stimulus is as a reinforcer compared to other stimuli
   d. All of these
   e. None of these

   Hint: (See "Reinforcer Assessment")
10. When two or more contingencies of reinforcement operate independently and simultaneously for two or more behaviors, what schedule of reinforcement is in effect?
    a. Multiple
    b. Mixed
    c. Progressive-Ratio
    d. Concurrent
    e. All of these
    f. None of these

    Hint: (See "Reinforcer Assessment")
11. Which schedule reinforcer assessment consists of two or more component schedules of reinforcement for a single response with only one component schedule in effect at any given time?
    a. Progressive-Ratio
    b. Multiple
    c. Mixed
    d. Concurrent
    e. All of these
    f. None of these

    Hint: (See "Reinforcer Assessment")
12. The model for predicting whether (a) access to one behavior will function as reinforcement for another behavior based on the relative baseline rates at which each behavior occurs and (b) whether contingent access to one of the behaviors represents a restriction compared to the baseline level of engagement is known as the:
    a. Response-satiation hypothesis
    b. Response-contingency hypothesis
    c. The Premack Principle
    d. Response-deprivation hypothesis
    e. None of these

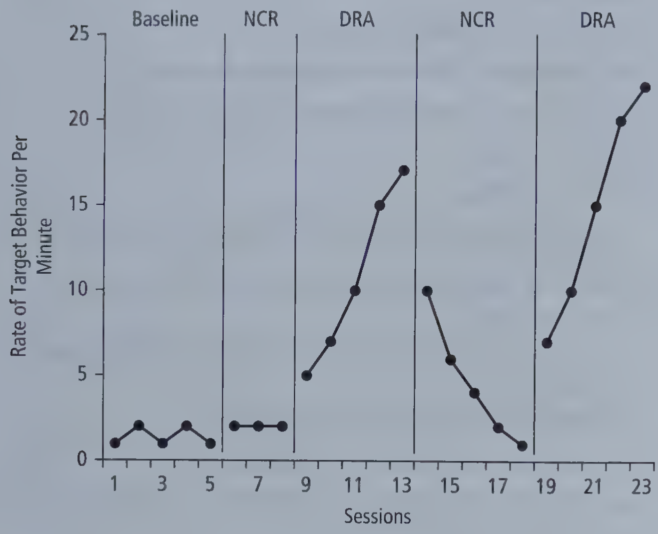
    Hint: (See "Classification of Reinforcers by Formal Properties")

13. The response-deprivation hypothesis was built on whose concept?
   a. Premack
   b. Skinner
   c. Watson
   d. Pavlov
   e. None of these
   Hint: (See "Classification of Reinforcers by Formal Properties")
14. Experimental control when evaluating positive reinforcement is demonstrated by comparing:
   a. Response rates in the presence of a contingency
   b. Response rates in the absence of a contingency
   c. Fixed time reinforcement to differential reinforcement
   d. Differential reinforcement of other behavior to another reinforcement schedule, such as differential reinforcement of alternate behavior
   e. All of these
   f. None of these
   Hint: (See "Control Procedures for Positive Reinforcement")
15. The presentation of a potential reinforcer on a fixed or variable schedule independent of the occurrence of the target behavior is also referred to as:
   a. Contingent reinforcement
   b. Noncontingent reinforcement
   c. Contingent punishment
   d. Noncontingent punishment
   e. None of these
   f. All of these
   Hint: (See "Control Procedures for Positive Reinforcement")
16. Which of the following could be used as a control condition when evaluating the effects of a reinforcement-based procedure?
   a. Noncontingent reinforcement
   b. Differential reinforcement of other behavior
   c. Differential reinforcement of alternative behavior
   d. All of these
   e. None of these
   Hint: (See "Control Procedures for Positive Reinforcement")
17. Which of the following are guidelines for effective reinforcement?
   a. Choosing reinforcers that are not relevant to the target behavior
   b. Using reinforcers of low magnitude
   c. Delaying the delivery of a reinforcer
   d. Using the same reinforcers over and over again
   e. None of these
   Hint: (See "Using Reinforcement Effectively")
18. Practitioners increase the effectiveness of positive reinforcement when they attend to the ________ of stimulus presentation.
   a. Arrangement
   b. Management
   c. Administration
   d. All of these
   e. None of these
   Hint: (See "Using Reinforcement Effectively")

ESSAY-TYPE QUESTIONS

1. Briefly explain the terms positive reinforcement and positive reinforcer.
   Hint: (See "Positive Reinforcement Defined")
2. Briefly explain the terms conditioned and unconditioned reinforcers and give an example of each.
   Hint: (See "Classifying Reinforcers")
3. Bob has just completed his morning workout routine. On the way to taking a shower, Bob walks past the refrigerator. Bob takes an apple from the refrigerator. Bob eats the apple on the way to taking his morning shower. Briefly describe the above example using the operant conditioning paradigm. (Be sure to include motivation in your answer.)
   Hint: (See "Positive Reinforcement Defined")
4. Briefly describe both the pros and cons of the three basic methods for stimulus preference assessments. (The three methods are asking the person or significant others, observing the individual, and measuring the person's responses to trial-based tests.)
   Hint: (See "Identifying Potential Reinforcers")
5. After identifying possible reinforcers how could it be determined if the stimulus is a reinforcer? Briefly describe what assessment procedure you would use and why.
   Hint: (See "Identifying Potential Reinforcers")
6. Describe and give an example of the response-deprivation procedure. Explain your answer.
   Hint: (See "Classifying Reinforcers")
7. Briefly explain whether or not "control" has been demonstrated in the graph. Support your explanation with evidence from the graph. (Control requires an experimental demonstration that the presentation of a stimulus

contingent on the occurrence of a target response functions as a positive reinforcement.)



Hint: (See "Control Procedures for Positive Reinforcement")

8. Shawn is overweight and does not currently do any form of daily exercise. His doctor has recommended that he walk 3 miles daily. Briefly explain how positive reinforcement could be utilized to help Shawn increase the behavior of walking. (Include a proposed reinforcer, timing of proposed reinforcer delivery, contingency, motivation, and a statement about the proposed way of evaluating the effectiveness of the proposed reinforcer).

   Hint: (See "Using Reinforcement Effectively")

NOTES

1. Phrases such as *strengthening the behavior* and *increasing the likelihood of future responding* are sometimes used to describe the basic effect of reinforcement. Although such terms appear occasionally in this book, recognizing Michael's (1995) concern that use of such terms "encourages a language of intervening variables, or an implied reference to something other than an observable aspect of behavior" (p. 274), we most often use *increased future occurrence (or rate)* to refer to the primary effect of reinforcement.
2. When the consequence that produced the increase in responding is best described as the *termination* or *withdrawal* of an already present stimulus, *negative reinforcement* has occurred. The fundamental nature and qualifying conditions for positive reinforcement and negative reinforcement are the same: Behavior increases in the future. Negative reinforcement is examined in detail in Chapter 12.
3. Excellent discussions of rule-governed behavior can be found in Baum (2017); Chase and Danforth (1991); Hayes (1989); Hayes, Zettle, and Rosenfarb (1989); Malott and Shane (2014); Reitman and Gross (1996); Schlinger and Blakely (1987); and Vaughan (1989).
4. Motivating operations are described in detail in Chapter 16.
5. It is a mistake to assume that all superstitious behavior is the direct result of adventitious reinforcement. Many superstitious behaviors are probably the result of following cultural practices. For example, high school baseball players may wear their caps inside out and backwards when a late-inning rally is needed because they have seen major leaguers don such "rally caps" in the same situation.
6. Mands, tacts, and intraverbals—three elementary verbal operants first described by Skinner (1957)—are explained in Chapter 18.
7. Remember, the environment does the pairing, not the learner. The learner does not have to "associate" the two stimuli.
8. The first volume of the *Journal of Applied Behavior Analysis* (1968) is a treasure trove of classic studies in which simple and elegant experimental designs revealed the powerful effects of operant conditioning and contingency management. We strongly encourage any serious student of applied behavior analysis to read it from cover to cover, and to return to it now and then for inspiration.
9. See https://www.kennedykrieger.org/sites/default/files/patient-care-files/paired_stimulus_preference_assessment.pdf for detailed procedural steps and associated sample forms to complete a variety of SPAs.
10. For additional details on conducting single-stimulus assessments, including a sample data sheet, refer to https://www.kennedykrieger.org/sites/default/files/patient-care-files/single_stimulus_preference_assessment.pdf and Hagopian et al. (2001).
11. For additional details on conducting paired-stimulus preference assessments, including a sample data sheet, refer to https://www.kennedykrieger.org/sites/default/files/patient-care-files/paired_stimulus_preference_assessment.pdf and Fisher et al. (1992).
12. For additional details on conducting multiple stimulus without replacement (MSWO) preference assessments, including a sample data sheet, refer to https://www.kennedykrieger.org/sites/default/files/patient-care-files/mswo_preference_assessment.pdf and DeLeon and Iwata (1996).
13. For additional information on comparative effects of SPA, see Verriden and Roscoe (2016) and Karsten et al. (2011).
14. These schedules of reinforcement and their effects on behavior are described in Chapter 13.
15. Chapter 8 presents the ABAB, NCR, DRO, and DRA control techniques in the context of single-case experimental designs, and Chapter 25 discusses NCR, DRO, and DRA in detail.
16. Chapter 25 describes DRO and DRA as behavior change tactics for decreasing the frequency of undesirable behavior.
17. Moving from continuous reinforcement to an intermittent schedule of reinforcement is sometimes described as a means of increasing reinforcer delay (e.g., Alberto & Troutman, 2013; Kazdin, 2013). However, an intermittent schedule of reinforcement does not entail "delayed reinforcement" unless specified. Although only some occurrences of the target behavior are reinforced on an intermittent schedule of reinforcement (see Chapter 13), reinforcement is delivered immediately following the response that meets the contingency. For example, on a fixed ratio 10 schedule of reinforcement, every 10th response produces immediate reinforcement. *Delay to reinforcement* or *reinforcement delay* describes the time lapse between the response and delivery of the reinforcer after the contingency has been met (e.g., the reinforcer was delivered 45 seconds after every 10th response).

CHAPTER 12

Negative Reinforcement

Richard G. Smith and Brian A. Iwata

LEARNING OBJECTIVES

- Define and provide examples of negative reinforcement.
- Identify and use negative reinforcers.
- Differentiate between escape and avoidance contingencies.
- Identify the characteristics of negative reinforcement.
- Use appropriate parameters and schedules of negative reinforcement.
- State and plan for the possible unwanted effects of and ethical issues in the use of negative reinforcement.

Have you ever been "that person" whose cell phone rings in an otherwise quiet classroom? If so, you probably felt the burning stares of the professor and the other students in the class as you quickly scrambled to turn off your ringer and sank deeply into your chair. You probably also make sure to turn your ringer off before you attend classes now. These are both instances of negative reinforcement contingencies, in which behavior increases when it results in escape from or avoidance of aversive events. Turning off the ringer in class produced escape from the judgmental stares of your classmates, and turning off the ringer before class now allows you to avoid any such future embarrassment.

As noted in Chapter 11, positive reinforcement involves an increase in responding as a function of contingent *presentation* of a stimulus. In a complementary way, responding can lead to the *termination or avoidance* of a stimulus, and when responding increases as a result of this arrangement, learning has occurred through *negative reinforcement*. This chapter expands the discussion of operant contingencies to include negative reinforcement. We define negative reinforcement, distinguish between escape and avoidance contingencies, describe events that may serve as the basis for negative reinforcement, illustrate ways negative reinforcement may be used to strengthen behavior, and discuss ethical issues that arise when using negative reinforcement. Readers interested in more in-depth discussions of basic and applied research on negative reinforcement are referred to reviews by Hineline and Rosales-Ruiz (2013) and Iwata (1987).

DEFINITION OF NEGATIVE REINFORCEMENT

A **negative reinforcement** contingency is one in which the occurrence of a response produces the termination, reduction, postponement, or avoidance of a stimulus, which leads to an increase in the future occurrence of that response. A full description of negative reinforcement requires specification of its four-term contingency (see Figure 12.1): (a) The establishing operation (EO) for behavior maintained by negative reinforcement is an antecedent event in whose presence escape (termination of the event) is reinforcing, (b) the discriminative stimulus (S^D) is another antecedent event in whose presence a response is more likely to be reinforced, (c) the response is the act that produces reinforcement, and (d) the reinforcer is the termination of the event that served as the EO.

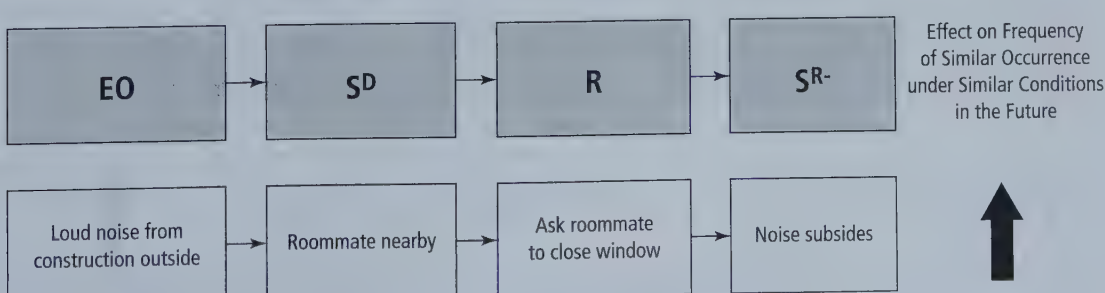


Figure 12.1 Four-term contingency illustrating negative reinforcement.

Positive Versus Negative Reinforcement

Positive and negative reinforcement have a similar effect on behavior in that both produce an increase in responding. They differ, however, with respect to the type of stimulus change that follows behavior, as illustrated in Figure 12.2. In both examples, a stimulus change (consequence) strengthens the behavior that preceded it: Asking the sibling to make a sandwich is strengthened by obtaining food; carrying rain protection is strengthened by blocking the rain. However, behavior maintained by positive reinforcement produces a stimulus that was absent prior to responding, whereas behavior maintained by negative reinforcement terminates a stimulus that was present prior to responding: Food was unavailable prior to asking for it but available after (positive reinforcement); rain was landing on one's clothing before raising the umbrella but not after (negative reinforcement).

Thus, the key distinction between positive and negative reinforcement is based on the type of stimulus change that occurs following a response. Many stimulus changes have discrete onsets and offsets and involve an "all-or-none" operation, as in turning on a television (positive reinforcement) or turning off the light in a bedroom (negative reinforcement). Other stimulus changes exist on a continuum from less to more, such as turning up the volume of a stereo to hear it better (positive reinforcement) or turning it down when it is too loud (negative reinforcement). Sometimes, however, it is difficult to determine whether an increase in responding resulted from positive or negative reinforcement because the stimulus change is ambiguous. For example, although a change in temperature can be measured quantitatively so we know that it either increased or decreased following behavior, it is unclear whether turning on a heater when the temperature is 40° F (5° C) is an example of positive reinforcement because the response "produced heat" or negative reinforcement because the response "removed cold." Another example can be found in a classic study by Osborne (1969) on the use of free time as a reinforcer in the classroom. During baseline, students were observed to get out of their seats frequently during long work periods. During treatment, the students were given 5 minutes of free time if they remained in their seats during 10-minute work periods, and in-seat behavior increased. At first glance, the free-time contingency appears to have involved negative reinforcement (termination of the in-seat requirement contingent on appropriate behavior). As Osborne noted, however, access to activities (games, social interaction, etc.) during free time may have functioned as positive reinforcement.

Given the ambiguous nature of some stimulus changes, Michael (1975) suggested that the distinction between positive and negative reinforcement, based on whether a stimulus is presented or removed, may be unnecessary. Instead, he emphasized the importance of specifying the type of environmental change produced by a response in terms of key stimulus features that constituted both the "prechange" and "postchange" conditions. This practice, he proposed, would eliminate the necessity of describing the transition between prechange and postchange conditions as one involving the presentation or removal of stimuli and would facilitate a more complete understanding of functional relations between environment and behavior.

Little has changed since the publication of Michael's (1975) article; the distinction between positive and negative reinforcement continues to be emphasized in every text on learning principles, and citations to the term *negative reinforcement* have increased in applied research (Iwata, 2006). In an attempt to renew the discussion, Baron and Galizio (2005) reiterated Michael's position and included some additional points of emphasis. This terminological issue is a complex one that can be considered from several perspectives—conceptual, procedural, and historical—and debate on the issue continues at this time. Readers interested in the topic are referred to a series of reactions to Baron and Galizio (Chase, 2006; Iwata, 2006; Lattal & Lattal, 2006;

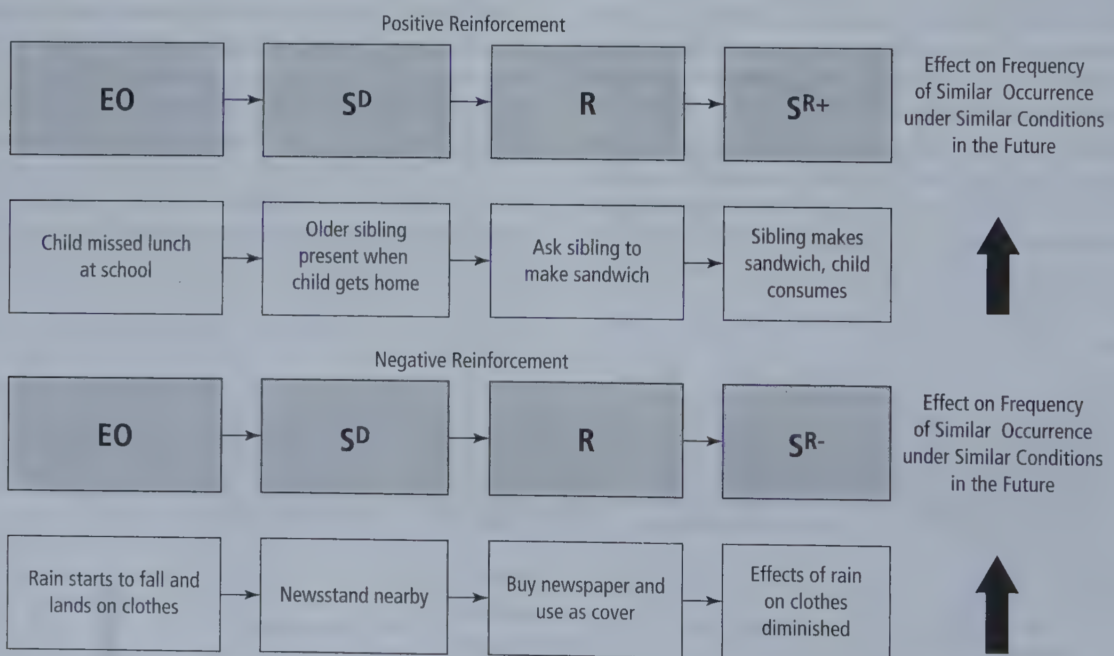

Figure 12.2 Four-term contingency illustrating similarities and the difference between positive and negative reinforcement.

Marr, 2006; Michael, 2006; Sidman, 2006) and their rejoinder (Baron & Galizio, 2006). One difficulty that arises when attempting to examine the issue empirically is equating the two types of contingencies. Magoon and colleagues did so in two human operant studies (Magoon & Critchfield, 2008; Magoon, Critchfield, Merrill, Newland, & Schneider, 2017) by pitting money-gain positive reinforcement against money-loss avoidance negative reinforcement. Their results showed differential outcomes under the two arrangements, supporting the proposition that the two types of contingencies are functionally unique.

Negative Reinforcement Versus Punishment

Negative reinforcement is sometimes confused with punishment for two reasons. First, because the lay term for positive reinforcement is *reward*, people mistakenly consider negative reinforcement as the technical term for the opposite of reinforcement (punishment). The terms *positive* and *negative*, however, do not refer to "good" and "bad" but to the type of stimulus change (presentation versus termination) that follows behavior (Catania, 2013). A second source of confusion stems from the fact that the stimuli involved in both negative reinforcement and punishment are, by definition, "aversive."[1] Although it is true that the same stimulus may serve as a negative reinforcer in one context and as a punisher in a different context, both the nature of the stimulus change and its effect on behavior differ. In a negative reinforcement contingency, a stimulus that was present is terminated by a response, which leads to an increase in responding; in a punishment contingency, a stimulus that was absent is presented following a response, which leads to a decrease in responding. Thus, a response that terminates loud noise would increase as a function of negative reinforcement, but one that produces loud noise would decrease as a function of punishment (see Chapter 14 for a more extensive discussion of punishment).

ESCAPE AND AVOIDANCE CONTINGENCIES

In its simplest form, negative reinforcement involves an **escape contingency**, in which a response terminates (produces escape from) an ongoing stimulus. An early study by Keller (1941) illustrates typical laboratory research on escape. When a rat was placed in an experimental chamber and a bright light was turned on, the rat quickly learned to press a lever, which turned off the light. Osborne's (1969) study on free-time contingencies may also serve as an example of escape learning in an applied context. To the extent that the important feature of the contingency was the termination of work requirements, in-seat behavior during 10-minute work periods produced 5 minutes of escape.

Although situations involving escape are commonly encountered in everyday life (e.g., we turn off loud noises, shield our eyes from the sun, flee from an aggressor), much behavior maintained by negative reinforcement is characterized by an **avoidance contingency**, in which a response prevents or postpones the presentation of a stimulus. Returning to the previous laboratory example, an experimenter can add to the escape contingency an arrangement in which another stimulus such as a tone precedes the presentation of the bright light, and a response in the presence of the tone eliminates the presentation of the light or postpones it until the tone is next presented. This type of arrangement has been called **discriminated avoidance**, in which responding in the presence of a signal prevents the onset of a stimulus from which escape is a reinforcer. Because responses in the presence of the tone are reinforced, whereas those in the absence of the tone have no effect, the tone is a discriminative stimulus (S^D) in whose presence there is an increased likelihood of reinforcement for responding. (See Chapter 17 for more on stimulus control.)

Avoidance behavior also can be acquired in the absence of a signal. Suppose the experimenter arranges a schedule in which the bright light turns on for 5 seconds every 30 seconds, and a response (or some number of responses) at any time during the interval resets the clock to zero. This type of arrangement is known as **free-operant avoidance** because the avoidance behavior is "free to occur" at any time and will delay the presentation of the bright light.

Each of the three types of contingencies described earlier was illustrated in an ingenious study by Azrin, Rubin, O'Brien, Ayllon, and Roll (1968) on postural slouching (see Figure 12.3). Participants wore an apparatus that closed an electrical circuit when slouching occurred. Closure of the switch produced an audible click, which was followed 3 seconds later by a 55-db

Figure 12.3 Three types of negative reinforcement contingencies used by Azrin and colleagues (1968) to maintain correct posture.

Free-Operant Avoidance

Correct posture maintained → Avoid click and tone

Discriminated Avoidance

Slouching (incorrect posture) → Audible click
Correct posture within 3 seconds of click → Avoid tone

Escape

Slouching (incorrect posture) → Audible click
Posture not corrected within 3 seconds → 55-db tone
Posture corrected → Tone turns off

tone. Postural correction in the presence of the tone turned off the tone (escape) but prevented the tone if correction occurred during the 3 seconds following the click (discriminated avoidance). Furthermore, maintenance of correct posture prevented the click (free-operant avoidance). A hypothetical example involving homework management also illustrates these contingencies. A parent who sends a child to his or her room immediately following school and allows the child to leave the room only after completing homework has arranged an escape contingency: Homework completion produces escape from the bedroom. A parent who first delivers a warning (e.g., "If you don't start your homework in 10 minutes, you'll have to do it in your bedroom") has arranged a discriminated avoidance contingency: Starting homework following the warning avoids having to do it in the bedroom. Finally, the parent who waits until later in the evening to impose the in-room requirement has arranged a free-operant avoidance contingency: Homework completion at any time after school avoids having to do it in the bedroom later.

As can be seen above, escape and avoidance contingencies illustrate very different arrangements, and one particular feature of some avoidance contingencies has raised questions about fundamental learning processes. Whereas the environment–behavior relationship in escape contingencies is clearly identifiable—that is, responding results in termination or reduction of a stimulus that was present initially—the evocative and maintaining influences involved in avoidance are less clear. Except in the case of discriminated avoidance, avoidance behavior often occurs in the absence of any apparent evocative condition and does not produce obvious consequential changes in the environment. This seems inconsistent with our A-B-C notion of operant behavior: We see the "B," but where are the "A" and "C"? How do we account for behavior that does not appear to fit a conceptual framework that emphasizes the importance of immediate antecedent and consequent events as determinants of behavior? (See Box 12.1 for further discussion of avoidance responding.)

BOX 12.1

Is Avoidance a Different Type of Learning?

Two-Factor Theory

In the 1940s, Mowrer conducted research showing that, after several trials in which a tone was presented just before a shock, rats began to emit escape responses (moving over a barrier to another location) in the presence of only the tone. Mowrer proposed that this behavior resulted from two independent processes. First, the shock was considered to be an unconditioned stimulus, eliciting reflexive "fear" responses. After being paired with the shock, the tone acquired fear-eliciting properties through respondent conditioning. Thus, Mowrer asserted that responding in the presence of the tone produced escape from the fear and anxiety elicited by the tone, rather than escape from the shock. He proposed a "two-factor" theory, incorporating both respondent and operant mechanisms, to account for avoidance behavior. Some subsequent research provided further evidence in support of this theory, such as a study by Kamin (1957) showing that avoidance behavior was disrupted when it canceled upcoming shocks but did not terminate the warning tone. Results of other research, however, have been inconsistent with Mowrer's theory. For example, Solomon, Kamin, and Wynne (1953) showed that dogs continued to emit avoidance responses in the presence of a warning signal long after shocks were no longer programmed to follow the signal. And work by Sidman (1953, 1962) and others (Herrnstein & Hineline, 1966; Perone & Galizio, 1987) showed that when shocks were presented according to time-based schedules, animals learned to postpone shocks in the absence of a programmed signal, further calling Mower's two-factor theory into question.

Anxiety as derived relational responding

Behavior analysts also have extended findings of research on derived relational responding to investigate clinical problems involving avoidance (Dymond, 2009). It has been suggested that anxiety and phobic disorders develop when aversive properties spread across classes of stimuli whose function is established through associative, or indirect, conditioning processes. For example, Dougher, Hamilton, Fink, and Harrington (2007) showed that fear responses spread in an orderly, hierarchical way across three otherwise arbitrary stimuli to which college students had been trained to respond according to a small, medium, and large relation. After the "medium" stimulus was paired with a mild shock, a smaller fear response was recorded for the "small" stimulus, whereas a larger fear response was recorded in the presence of the "large" stimulus—even though neither of these stimuli had ever been paired with the shock! The authors suggested that these results were relevant to clinical problems involving excessive fear responses to stimuli that had not been previously paired with aversive experiences (e.g., excessive fear of photos of anything resembling a spider) and offered an alternative account to cognitive interpretations based on hypothetical constructs such as schema, beliefs, and expectancies.

As behavior analysts continue to study the nature of avoidance, scientists in other fields are producing better ways to predict what sorts of challenges—environmental as well as social—we will face in the future. Solutions to problems such as disease, poverty, and pollution depend on being able not only to predict their occurrence but also to change human behavior so as to avoid, to the extent possible, their disastrous outcomes. Thus, behavior analysts' contribution to an understanding of the fundamental determinants of avoidance and of ways to promote effective avoidance repertoires can directly influence our ability to prosper in an increasingly challenging world.

CHARACTERISTICS OF NEGATIVE REINFORCEMENT

Responses Acquired and Maintained by Negative Reinforcement

It is a well-known fact that aversive stimulation produces a variety of responses (Hutchinson, 1977). Some of these may be respondent behaviors (as in reflexive actions to intense stimuli), but the focus in this chapter is on operant behaviors. Recall that the presentation of an aversive stimulus serves as an EO for escape and occasions behavior that has produced escape from similar stimulation in the past. Any response that successfully terminates the stimulation will be strengthened; as a result, a wide range of behaviors may be acquired and maintained by negative reinforcement. All of these behaviors are adaptive because they enable one to interact effectively with the environment; some behaviors, however, are more socially appropriate than others. As will be seen later in the chapter, negative reinforcement may play an important role in the development of academic skills, but it also can account for the development of disruptive or dangerous behavior.

Events That Serve as Negative Reinforcers

In discussing the types of stimuli that can strengthen behavior through negative reinforcement, a problem arises when attempting to use the same terminology as that applied to the description of positive reinforcers. It is quite common to refer to positive reinforcers by listing stimuli such as food, money, praise, and so on. It is, however, the presentation of the stimulus that strengthens behavior: Food presentation, and not food per se, is a positive reinforcer. Nevertheless, we often simply list the stimulus and assume that "presentation" is understood. In a similar way, to say that negative reinforcers include shock, noise, parental nagging, and so on, is an incomplete description. It is important to remember that a stimulus described as a negative reinforcer refers to its removal because, as noted previously, the same stimulus serves as an EO when presented prior to behavior and as punishment when presented following behavior.

Learning History

As is the case with positive reinforcers, negative reinforcers influence behavior because (a) we have the inherited capacity to respond to them or (b) their effects have been established through a history of learning. Stimuli whose removal strengthens behavior in the absence of prior learning are **unconditioned negative reinforcers**. These stimuli typically are noxious events such as shock, loud noise, intense light, extremely high or low temperature, or strong pressure against the body. In fact, any source of pain or discomfort (e.g., a headache) will occasion behavior, and any response that successfully eliminates the discomfort will be reinforced. Other stimuli are **conditioned negative reinforcers**, which are previously neutral events that acquire their effects through pairing with an existing (unconditioned or conditioned) negative reinforcer. A bicyclist, for example, usually heads for home when seeing a heavily overcast sky because dark clouds have been highly correlated with impending bad weather. Various forms of social coercion, such as parental nagging, are perhaps the most commonly encountered conditioned negative reinforcers. For example, reminding a child to clean his or her bedroom may have little effect on the child's behavior unless failure to respond is followed by another consequence, such as having to stay in the room until it is clean. To the extent that the nagging is reliably "backed up" by sending the child to the room, the child will eventually respond simply to stop or prevent the nagging. It is interesting that, in the case of negative reinforcement, neutral events (dark sky, nagging) function as both (a) discriminative stimuli because responding in their presence avoids another consequence and (b) conditioned aversive stimuli (i.e., conditioned negative reinforcers) because, due to their pairing with another consequence, they become stimuli to avoid or escape.

The Source of Negative Reinforcement

Another way to classify negative reinforcers is based on how they are removed (i.e., the source of the stimulus change). In Chapter 11, a distinction was made between socially mediated reinforcement, in which the consequence results from the action of another person, and automatic reinforcement, in which the consequence is produced directly by a response independent of the actions of another. This distinction also applies to negative reinforcement. Returning to the example in Figure 12.1, we can see that termination of the construction noise was an instance of *social negative reinforcement* (the roommate's action closed the window). The person "being bothered" by the noise, however, could simply have walked across the room and closed the window (*automatic negative reinforcement*). This example illustrates the fact that many reinforcers can be removed or terminated either way: You can consult a physician when experiencing a headache (social) or take a pain medication (automatic), ask your roommate to turn off the stereo when you're studying for a test (social) or turn it off yourself (automatic), and so on.

Considering the source of negative reinforcement may facilitate the design of behavior-change procedures by determining the focus of intervention. For example, when faced with a perplexing work task, an employee may finish it incorrectly just to get it out of the way (automatic reinforcement) or ask for help (social reinforcement). Aside from reassigning the employee, the quickest solution would be to reinforce the employee's seeking help by offering assistance. Ultimately, however, the supervisor would want to teach the employee the necessary skills to complete the work tasks independently.

Identifying the Context of Negative Reinforcement

Chapter 11 outlined several ways to identify positive reinforcers; the difference with negative reinforcers is that equal emphasis must be placed on the antecedent event (EO) as well as on the reinforcing consequence because, once the behavior occurs, the negative reinforcer may be gone and cannot be observed. The identification of EOs may be difficult with individuals who have limited verbal ability and cannot tell someone they are experiencing aversive stimulation. These people may engage in other behaviors, such as tantrums, attempts to leave the situation, destructive behavior, aggression, or even self-injury. Weeks and Gaylord-Ross (1981), for example, observed students with severe disabilities when no

task, an easy task, and a difficult task were presented. Little or no problem behavior occurred during the no-task condition, and problem behavior occurred somewhat more often in the difficult-task condition than in the easy-task condition. These results suggested that the students' problem behavior was maintained by escape from task demands and that difficult tasks were more "aversive" than were easy tasks. However, because the consequences that followed problem behavior were unknown, it is possible that the behaviors were maintained by some other consequence, such as attention, which would be a positive reinforcer.

Iwata, Dorsey, Slifer, Bauman, and Richman (1994) developed a method for identifying the types of contingencies that maintain problem behavior by observing people under a series of conditions that differed with respect to both antecedent and consequent events. One condition involved the presentation of task demands (EO) and removal of the demands (escape) if problem behavior occurred; higher rates of problem behavior under this condition relative to others indicated that problem behavior was maintained by negative reinforcement (see Chapter 24 for further discussion of this approach to assessment).

Smith, Iwata, Goh, and Shore (1995) extended the findings of Weeks and Gaylord-Ross (1981) and Iwata et al. (1994) by identifying some characteristics of task demands that make them aversive. After first determining that their participants' (people with severe disabilities) problem behavior was maintained by escape from task demands, Smith and colleagues examined several dimensions along which tasks might differ: task novelty, duration of the work session, and rate of demand presentation. Results of one of these analyses are shown in Figure 12.4, which depicts frequency distributions and cumulative records of problem behavior from the beginning to the end of sessions. These data illustrate the importance of individualized assessments in

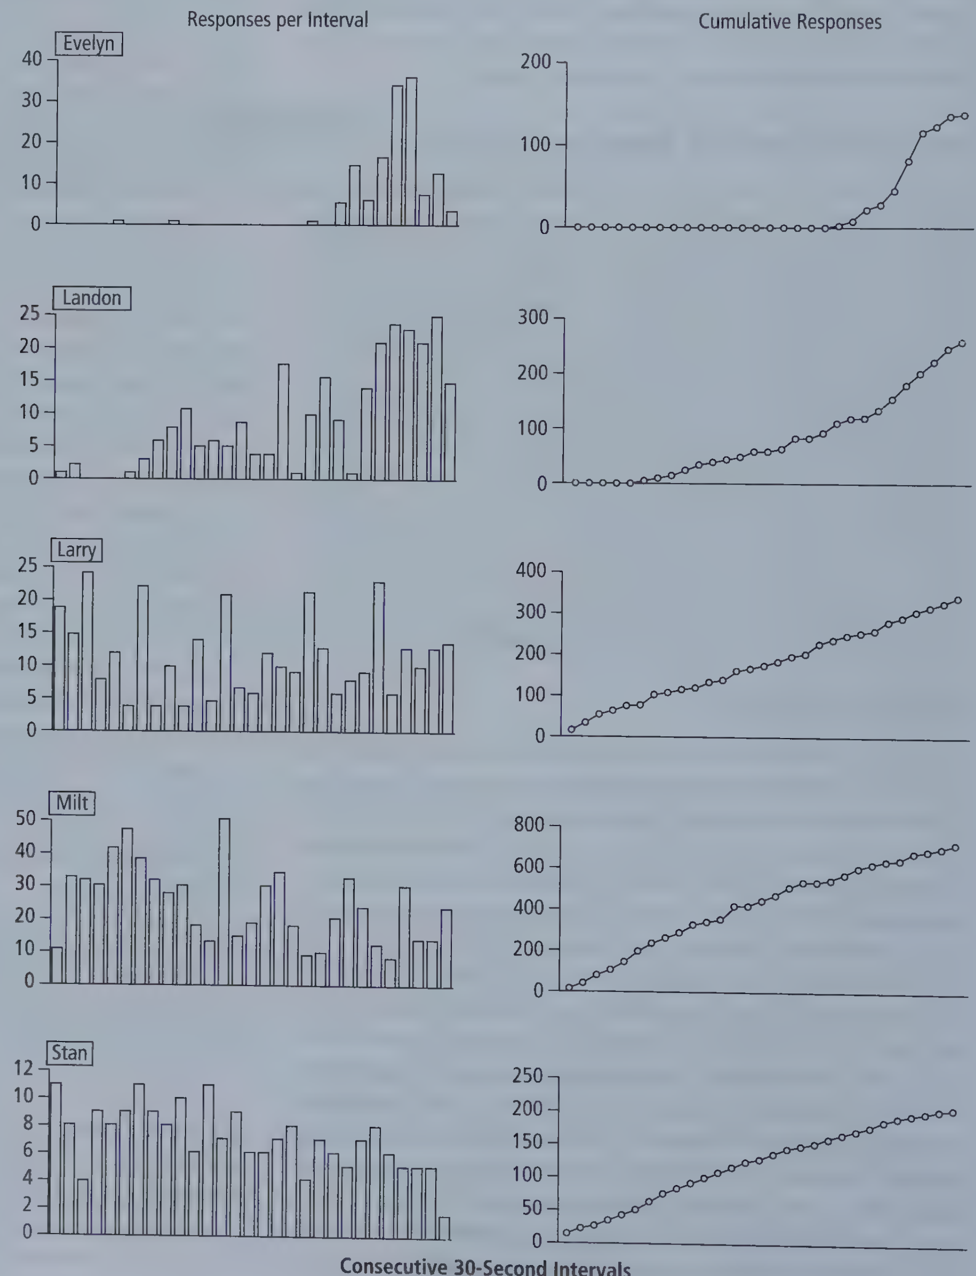

Figure 12.4 Frequency distributions (left column) and cumulative records (right column) summed over sessions of self-injurious behavior (SIB) by five adults with developmental disabilities as work sessions progressed.

identifying the basis for negative reinforcement because two participants (Evelyn and Landon) showed increasing rates of problem behavior as work sessions progressed, whereas two other participants (Milt and Stan) showed decreasing rates of problem behavior as work sessions progressed, as illustrated by the declining height of the bars in their histograms and of the slopes of their cumulative curves. In fact, subsequent studies (e.g., Roscoe, Rooker, Pence, & Longworth, 2009) have shown that failure to consider the idiosyncratic nature of aversive stimuli may lead to erroneous conclusions during assessment of problem behavior.

Determinants of Negative Reinforcement Effects

The factors that determine whether a negative reinforcement contingency will be effective in changing behavior are similar to those that influence positive reinforcement (see Chapter 11) and are related to (a) the strength of the contingency and (b) the presence of competing contingencies. In general, negative reinforcement for a given response will be more effective under the following conditions:

1. The stimulus change *immediately* follows the occurrence of the target response.
2. The *magnitude* of reinforcement is large, referring to the difference in stimulation present before and after the response occurs.
3. Occurrence of the target response *consistently* produces escape from or postponement of the EO.
4. Reinforcement is *unavailable* for competing (nontarget) responses.

APPLICATIONS OF NEGATIVE REINFORCEMENT

Negative reinforcement is a fundamental principle of learning that has been studied extensively in basic research (Hineline & Rosales-Ruiz, 2013). Although many examples of escape and avoidance learning can be found in everyday life, research in applied behavior analysis has heavily emphasized the use of positive reinforcement over negative reinforcement, mostly for ethical reasons, which are noted in the final section of this chapter. Still, negative reinforcement has been used as one means of establishing a variety of behaviors. This section illustrates several therapeutic uses of negative reinforcement, as well as the unintended role it may play in strengthening problem behavior.

Acquisition and Maintenance of Appropriate Behavior

Interventions for Chronic Food Refusal

Pediatric feeding problems are common and are especially prevalent among children with developmental disabilities. These disorders may take a variety of forms, including selective eating, failure to consume solid foods, and complete food refusal, and may be serious enough to require tube feeding or other artificial means to ensure adequate nutritional intake. A large proportion of feeding problems cannot be attributed to a medical cause but, instead, appear to be learned responses most likely maintained by escape or avoidance.

Results from a number of studies have shown that operant learning–based interventions can be highly effective in treating many childhood feeding disorders, and a study by Ahearn, Kerwin, Eicher, Shantz, and Swearingin (1996) illustrated the use of negative reinforcement as a form of intervention. Three children admitted to a hospital who had histories of chronic food refusal were first observed under a baseline (positive reinforcement) condition in which food was presented and access to toys was available contingent on accepting food. Food refusal, however, produced escape in that it terminated a trial. Subsequently, the experimenters compared the effects of two interventions. One treatment condition (nonremoval of the spoon) involved presenting food and keeping the spoon positioned at the child's lower lip until the bite was accepted. The other treatment (physical guidance) involved presenting food and, if the child did not accept, opening the child's mouth so that the food could be delivered. Both treatments involved a negative reinforcement contingency because food acceptance terminated the trial by producing removal of the spoon or avoidance of the physical guidance.

Figure 12.5 shows the results obtained for the three children. All children exhibited low rates of acceptance during baseline in spite of the availability of positive reinforcement. The two interventions were implemented in a multiple baseline across subjects design and were compared in a multielement design. As can be seen in the second phase of the study, both interventions produced immediate and large increases in food acceptance. Numerous subsequent studies have replicated these findings. Of particular interest is a study by Piazza, Patel, Gulotta, Sevin, and Layer (2003), who compared the effects of positive reinforcement (access to preferred toys and attention), negative reinforcement (physical guidance or nonremoval of the spoon, both labeled as "escape extinction" because food refusal no longer terminated feeding trials), and positive and negative reinforcement combined on chronic food refusal exhibited by four children. Results showed that positive reinforcement was not effective in increasing food consumption for any of the children. By contrast, negative reinforcement produced increases in consumption regardless of whether it was implemented alone or in combination with positive reinforcement. Collectively, results of these studies showed that positive reinforcement for appropriate behavior may have limited effects if competing behavior (food refusal) produces negative reinforcement, and that negative reinforcement, which maintained the children's problem behavior, could be used to establish alternative behavior.

Error-Correction Strategies

As noted in Chapter 11, positive reinforcement is a basic motivational component of effective instruction. Teachers commonly deliver praise, privileges, and other forms of reward contingent on correct performance. Another common procedure, but one that has received less attention than positive reinforcement, involves the correction of student errors by repeating a learning trial, having the student practice correct performance, or giving the student additional work. To the extent that correct performance avoids these remedial procedures, improvements may be just as much a function of negative reinforcement as positive reinforcement.

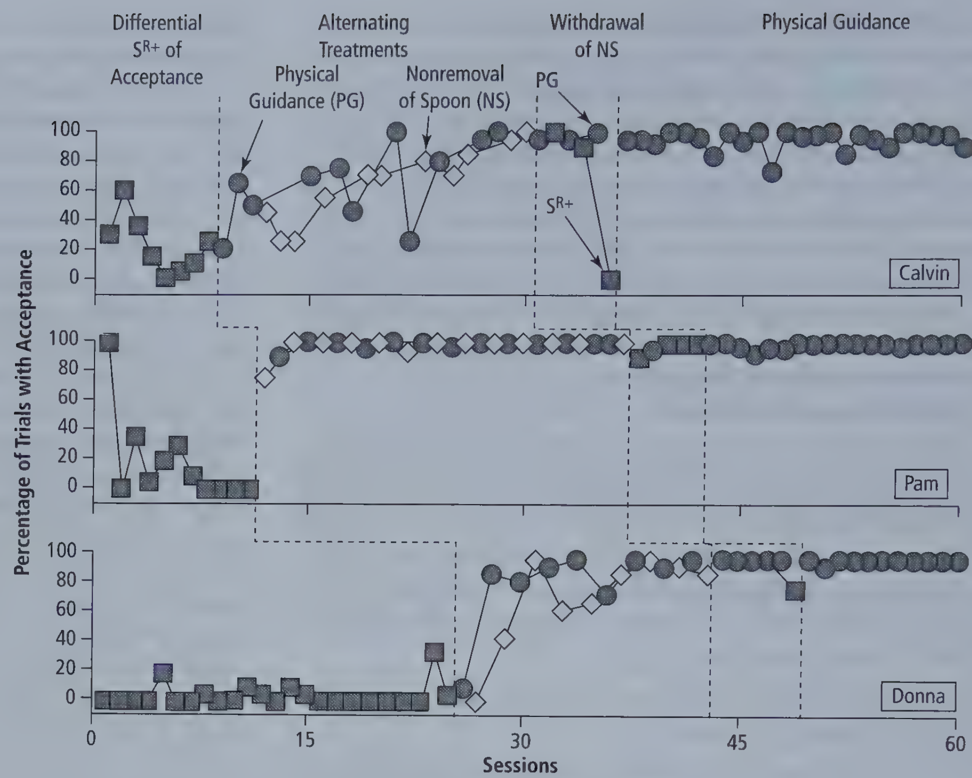

Figure 12.5 Percentage of trials in which three children with histories of chronic food refusal accepted bites during a baseline condition of positive reinforcement and two treatment conditions, nonremoval of the spoon and physical guidance, both of which involved a negative reinforcement contingency.

From "An Alternating Treatments Comparison of Two Intensive Interventions for Food Refusal" by W. H. Ahearn, M .E. Kerwin, P. S. Eicher, J. Shantz, and W. Swearingin, 1996, *Journal of Applied Behavior Analysis*. Reproduced with permission of John Wiley &Sons, Inc.

Worsdell and colleagues (2005) examined the relative contributions of these contingencies during behavioral acquisition. The learning task involved reading words presented on flash cards, and the intervention of interest involved the correct repetition of misread words during remedial trials. The procedure provided additional practice of correct responses but also represented an avoidance contingency. To separate these effects (in Study 3), the authors implemented two error correction conditions. In the "relevant" condition, which combined the effects of practice and negative reinforcement, students were prompted to pronounce the misread word correctly 5 times contingent on an error. In the "irrelevant" condition, students were prompted to repeat an unrelated, nontarget word 5 times contingent on an error. The irrelevant condition contained only the negative reinforcement contingency because repetition of irrelevant words provided no practice in correctly reading misread words.

Figure 12.6 shows the results of Study 3, expressed as the cumulative number of words mastered by the 9 participants. All participants' performance improved during both error-correction conditions relative to baseline, when no error-correction procedure was in effect. Performance by 3 participants (Tess, Ariel, and Ernie) was better during relevant error correction. However, Mark's performance was clearly superior during irrelevant error correction, and performance of the remaining 5 participants (Hayley, Becky, Kara, Maisy, and Seth) was similar in both conditions. Thus, all participants showed improvement in reading performance even when they practiced irrelevant words, and most participants (6 of 9) did just as well or better practicing irrelevant rather than relevant words. These results suggest that the success of many remedial (error-correction) procedures may be due at least in part to negative reinforcement. Subsequent studies (Carroll, Joachim, St. Peter, & Robinson, 2015; Kodak et al., 2016; McGhan & Lerman, 2013) have examined specific features of error-correction procedures that may enhance their effectiveness, and a consistent finding has been the contribution of avoidance contingencies to learning in instructional contexts. That is, the inclusion of a remedial-trial contingency produces faster learning than that resulting from positive reinforcement of correct responses alone.

Acquisition and Maintenance of Problem Behavior

Well-designed instructional procedures maintain a high degree of task engagement and lead to improved learning. Occasionally, however, the presentation of task demands may function as an EO for escape behavior due to some aversive feature of the work requirements. Initial forms of escape may include lack of engagement or mild forms of disruption. To the extent that positive reinforcement for compliance is less than optimal, attempts to escape may persist and may escalate to severe forms of problem behavior. In fact, research on the assessment and treatment of problem behavior has shown that escape from task demands is a common source of negative reinforcement for property destruction, aggression, and even self-injury. This topic is covered more extensively in Chapter 27 and is included here as well because of its special relevance to negative reinforcement.

O'Reilly (1995) conducted an assessment of a person's episodic aggressive behavior. The participant was an adult with severe intellectual disability who attended a vocational day program. To determine whether aggressive behavior was maintained by positive versus negative reinforcement, O'Reilly observed the participant under two conditions, which were alternated in a multielement design. In one condition (attention), a

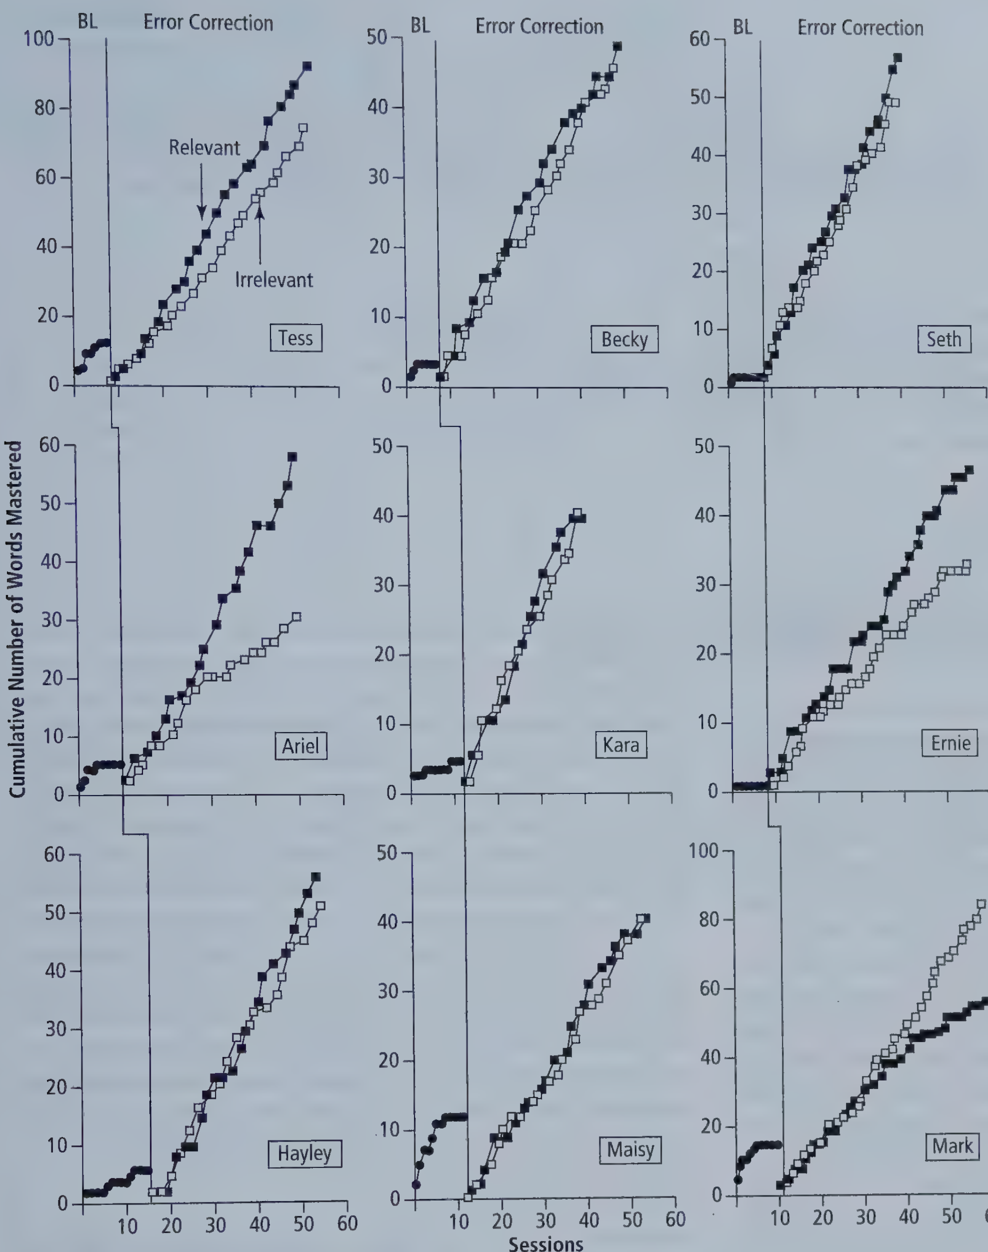

Figure 12.6 Cumulative number of words read correctly during baseline (positive reinforcement for correct responses) and during two error-correction conditions: one in which correct responses avoided repeated practice of the misread (relevant) word, and another in which correct responses avoided practice of an unrelated (irrelevant) word. Improvements in performance in the "irrelevant" condition indicated that negative reinforcement plays a role in error-correction procedures.

"Analysis of Response Repetition as an Error-Correction Strategy During Sight-Word Reading" by A. S. Worsdell, B. A. Iwata, C. L. Dozier, A. D. Johnson, P. L. Neidert, and J. L. Thomason, 2005, *Journal of Applied Behavior Analysis*, *38*, p. 524. Copyright 2005 by the Society for the Experimental Analysis of Behavior, Inc.

therapist ignored the participant (EO) except to deliver reprimands following aggression (positive reinforcement). In the second condition (demand), a therapist presented difficult tasks to the participant (EO) and briefly terminated the trial following aggression (negative reinforcement).

As Figure 12.7 shows, aggressive behavior occurred more often in the demand condition, indicating that it was maintained by negative reinforcement. Because anecdotal reports suggested that the participant also was more likely to be aggressive following nights when he had not slept well, the data for both conditions were further divided based on whether the participant slept for more or less than 5 hours the previous night. The highest rates of aggression occurred following sleep deprivation. These data are particularly interesting in that they illustrate the combined influence of two antecedent events—EOs on behavior maintained by negative reinforcement: Work tasks (EO #1) generally occasioned escape but even more so in the absence of sleep (EO #2).

Other studies have had similar outcomes, suggesting that a number of "contextual" factors can mediate the "aversiveness" of demand situations. For example, task demands may be more likely to evoke escape behavior when a medical condition such as otitis media (ear infection) is present (O'Reilly, 1997) or when demands are presented in the context of low-quality attention (e.g., negative verbal statements) from caregivers (Gardner, Wacker, & Boelter, 2009). By contrast, contextual manipulations such as presenting the opportunity to choose among tasks (Dyer, Dunlap, & Winterling, 1990) or to choose the order in which tasks are completed (Kern, Mantegna, Vorndran, Bailin, & Hilt, 2001), or presenting demands in the context of pleasant stories (Carr, Newsom, & Binkoff, 1976), have been shown to decrease problem behaviors maintained by escape.

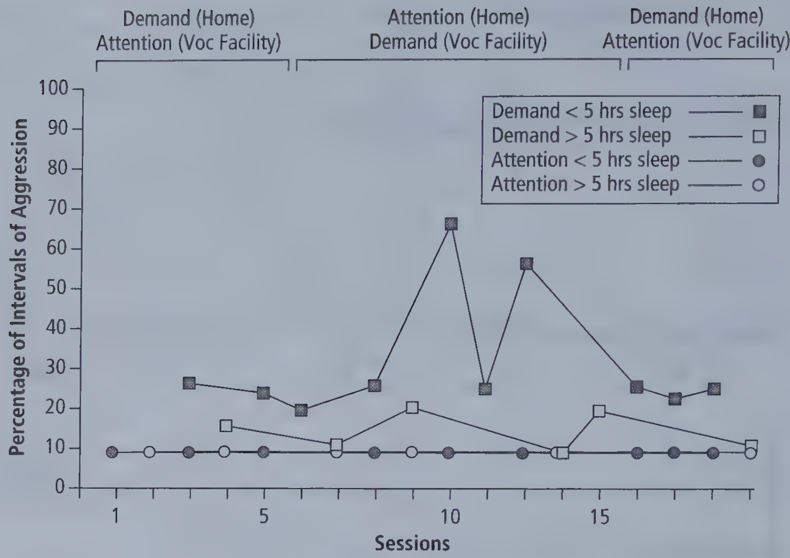

Figure 12.7 Data showing that the effects of work tasks as EOs for escape-maintained aggression by an adult male with severe intellectual disability were exacerbated by sleep deprivation.

"Functional Analysis and Treatment of Escape-Maintained Aggression Correlated with Sleep Deprivation" by M. F. O'Reilly, 1995, *Journal of Applied Behavior Analysis, 28*, p. 226. Copyright 1995 by the Society for the Experimental Analysis of Behavior, Inc.

Extinction of Behavior Maintained by Negative Reinforcement

When operant behavior no longer produces reinforcement, its frequency decreases through a process known as extinction. As is the case with reinforcement, extinction involves both an operation (termination of reinforcement) and an effect (a reduction in responding). Although simple in concept, the application of extinction requires consideration of numerous factors: (a) its functional as well as procedural variations; (b) its direct and indirect effects, some of which may be undesirable; and (c) historical influences that may facilitate or impede its outcome. As a result, a chapter of this text (Chapter 24) is devoted to the topic of extinction. We introduce it here just to note that extinction represents one way (the most direct way) to decrease behavior maintained by negative reinforcement and to emphasize the fact that termination of a negative reinforcement contingency by "no longer reinforcing behavior" means presenting the consequence that responding previously escaped or avoided (i.e., withholding negative reinforcement). For example, if a child's loud whining and complaining allow the child to delay preforming an undesirable task or perhaps to avoid it altogether, extinction would involve reinstating the requirement to complete the task.

Behavioral Replacement Strategies

Differential Negative Reinforcement

Problem behaviors maintained by negative reinforcement can be treated in a number of ways. One strategy is to strengthen a more socially appropriate replacement behavior using negative reinforcement, as illustrated in a study by Durand and Carr (1987). After determining that the "stereotypic" behaviors of four special education students were maintained by escape from task demands, the authors taught the students an alternative response ("Help me"), which was followed by assistance with the task at hand. As can be seen in Figure 12.8, all students engaged in moderate-to-high levels of stereotypy during baseline. After being taught to use the phrase "Help me," the students began to exhibit that behavior, and their stereotypy decreased.

Results of the Durand and Carr (1987) study showed that a desirable behavior could replace an undesirable one; however, the replacement behavior might be considered less than ideal because it did not necessarily facilitate improved task engagement. This limitation was addressed in a subsequent study by Marcus and Vollmer (1995). After collecting baseline data on a young girl's compliant and disruptive behavior, the authors compared the effects of two treatments in a reversal design. In a differential negative reinforcement (DNR) communication condition, the girl was given a brief break from the task when she said "Finished." In a second condition, called DNR compliance, the girl was given a break after complying with an instruction (the criterion for a break was later increased to compliance with three instructions). Results of this comparison (see Figure 12.9) showed that both treatments produced marked reductions in disruptive behavior. However, only the DNR compliance condition produced an improvement in task performance.

Differential Positive Reinforcement

Research on the treatment of problem behavior has emphasized the importance of extinction as a critical component of intervention. Results of a small but growing number of studies, however, indicate that reinforcement-based procedures occasionally can be effective even though problem behavior might continue to be reinforced. Furthermore, some of these studies have shown that applications of positive reinforcement can be successful in strengthening appropriate replacement behavior when problem behavior has been maintained by negative reinforcement (see Payne & Dozier, 2013, for a recent review).

A study by Slocum and Vollmer (2015) illustrated this approach with five children who engaged in high rates of problem behavior maintained by escape from task demands and correspondingly low levels of compliance. The authors compared two interventions in a multielement design, both of which were implemented without extinction (i.e., problem behavior continued to produce escape). Positive reinforcement involved delivery of a small edible item contingent on compliance, whereas negative reinforcement involved delivering a 30-sec break from the task contingent on compliance. The authors reported

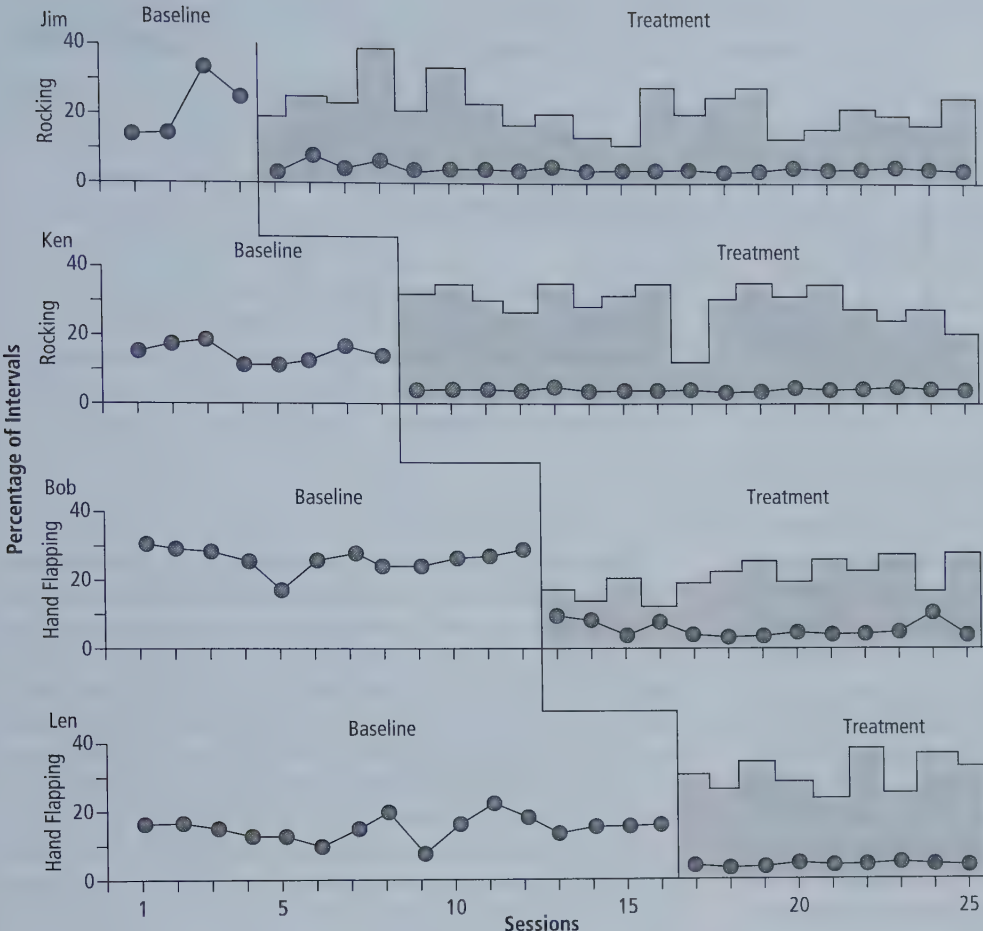

Figure 12.8 Percentage of intervals of stereotypic behaviors maintained by escape from task demands of four special education students during baseline and treatment in which the students were taught an alternative response ("Help me") to attain assistance with the task at hand. Shaded bars show students' use of the "Help me" response.

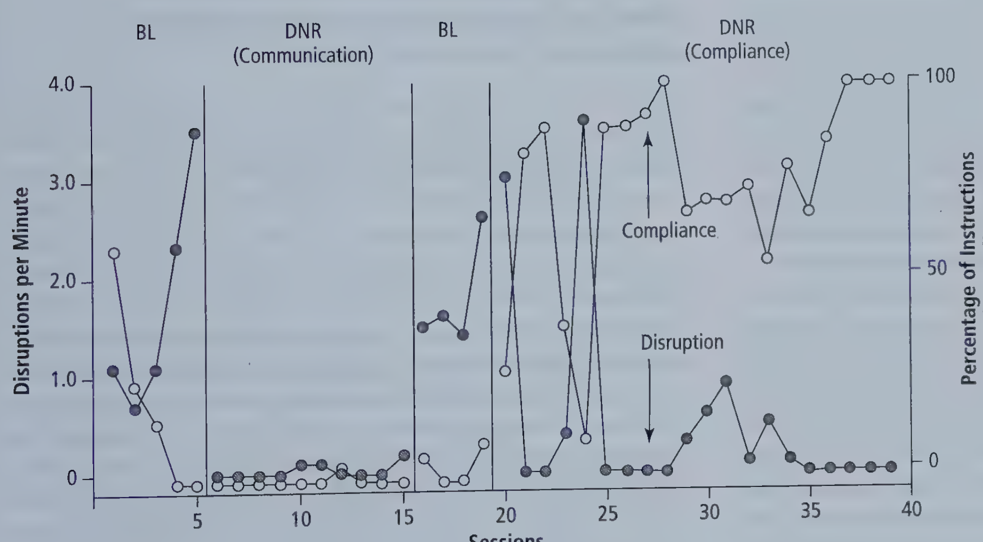

Figure 12.9 Disruptions and compliance by a 5-year-old girl during baseline and two differential negative reinforcement conditions.

"Effects of Differential Negative Reinforcement on Disruption and Compliance" by B. A. Marcus and T. R. Vollmer, 1995, *Journal of Applied Behavior Analysis*, *28*, p. 230. Copyright 1995 by the Society for the Experimental Analysis of Behavior, Inc.

that positive reinforcement produced more consistent effects, as illustrated in Figure 12.10, which shows data on problem behavior for one of the participants. During the first treatment phase, both interventions were effective, although lower rates of problem behavior were observed under the positive reinforcement condition. During the second treatment phase, positive reinforcement was effective, whereas negative reinforcement was not.

CHANGES IN TEACHER AND CAREGIVER RESPONDING AS A FUNCTION OF NEGATIVE REINFORCEMENT

A great deal of research has focused on the use of procedures such as those described above to improve the behavior of students and clients. By contrast, very little work has examined the complementary effect of client behavior change on the behavior

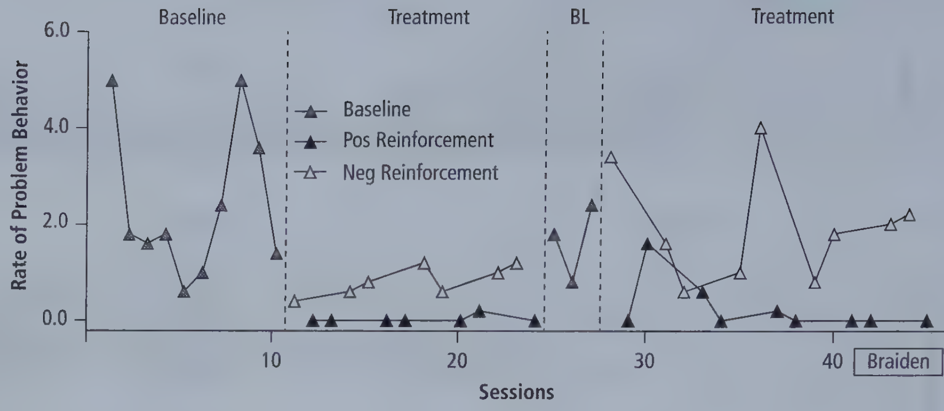

Figure 12.10 The rate of problem behavior during baseline and treatment conditions (left) and the percentage of compliance during baseline and treatment conditions (right) across sessions. (*Note*: This graph shows results for one of the study' five subjects).

From "A comparison of positive and negative reinforcement for compliance to treat problem behavior maintained by escape." by S. K. Slocum and T. R. Vollmer, 2015, *Journal of Applied Behavior Analysis*. Reproduced with permission of John Wiley & Sons,Inc.

of the agent (teacher, therapist, etc.), yet this relation may reflect an important negative reinforcement contingency. When a teacher implements a behavior change procedure that results in a reduction of problem behavior, teacher behavior has terminated an aversive event. This type of relation may strengthen any behavior—inappropriate as well as appropriate—that has the same effect, a possibility suggested by results from descriptive studies of teacher behavior (Addison & Lerman, 2009; Sloman et al., 2005).

Negative reinforcement effects have been examined more directly in two experimental simulations. Miller, Lerman, and Fritz (2010) observed seven teachers in training who were instructed to teach a variety of skills to a "student" (role played by a research assistant). The student engaged in problem behavior at prearranged times throughout sessions and either stopped when the teacher delivered a reprimand (negative reinforcement condition) or continued to engage in problem behavior regardless of the teacher's behavior (extinction). Results showed that student behavior had a clear effect on teacher behavior in that the rate of reprimands was higher during the negative reinforcement condition. The authors also reported that three of the teachers terminated their participation in the study during an extinction condition, which provided further evidence that "problem behavior" was an aversive event. Using a similar methodology, Thompson, Bruzek, and Cotnoir-Bichelman (2011) observed 11 undergraduate students during simulated caretaking sessions in which the student interacted with a "baby" (a doll). An experimenter presented a recorded infant cry at the beginning of sessions and terminated the cry contingent on different caregiver responses (horizontal rocking, vertical rocking, simulated feeding, playing) in different conditions. Results generally showed persistence of responses that were "effective" in terminating crying and extinction of responses that no longer were effective.

Data from this line of research have several implications. First, the occurrence of problem behavior appears to be an EO for caregiver escape and avoidance and is likely to occasion any caregiver response that is effective in terminating it, ranging from active (delivering a reprimand) to passive (limiting social interaction) responding. Second, this fact underscores the importance of instructing parents and teachers in appropriate behavior management strategies to prevent the emergence of inappropriate ones. Finally, the maintenance of newly taught therapeutic skills may be more than a function of the quality of training; an equally important determinant may be how successful those skills are in quickly solving problems.

ETHICAL CONSIDERATIONS IN USING NEGATIVE REINFORCEMENT

Ethical concerns about the use of positive and negative reinforcement arise primarily from the severity of the antecedent event (EO) that occasions the target behavior. Many EOs for behavior maintained by positive reinforcement can be characterized as deprivation states, which, if severe, can constitute undue restriction of rights. By contrast, EOs for behavior maintained by negative reinforcement are, by definition, aversive events. Extremely noxious events, when presented as antecedent stimuli, cannot be justified as part of a typical behavior change program.

Another concern with negative reinforcement is that the presence of aversive stimuli can itself generate behaviors that compete with the acquisition of desired behavior (Hutchinson, 1977; Myer, 1971). For example, a socially withdrawn child, when placed in the midst of others, may simply scream and run away instead of playing with the peers, and running away is incompatible with social interaction. Finally, undesirable side effects typically associated with punishment (see Chapter 14) might also be observed when implementing behavior change programs based on negative reinforcement.

SUMMARY

Definition of Negative Reinforcement

1. Negative reinforcement involves the termination, reduction, or postponement of a stimulus contingent on the occurrence of a response, which leads to an increase in the future occurrence of that response.

2. A negative reinforcement contingency involves (a) an establishing operation (EO) in whose presence escape is reinforcing, (b) a discriminative stimulus (S^D) in whose presence a response is more likely to be reinforced, (c) the response that produces reinforcement, and (d) termination of the event that served as the EO.

3. Positive and negative reinforcement are similar in that both lead to an increase in responding; they differ in that positive reinforcement involves contingent stimulus presentation, whereas negative reinforcement involves contingent stimulus termination.

4. Negative reinforcement and punishment differ in that (a) negative reinforcement involves contingent stimulus termination, whereas punishment involves contingent stimulation, and (b) negative reinforcement leads to an increase in responding, whereas punishment leads to a decrease in responding.

Escape and Avoidance Contingencies

5. An escape contingency is one in which responding terminates an ongoing stimulus. An avoidance contingency is one in which responding delays or prevents the presentation of a stimulus.

6. In discriminated avoidance, responding in the presence of a signal prevents stimulus presentation; in free-operant avoidance, responding at any time prevents stimulus presentation.

Characteristics of Negative Reinforcement

7. Any response that successfully terminates aversive stimulation will be strengthened; as a result, a wide range of behaviors may be acquired and maintained by negative reinforcement.

8. Negative reinforcement may play an important role in the development of academic skills, but it can also account for the development of disruptive or dangerous behavior.

9. Unconditioned negative reinforcers are stimuli whose removal strengthens behavior in the absence of prior learning. Conditioned negative reinforcers are stimuli whose removal strengthens behavior as a result of previous pairing with other negative reinforcers.

10. Social negative reinforcement involves stimulus termination through the action of another person. Automatic negative reinforcement involves stimulus termination as a direct result of a response.

11. Identification of negative reinforcers requires the specification of the stimulus conditions in effect prior to and following responding.

12. In general, negative reinforcement for a given response will be more effective when (a) the stimulus change immediately follows the occurrence of the target response, (b) the magnitude of reinforcement is large, (c) the target response consistently produces escape from or postponement of the EO, and (d) reinforcement is unavailable for competing responses.

Applications of Negative Reinforcement

13. Although negative reinforcement is a fundamental principle of learning that has been studied extensively in basic research, applied behavior analysis has heavily emphasized the use of positive reinforcement over negative reinforcement.

14. Applied researchers have explored the therapeutic uses of negative reinforcement in treating pediatric feeding problems.

15. Improvements in student performance as a result of error correction that involves repeating a learning trial, having the student practice correct performance, or giving the student additional work may be a function of negative reinforcement.

16. The presentation of task demands during instruction may function as an EO for escape; initial forms of escape may include lack of attention or mild forms of disruption. To the extent that positive reinforcement for compliance is less than optimal, escape behaviors may persist and may even escalate.

17. Extinction of behavior maintained by negative reinforcement involves *not* allowing a response to avoid or terminate its programmed consequence.

18. One strategy for treating problem behaviors maintained by negative reinforcement is to strengthen a more socially appropriate replacement behavior through negative reinforcement.

19. Results of some research have shown that interventions based on positive reinforcement also can be effective as treatment for problem behavior maintained by negative reinforcement.

Changes in Teacher and Caregiver Responding as a Function of Negative Reinforcement

20. Another dimension of negative reinforcement involves effects on caregiver behavior. Student problem behavior serves as an EO teacher escape and avoidance, and teacher responses to problem behavior are maintained by negative reinforcement.

Ethical Considerations in Using Negative Reinforcement

21. Ethical concerns about the use of positive and negative reinforcement are similar and arise from the severity of the antecedent event (EO) that occasions behavior. Most EOs for behavior maintained by negative reinforcement can be viewed as aversive events. Extremely noxious events, when presented as antecedent stimuli, cannot be justified as part of a typical behavior change program.

22. Another concern with negative reinforcement is that the presence of aversive stimuli can itself generate behaviors that compete with the acquisition of desired behavior.

KEY TERMS

avoidance contingency
conditioned negative reinforcer
discriminated avoidance
escape contingency
free-operant avoidance
negative reinforcement
unconditioned negative reinforcer

MULTIPLE-CHOICE QUESTIONS

1. Negative reinforcement can be defined as: Stimulus _______________, contingent upon a response, which _______________ the future probability of that response.

a. Presented, increases

b. Presented, decreases

c. Removed, increases

d. Removed, decreases

Hint: (See "Definition of Negative Reinforcement")

2. Which of the following is an example of a negative reinforcement contingency?

a. Jo is sitting near a window at Starbucks and having a cup of coffee. The sun is streaming in the window, and it is too warm for Jo—she is beginning to perspire. Jo moves to another chair away from the window, where it is shady. The next time Jo goes to Starbucks, she sees the sun shining in the window again and sits in the chair in the shade instead.

b. Frank often goes to Starbucks for coffee as well. After receiving his coffee, he sits down in his seat. It is 9:00 am, and Starbucks is very busy. Most of the tables are full. As a result, a smart woman approaches Frank and asks if she can share his table. Frank agrees, and the woman sits down and has coffee with Frank. Frank decides he will come to Starbucks at 9:00 am for coffee more often in the future.

c. Cheryl loves coffee. She orders a coffee at Starbucks but burns her mouth on it because it is too hot. After a couple of occurrences of this, Cheryl stops coming to Starbucks for coffee.

d. Sam was walking to Starbucks for coffee. On his way, he lost his wallet to a pickpocket. Sam no longer walks to that Starbucks for coffee.

Hint: (See "Definition of Negative Reinforcement")

3. Mary Jo decides to implement a negative reinforcement intervention with one of her students, Anjali, to increase the amount of work Anjali completes. Mary Jo tells Anjali, "If you complete 15 math problems today (Monday), you don't have to do your math worksheet on Friday." What is one problem that might arise with this intervention?

a. Reinforcement is available for a competing behavior.

b. There is little difference in the stimulus conditions before the response (completing work) occurs and after the response occurs.

c. The stimulus change following the occurrence of target behavior is not immediate.

d. Mary Jo is being inconsistent in her delivery of reinforcement.

Hint: (See "Determinants of Negative Reinforcement Effects")

4. Unlike assessments for identifying positive reinforcers, assessments for negative reinforcers must place equal emphasis on _______________ as well as the consequence events for target behavior.

a. The EO or antecedent event

b. The future occurrence of the target behavior

c. The stimulus

d. Punishment

Hint: (See "Identifying the Context of Negative Reinforcement")

5. The key difference between an escape contingency and an avoidance contingency is:

a. In an escape contingency, the future probability of the target behavior increases, while the future probability of the target behavior decreases with an avoidance contingency.

b. In an escape contingency, the EO is present prior to the occurrence of the target behavior, while in an avoidance contingency, the EO is not present prior to the occurrence of the target behavior.

c. In an escape contingency, the EO is not present prior to the occurrence of the target behavior, while in an avoidance contingency, the EO is present prior to the occurrence of the target behavior.

d. In an escape contingency, there is a warning stimulus that signals an aversive stimulus is imminent, while in an avoidance contingency, there is no such warning stimulus.

Hint: (See "Escape and Avoidance Contingencies")

6. Which of the following is an example of free-operant avoidance?

a. Jackie crosses the street when she sees Donna come around the corner on the next block so that she doesn't have to talk to her.

b. Lavonda puts on a bicycle helmet when she rides her bike so that she doesn't hurt her head if she falls off her bike.

c. Nathaniel puts down the hurricane shutters on his Florida home when he hears that a tropical storm is approaching so that his windows do not break.

d. All of these

Hint: (See "Escape and Avoidance Contingencies")

7. Which of the following behaviors could be maintained by negative reinforcement?

a. Completing school work.

b. Cleaning a bedroom

c. Tantrums

d. All of these

Hint: (See "Characteristics of Negative Reinforcement")

8. An unconditioned negative reinforcer:

a. Is one that began as a neutral stimulus

b. Acquired its aversive qualities by being paired with another aversive stimulus

c. Is one that strengthens behavior in the absence of prior learning

d. Can be thought of as an inherited negative reinforcer

e. Third and fourth choices

Hint: (See "Characteristics of Negative Reinforcement")

9. The textbook describes a study by Ahearn and colleagues (1996), in which negative reinforcement was used to increase food acceptance in children. In this example, during baseline, bite acceptances produced access to toys and bite refusals produced removal of the spoon (negative reinforcement). During the intervention, bite refusals no longer produced removal of the spoon. Instead, the spoon was only removed if a bite was accepted. As soon as a bite was accepted and every time a bite was accepted, the spoon was briefly removed. Which factors that are important to consider for effectively changing behavior with negative reinforcement are illustrated in this example?

a. The stimulus change following the occurrence of the target behavior was immediate.

b. The difference in stimulation prior to and after the response occurred was large.

c. The occurrence of the target response consistently produced escape.

d. Reinforcement was unavailable for competing responses.

e. All of these

f. None of these

Hint: (See "Factors That Influence the Effectiveness of Negative Reinforcement")

10. The study by Rodgers and Iwata (1991) that analyzed the effects of positive reinforcement, error correction procedures, and an avoidance procedure demonstrated that:

a. Error correction procedures may produce learning, at least in part, due to an avoidance contingency.

b. Positive reinforcement was the most effective procedure for producing correct performance.

c. Error correction procedures and avoidance procedures produced the most correct responding.

d. All of these

e. None of these

Hint: (See "Applications of Negative Reinforcement")

11. Ethical concerns about the use of negative reinforcement stem from:

a. Having to deprive the individual of positive reinforcement for an extended period of time

b. The presence of antecedent aversive stimuli in the individual's environment

c. The potential for creating a context that generates undesired behaviors

d. The presentation of aversive stimuli contingent upon a target behavior displayed by an individual

e. Second and third choices

Hint: (See "Ethical Considerations in Using Negative Reinforcement")

12. The potential negative side effects (e.g., crying, running away) of negative reinforcement are similar to the side effects associated with:

a. Positive Reinforcement

b. Punishment

c. Stimulus Control

d. All of these

e. None of these

Hint: (See "Ethical Considerations in Using Negative Reinforcement")

ESSAY-TYPE QUESTIONS

1. Write the definition of negative reinforcement and provide an example of negative reinforcement that has not been discussed in class or presented in the textbook. When giving your example, write it in the form of the diagrams found in the textbook, and be sure to include all four components of the diagram.

   Hint: (See "Definition of Negative Reinforcement")

2. What are some stimuli that might serve as negative reinforcers? Identify at least one negative reinforcer that is unconditioned and one negative reinforcer that is conditioned. Then, select one and show how that negative reinforcer could be used to teach a behavior (the behavior can either be socially appropriate or socially inappropriate). Use the diagramming notation presented in class to illustrate the negative reinforcement contingency.

   Hint: (See "Characteristics of Negative Reinforcement")

3. What is the key difference between an escape contingency and an avoidance contingency?

   Hint: (See "Escape and Avoidance Contingencies")

4. Explain the difference between social negative reinforcement and automatic negative reinforcement.

   Hint: (See "Characteristics of Negative Reinforcement")

5. What are four things you can do to increase the effectiveness of negative reinforcement?

   Hint: (See "Determinants of Negative Reinforcement Effects")

6. You are working with a child with autism, who engages in problem behavior to escape completing daily living tasks, such as washing his hands before lunch. You would like to teach this student to politely say, "Don't want to wash hands," rather than to throw tantrums when told to wash his hands. You set up an instructional program where you will make several hand-washing requests throughout the day in order to provide the child with opportunities to practice saying "Don't want to wash hands." Each time the child makes this request, you allow him to escape washing his hands. What are the ethical issues that might arise from such a plan and how can you plan for and/or decrease these negative effects?

   Hint: (See "Ethical Issues in Using Negative Reinforcement")

NOTES

1. The term *aversive* is not meant to describe an inherent characteristic of a stimulus but, rather, a stimulus whose presentation functions as punishment or whose removal functions as negative reinforcement.

CHAPTER 13

Schedules of Reinforcement

LEARNING OBJECTIVES

- Define schedule of reinforcement.
- Define continuous reinforcement.
- Define intermittent reinforcement.
- Be able to identify the importance of naturally occurring reinforcement.
- Identify the two main intermittent schedules of reinforcement.
- Compare and contrast fixed and variable ratio schedules.
- Explain the fixed ratio schedule consistency of performance.
- Explain the phenomenon of a post-reinforcement pause.
- Explain and define a variable ratio.
- Explain and describe fixed interval schedules of reinforcement.
- Explain and define variable interval schedules of reinforcement.
- Be able to define and explain the variables associated with "ratio strain."
- Identify four variations of basic intermittent schedules of reinforcement.

A **schedule of reinforcement** is a rule that describes a contingency of reinforcement, the environmental arrangements that determine conditions by which behaviors will produce reinforcement. Continuous reinforcement and extinction provide the boundaries for all other schedules of reinforcement. A schedule of **continuous reinforcement (CRF)** provides reinforcement for each occurrence of behavior. For example, a teacher using a continuous schedule of reinforcement would praise each occurrence of a correctly identified sight word emitted by a student. Examples of behaviors that tend to produce continuous reinforcement include turning on a water faucet (water comes out), turning on a light switch in a dark room (a light comes on), and putting money into a vending machine (a product is obtained). During extinction (EXT), no occurrence of the behavior produces reinforcement. (For a detailed description of extinction, see Chapter 24.)

INTERMITTENT REINFORCEMENT

Between continuous reinforcement and extinction, many **intermittent schedules of reinforcement (INT)** are possible in which some, but not all, occurrences of the behavior are reinforced. Only selected occurrences of behavior produce reinforcement with an intermittent schedule of reinforcement. CRF is used to strengthen behavior, primarily during the initial stages of learning new behaviors. INT is used to maintain an established behavior, especially during maintenance stages of learning.

Maintenance of Behavior

Maintenance of behavior refers to a lasting change in behavior. Regardless of the type of behavior change technique employed or the degree of success during treatment, applied behavior analysts must be concerned with sustaining gains after terminating a treatment program. For example, Zofia is in the seventh grade and taking French, her first foreign language class. After a few weeks, the teacher informs Zofia's parents that she is failing the course. The teacher believes that Zofia's problems in French have resulted from lack of daily language practice and study. The parents and teacher decide that Zofia will record a tally on a chart kept on the family bulletin board each evening that she studies French for 30 minutes. Zofia's parents praise her practice and study accomplishments and offer encouragement. During a follow-up meeting 3 weeks later, the parents and teacher decide that Zofia has done so well that the tally procedure can be stopped. Unfortunately, a few days later Zofia is once again falling behind in French.

A successful program was developed to establish daily French language practice. However, gains were not maintained after removing the tally procedure. The parents and the teacher did not establish intermittent reinforcement procedures. Let us review what happened and what could have happened. Continuous reinforcement was used correctly to develop daily study behavior. However, after the study behavior was established and the tally procedure removed, the parents should have continued to praise and encourage daily practice and

gradually offer fewer encouragements. The parents could have praised Zofia's accomplishments after every second day of daily practice, then every fourth day, then once per week, and so on. With the intermittent praise, Zofia might have continued daily practice after removing the tally procedure.

Progression to Naturally Occurring Reinforcement

A major goal of most behavior change programs is the development of naturally occurring activities, stimuli, or events to function as reinforcement. It is more desirable for people to read because they like to read, rather than to obtain contrived reinforcement from a teacher or parent; to engage in athletics for the enjoyment of the activity, rather than for a grade or because of a physician's directive; to help around the house for the personal satisfaction it brings, rather than to earn an allowance. Intermittent reinforcement is usually necessary for the progression to naturally occurring reinforcement. Even though some individuals spend hours each day practicing a musical instrument because they enjoy the activity, chances are good that this persistent behavior developed gradually. At first, the beginning music student needs a great deal of reinforcement to continue the activity: "You really practiced well today," "I can't believe how well you played," "Your mother told me you received a first place in the contest—that's super!" These social consequences are paired with other consequences from teachers, family members, and peers. As the student develops more proficiency in music, the outside consequences occur less frequently, intermittently. Eventually, the student spends long periods making music without receiving reinforcement from others because making music has itself become a reinforcer for doing that activity.

Some might explain the transition of our music student from an "externally reinforced person" to a "self-reinforced musician" as the development of intrinsic motivation, which seems to imply that something inside the person is responsible for maintaining the behavior. This view is incorrect from a behavioral standpoint. Applied behavior analysts describe intrinsic motivation as reinforcement that is received by manipulating the physical environment. Some individuals ride bicycles, go backpacking, read, write, or help others because manipulations of the environment provide reinforcement for engaging in those activities.

DEFINING BASIC INTERMITTENT SCHEDULES OF REINFORCEMENT

Ratio and Interval Schedules

Applied behavior analysts directly or indirectly embed ratio and interval intermittent schedules of reinforcement in most treatment programs, especially ratio schedules (Lattal & Neef, 1996). Ratio schedules require a number of responses before one response produces reinforcement. If the ratio requirement for a behavior is 10 correct responses, only the 10th correct response produces reinforcement. Interval schedules require an elapse of time before a response produces reinforcement. If the interval requirement is 5 minutes, reinforcement is contingent on the first correct response that occurs after 5 minutes has elapsed. Thereafter, reinforcement is contingent on the first correct response after 5 minutes has elapsed since the last reinforced response.

Ratio schedules require a number of responses to be emitted for reinforcement; an elapse of time does not change the number contingency. The participant's response rate determines the rate of reinforcement. The more quickly the person completes the ratio requirement, the sooner reinforcement will occur. Conversely, interval schedules require an elapse of time before a single response produces reinforcement. The total number of responses emitted on an interval schedule is irrelevant to when and how often the reinforcer will be delivered. Emitting a high rate of response during an interval schedule does not increase the rate of reinforcement. Reinforcement is contingent only on the occurrence of one response after the required time has elapsed. The availability of reinforcement is time-controlled with interval schedules, and rate of reinforcement is "self-controlled" with ratio schedules, meaning that the more quickly the individual completes the ratio requirement, the sooner reinforcement will occur.

Fixed and Variable Schedules

Applied behavior analysts can arrange ratio and interval schedules to deliver reinforcement as a fixed or a variable contingency. With a fixed schedule, the response ratio or the time requirement remains constant. With a variable schedule, the response ratio or the time requirement can change from one reinforced response to another. The combinations of ratio or interval and fixed or variable contingencies define the four basic schedules of intermittent reinforcement: fixed ratio, variable ratio, fixed interval, and variable interval.

SCHEDULE EFFECTS AND CONSISTENCY OF PERFORMANCE

The following sections define the four basic schedules of intermittent reinforcement, provide examples of each schedule, and present some well-established schedule effects derived from basic research.

Early experimental and applied behavior analysts (e.g., 1950–1970) reported similar consistencies of schedule effects among nonhuman animals and humans. Many behavior analysts today question the generality of the schedule effects presented in the next sections. This issue developed as an outcome of advancing research with human subjects, and the acceptance that humans—not nonhuman animals—have language. Verbal behavior allows humans to make and use rules that can influence their responses to schedules of reinforcement (i.e., rule-governed behavior). Jack Michael (1987) provides an example of a verbal rule controlling a schedule contingency.

> Humans differ behaviorally from nonhumans in one overwhelmingly significant way; humans have an extensive language repertoire which influences most aspects of their

> behavior. With the exception of very young children and the profoundly retarded the human subjects used in studies of the effects of complex contingencies have all had this language repertoire, and one would certainly expect it to play a role in determining the experimental results. One of my first attempts to study human behavior in a situation somewhat analogous to a nonhuman operant conditioning experiment involved a simple discrimination schedule. The human subject pressed a telegraph key and received—on a variable interval schedule—nickels as reinforcement. The VI schedule, however, was alternated with a period of extinction, and a light on the response panel was on when the VI schedule was in effect, and off when it was not. Only minimal instructions were given, and they did not mention the role of the light. My first subject pressed the telegraph key at a moderately high rate throughout the 30-minute session, and his rate during the light-off condition was no different than during the light-on condition. When he finished his session I asked him to tell me as much as he could about what he was doing. He stated that he received nickels for pressing the telegraph key—not for every press, but once in a while, and never when the light was off. I asked him why he continued to press when the light was off. He said he thought that maybe I was trying to see if he was a persistent type of person, one who would continue trying even though success seemed unlikely, and he wanted to show me that he was exactly that type of person.
>
> His explanation was quite reasonable, at least in its suggestion of the possible role of his social history and language repertoire, but I certainly did not interpret this event as a challenge to the generality of the effect of discrimination training on behavior. (pp. 38–39)

As you study the schedule effects sections that follow, recognize that participants' performance on schedules of reinforcement arranged in applied settings may differ considerably from that predicted by basic laboratory research as rule-governed behavior. Always remember, however, Michael's concluding comment on generality in the above quote. (See also "Perspectives on Using Schedules of Reinforcement in Applied Settings: Applied Research with Intermittent Schedules" in this chapter.)

Fixed Ratio Defined

A **fixed ratio (FR)** schedule of reinforcement requires the completion of a fixed number of responses for a reinforcer. For example, every fourth correct (or target) response produces reinforcement on an FR 4 schedule. An FR 15 schedule requires 15 responses to produce reinforcement. Skinner (1938) conceptualized each ratio requirement as a response unit. Accordingly, the response unit produces the reinforcer, not just the last response of the ratio.

Some business and industrial tasks are paid on an FR schedule (e.g., piecework). A worker might receive a pay credit after completing a specified number of tasks (e.g., assembling 15 pieces of equipment or picking a box of oranges). A student might receive either a happy face after learning 5 new sight words or a certain number of points after completing 10 math problems.

Jeffries, Crosland, and Miltenberger (2016) assessed the effectiveness of the tablet application *Look in My Eyes Steam Train* and differential reinforcement. During the tablet condition, a child looked into eyes on the iPad to see a number, and then picked a matching number on a grid. If the numbers matched, "a piece of coal appeared on the screen and a praise statement was provided by the [iPad] narrator." The interactive Steam Train game appeared on the tablet screen for 1 minute after the child received four pieces of coal. This example combined CRF and FR 4 schedules of reinforcement. Each correct number match produced a piece of coal and praise. Following four correct matches, the child received 1 minute of screen time to play the Steam Train game. (see also "Tandem Schedules" in this chapter under "Compound Schedules of Reinforcement").

Fixed Ratio Schedule Effects

Consistency of Performance

FR schedules produce a typical pattern of responding: (a) After the first response of the ratio requirement, the participant completes the required responses with little hesitation between responses; and (b) a **postreinforcement pause** follows reinforcement (i.e., the participant does not respond for a period following reinforcement). The *size of the ratio* and the *reinforcement magnitude* can influence the duration of the postreinforcement pause (Powell, 1969; Schlinger, Derenne, & Baron, 2008): Large ratio requirements may produce long pauses; small ratios produce short pauses. Lower reinforcement magnitudes—an inverse relation to the large ratio—may produce long pauses "indicating that magnitude and ratio size interact to determine the extent of pausing" (Schlinger et al., 2008, p. 43). Following the pause, the participant again completes the fixed ratio with little hesitation between responses. Analysts often identify this characteristic of FR responding as a *break-and-run* pattern.

Rate of Response

FR schedules often produce high rates of response. Quick responding on FR schedules maximizes the delivery of reinforcement because the higher the rate of response, the greater the rate of reinforcement. People work rapidly with a fixed ratio because they receive reinforcement upon completion of the ratio requirements.

The size of the ratio can influence the rate of response on FR schedules. To a degree, the larger the ratio requirement, the higher the rate of response. A teacher could reinforce every third correct answer to arithmetic facts. With this ratio requirement, the student might complete 12 problems within the specified time, producing reinforcement four times. The student might complete more problems in less time if the teacher arranged reinforcement contingent on 12 correct answers rather than 3. The higher ratio is likely to produce a higher rate of response. The rate of response decreases, however, if the ratio requirements are too large. The maximum ratio is determined in part by the participant's past FR history of reinforcement, motivating operations, the quality and magnitude of the reinforcer, and the

procedures that change the ratio requirements. For example, if ratio requirements are raised gradually over an extended period, extremely high ratio requirements can be reached.

Figure 13.1 depicts and summarizes the schedule effects typically produced by FR schedules of reinforcement.

Variable Ratio Defined

A **variable ratio (VR)** schedule of reinforcement requires the completion of a variable number of responses to produce a reinforcer. A number representing the average (e.g., mean) number of responses required for reinforcement identifies the VR schedule. For example, with a VR 10 schedule every 10th correct response on the average produces reinforcement. Reinforcement can come after 1 response, 14 responses, 5 responses, 19 responses, or *n* responses, but the average number of responses required for reinforcement is 10 (e.g., $1 + 14 + 5 + 19 + 11 = 50$; $50/5 = 10$).

The operation of a slot machine, the one-armed bandit, provides a good example of a VR schedule. These machines are programmed to pay off only a certain proportion of the times they are played. A player cannot predict when the next operation of the machine will pay off. The player might win 2 or 3 times in succession and then not win again for 20 or more plays.

De Luca and Holborn (1992) examined the effects of a VR schedule on three obese and three nonobese children's rate of pedaling an exercise bicycle. The children could use the exercise bicycle Monday to Friday during each week of the analysis, but received no encouragement to do so. The participants received the instruction to "exercise as long as you like" to initiate the baseline condition. De Luca and Holborn introduced the VR schedule of reinforcement after establishing a stable baseline rate of pedaling. They calculated the baseline mean number of pedal revolutions per minute and programmed the first VR contingency at approximately 15% faster pedaling than the baseline mean. The children received points on the VR schedule to exchange for backup reinforcers. De Luca and Holborn increased the VR schedule in two additional increments by approximately 15% per increment. All participants had systematic increases in their rate of pedaling with each VR value, meaning that the larger the variable ratio, the higher the rate of response. De Luca and Holborn reported that the VR schedule produced higher rates of response than did the FR schedule in their previous study (De Luca & Holborn, 1990). Figure 13.2 presents the participants' performances under baseline and VR (i.e., VR ranges of 70 to 85, 90 to 115, 100 to 130) conditions.

Student behaviors usually produce reinforcement following the completion of variable ratios. Normally a student cannot predict when the teacher will call on him to give an answer and thereby receive reinforcement. Good grades, awards, and promotions all may come after an unpredictable number of responses. And in checking seatwork, the teacher might reinforce a student's work after the completion of 10 tasks, another student's work after 3 tasks, and so on.

Variable Ratio Schedule Effects

Consistency of Performance

VR schedules produce consistent, steady rates of response. They typically do not produce a postreinforcement pause, as do FR schedules. Perhaps the absence of pauses in responding is due to the absence of information about when the next response will produce reinforcement. Responding remains steady because the next response may produce reinforcement.

Rate of Response

Like the FR schedule, the VR schedule tends to produce a quick rate of response. Also similar to the FR schedule, the size of the ratio influences the rate of response. To a degree, the larger the ratio requirement, the higher the rate of response. Again like FR schedules, when variable ratio requirements are thinned gradually over an extended period, participants will respond to extremely high ratio requirements. Figure 13.3 summarizes the schedule effects typically produced by VR schedules of reinforcement.

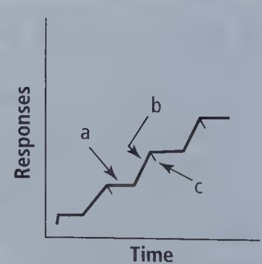
Variable Ratio Schedules in Applied Settings

Basic researchers use computers to select and program VR schedules of reinforcement. In applied settings, VR schedules are seldom implemented with a planned and systematic approach. In other words, the reinforcer is delivered by chance, hit or miss

Definition: Reinforcement delivered contingent on emission of a specified number of responses.

Schedule Effects:
After reinforcement a postreinforcement pause occurs. After the pause the ratio requirement is completed with a high rate of response and very little hesitation between responses. The size of the ratio influences both the pause and the rate.

Stylized Graphic Curve of Cumulative Responses:



a = postreinforcement pause
b = high rate of response "run"
c = reinforcer delivered upon emission of n^{th} response

Figure 13.1 Summary of FR schedule effects during ongoing reinforcement.

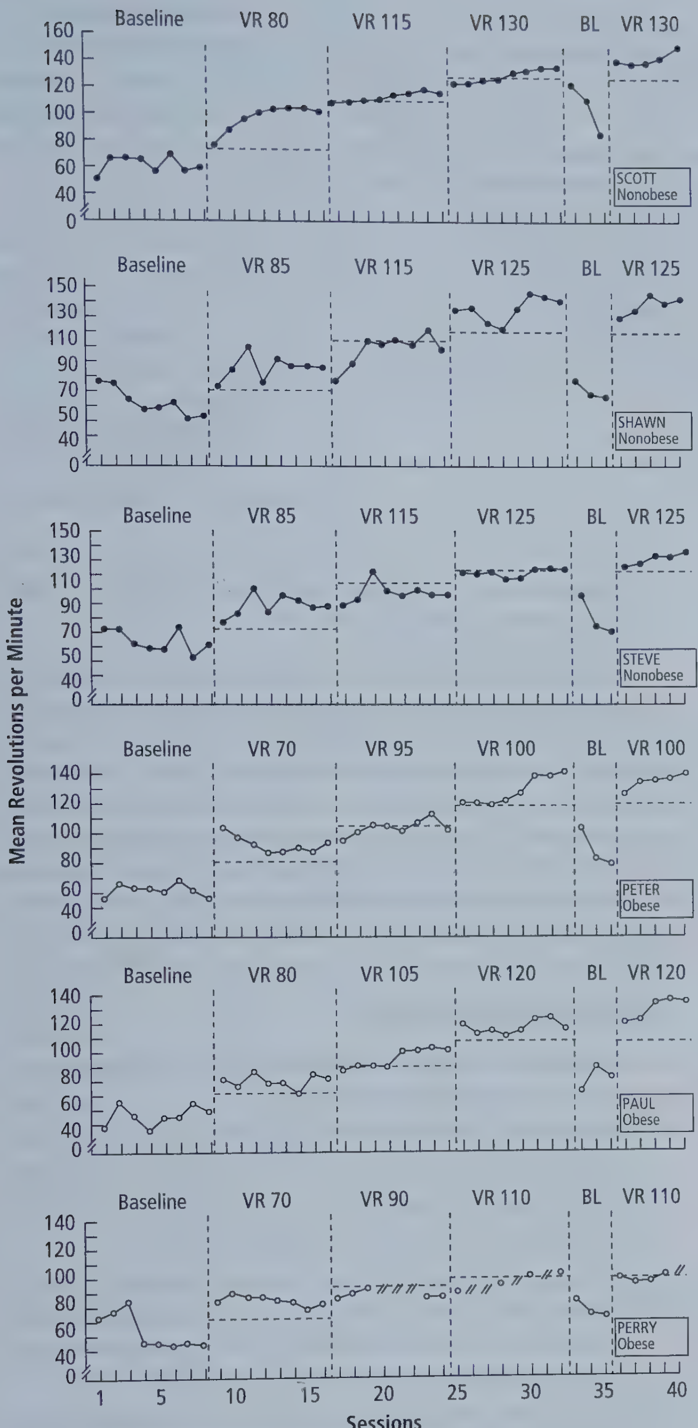


Figure 13.2 Mean revolutions per minute during baseline, VR 1 (VR range, 70 to 85), VR 2 (VR range, 90 to 115), and VR 3 (VR range, 100 to 130), return to baseline, and return to VR 3 phases for obese and nonobese subjects.

"Effects of a Variable-Ratio Reinforcement Schedule with Changing Criteria on Exercise in Obese and Nonobese Boys", R. V. De Luca and S. W. Holborn, 1992, Reproduced with permission of John Wiley and Sons Inc.

in most interventions. This nonsystematic delivery of reinforcement is not an effective use of VR schedules. Teachers can select and preplan VR schedules that approximate the VR schedules used in basic research. For example, teachers can plan variable ratios by (a) selecting a maximum ratio for a given activity (e.g., 15 responses) and (b) using a table of random numbers to produce the specific variable ratios for the schedule of reinforcement. A table of random numbers might generate the following sequence of ratios: 8, 1, 1, 14, 3, 10, 14, 15, and 6, producing a VR 8 schedule of reinforcement (on the average each eighth response produces the reinforcer) with the ratios ranging from 1 to 15 responses.

Teachers can apply the following VR procedures as individual or group contingencies of reinforcement for academic or social behavior:

Tic-Tac-Toe VR Procedure

1. The teacher establishes a maximum number for the individual student or group. The larger the maximum number selected, the greater the odds against meeting the contingency. For example, 1 chance out of 100 has less chance of being selected than 1 chance out of 20.
2. The teacher gives the individual or group a tic-tac-toe grid.

Definition: Reinforcer is delivered after the emission of a variable number of responses.

Schedule Effects: Ratio requirements are completed with a very high rate of response and little hesitation between responses. Postreinforcement pauses are not a characteristic of the VR schedule. Rate of response is influenced by the size of the ratio requirements.

Stylized Graphic Curve of Cumulative Responses:

a = high, steady rate of responding
b = reinforcement delivered after a varying number of required responses are emitted

Figure 13.3 Summary of VR schedule effects during ongoing reinforcement.

3. Students fill in each square of the grid with a number no greater than the maximum number. For example, if the maximum number is 30, the score sheet might look like this:

1	20	13
3	5	30
7	11	6

4. The teacher fills a box or some other type of container with numbered slips of paper (with numbers no higher than the maximum number). Each number should be included several times—for example, five 1s, five 2s, five 3s.
5. Contingent on the occurrence of the target behavior, students withdraw one slip of paper from the box. If the number on the paper corresponds to a number on the tic-tac-toe sheet, the students mark out that number on the grid.
6. The reinforcer is delivered when students have marked out three numbers in a row—horizontally, vertically, or diagonally.

For example, a student might withdraw one slip of paper for each homework assignment completed. Selecting an activity from the class job board (e.g., teacher's helper, collecting milk money, running the projector) could serve as the consequence for marking out three numbers in a row.

Classroom Lottery VR Procedure

1. Students write their names on index cards after successfully completing assigned tasks.
2. Students put signature cards into a box located on the teacher's desk.
3. After an established interval of time (e.g., 1 week), the teacher draws a signature card from the box and declares that student the winner. The lottery can have first, second, and third place, or any number of winners. The more cards students earn, the greater is the chance that one of their cards will be picked.

Teachers have used classroom lotteries with a variety of student accomplishments, such as reading non-assigned books. For example, for each book read, students write their names and the title of the book they have read on a card. Every 2 weeks the teacher picks one card from the box and gives the winning student a new book. To make the book an especially desirable consequence, the teacher lets students earn the privilege of returning the book to the school, inscribed with the student's name, class, and date (e.g., *Brian Lee, fifth grade, donated this book to the High Street Elementary School Library on May 8, 2019*).

Desk Calendar VR Procedure

1. Students receive desk calendars with loose-leaf date pages secured to the calendar base.
2. The teacher removes the loose-leaf date pages from the calendar base.
3. The teacher establishes a maximum ratio for the students.
4. The teacher numbers index cards consecutively from 1 to the maximum ratio. Multiple cards are included for each number (e.g., five 1s, five 2s). If a large average ratio is desired, the teacher includes more large numbers; for small average ratios, the teacher uses smaller numbers.
5. The teacher uses a paper punch to punch holes in the index cards for attaching the cards to the calendar base.
6. The teacher or student shuffles the index cards to quasi-randomize the order and attaches the index cards to a calendar base face down.
7. Students produce their own VR schedules by turning over one index card at a time. After meeting that ratio requirement, students flip the second card to produce the next ratio, and so on.

Students can use the desk calendar base to program VR schedules for most curriculum areas (e.g., arithmetic facts). For example, after receiving an arithmetic worksheet, the student flips the first card. It has a 5 written on it. After completing

five problems, she holds up her hand to signal her teacher that she has completed the ratio requirement. The teacher checks the student's answers, provides feedback, and presents the consequence for correct problems. The student flips the second card; the ratio requirement is 1. After completing that single problem, she receives another consequence and flips the third card. This time the ratio is 14. The cycle continues until all of the cards in the stack are used. New cards can then be added or old cards reshuffled to create a new sequence of numbers. The average of the numbers does not change in the reshuffling. (See Kauffman, Cullinan, Scranton, & Wallace, 1972, for a description of using a deck of playing cards, mounted on a refillable calendar base, to create FR and VR schedules of reinforcement that function in most environments.)

Fixed Interval Schedules

A **fixed interval (FI)** schedule of reinforcement provides reinforcement for the first response following a fixed duration of time. With an FI 3-min schedule, the first response following the elapse of 3 minutes produces the reinforcer. A common procedural misunderstanding with the FI schedule is to assume that the elapse of time alone is sufficient for the delivery of a reinforcer, assuming that the reinforcer is delivered at the end of each fixed interval of time. However, more time than the fixed interval can elapse between reinforced responses. The reinforcer is available after the fixed time interval has elapsed, and it remains available until the first response. When the first response occurs sometime after the elapse of a fixed interval, that response is immediately reinforced, and the timing of another fixed interval is usually started with the delivery of the reinforcer. This FI cycle is repeated until the end of the session.

Examples of FI schedules in everyday life are difficult to find. However, some situations do approximate and in reality function as FI schedules. For example, mail is often delivered close to a fixed time each day. An individual can make many trips to the mailbox to look for mail, but only the first trip to the mailbox following the mail delivery will produce reinforcement. Many textbook examples of FI schedules, such as the mail example, do not meet the definition of an FI schedule; but the examples do appear similar to an FI schedule. For example, receiving a paycheck as wages for work by the hour, day, week, or month is contingent on the first response on payday that produces the paycheck. Of course, earning the paycheck requires many responses during the interval that eventually lead to receiving the paycheck. In a true FI schedule, responses during the interval do not influence reinforcement.

FI schedules are relatively easy to use in applied settings. A teacher could make reinforcement available on an FI 2-min schedule for correct answers on an arithmetic worksheet. The teacher or student could use an electronic timer with a countdown function to signal the elapse of the 2-minute interval. The student's first correct answer following the interval produces reinforcement, and then the teacher resets the timer for another 2-minute interval. Similarly, the teacher could use a timing app or MotivAider® (www.habitchange.com) that vibrates to signal the elapse of an interval.

Fixed Interval Schedule Effects

Consistency of Performance

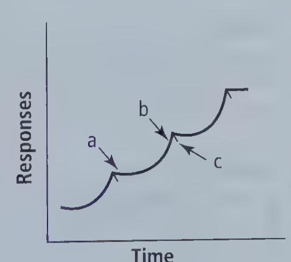
FI schedules typically produce a postreinforcement pause in responding during the early part of the interval. An initially slow but accelerating rate of response is evident toward the end of the interval, usually reaching a maximum rate just before delivery of the reinforcer. This gradually accelerating rate of response toward the end of the interval is called an *FI scallop* because of the rounded curves that are shown on a cumulative graph (see Figure 13.4).

FI postreinforcement pause and scallop effects can be seen in many everyday situations. When college students are assigned a term paper, they typically do not rush to the library and start to work on the paper immediately. More often they wait a few days or weeks before starting to work. However, as the due date approaches, their work on the assignment increases in

Definition: The first response after a designated and constant amount of time produces the reinforcer.

Schedule Effects: FI schedules generate slow to moderate rates of responding with a pause in responding following reinforcement. Responding accelerates toward end of the interval.

Stylized Graphic Curve of Cumulative Responses:



a = postreinforcement pause
b = increase in response rates as interval progresses and reinforcer becomes available
c = reinforcer delivered contingent on first correct response after interval

Figure 13.4 Summary of FI schedule effects during ongoing reinforcement.

an accelerating fashion, and many are typing the final draft just before class. Cramming for a midterm or final examination is another example of the FI scallop effect.

These examples with the reinforcement pause and scallop effects appear to be produced by FI schedules of reinforcement. They are not, however, because like the paycheck example, college students must complete many responses during the interval to produce the term paper or a good grade on the examinations, and the term paper and examinations have deadlines. With FI schedules, responses during the interval are irrelevant, and FI schedules have no deadlines for the response.

Why does an FI schedule produce a characteristic pause and scallop effect? After adjustment to an FI schedule, participants learn (a) to discriminate the elapse of time and (b) that responses emitted right after a reinforced response are never reinforced. Therefore, extinction during the early part of the interval might account for the postreinforcement pause. The effects of FI and FR schedules of reinforcement are similar in that both schedules produce postreinforcement pauses. However, it is important to recognize the different characteristics of behavior that emerge under each schedule. Responses under an FR schedule are emitted at a consistent rate until completing the ratio requirement, whereas responses under an FI schedule begin at a slow rate and accelerate toward the end of each interval.

Rate of Responding

Overall, FI schedules tend to produce a slow to moderate rate of response. The duration of the time interval influences the postreinforcement pause and the rate of response; to a degree, the larger the fixed interval requirement, the longer the postreinforcement pause and the lower the overall rate of response.

Variable Interval Schedules

A **variable interval (VI)** schedule of reinforcement provides reinforcement for the first correct response following the elapse of variable durations of time. The distinguishing feature of VI schedules is that "the intervals between reinforcement vary in a random or nearly random order" (Ferster & Skinner, 1957, p. 326). Behavior analysts use the average (i.e., mean) interval of time before the opportunity for reinforcement to describe VI schedules. For example, in a VI 5-min schedule the average duration of the time intervals between reinforcement and the opportunity for subsequent reinforcement is 5 minutes. The actual time intervals in a VI 5-min schedule might be 2 minutes, 5 minutes, 3 minutes, 10 minutes, or *n* minutes (or seconds).

Variable Interval Schedule Effects

Consistency of Performance

A VI schedule of reinforcement tends to produce a constant, stable rate of response. The slope of the VI schedule on a cumulative graph appears uniform with few pauses in responding (see Figure 13.5). A VI schedule typically produces few hesitations between responses. For example, pop quizzes at unpredictable times tend to occasion more consistent study behavior from students than do quizzes scheduled at fixed intervals of time. Furthermore, students are less apt to engage in competing off-task behaviors during instructional and study periods when a pop quiz is likely. The pop quiz is used often as an example of a VI schedule because the performance effect is similar to a VI performance. The pop quiz does not represent a true VI schedule, however, because of the required responses during the interval, and the deadline for receiving reinforcement.

Rate of Responding

VI schedules of reinforcement tend to produce low to moderate rates of response. Like the FI schedule, the average duration of the time intervals on VI schedules influences the rate of response; to a degree, the larger the average interval, the lower the overall rate of response. Figure 13.5 summarizes the schedule effects typically produced by VI schedules during ongoing reinforcement.

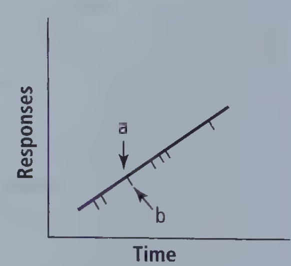
Variable Interval Schedules in Applied Settings

Basic researchers use computers to select and program VI schedules of reinforcement, as they do with VR schedules. Teachers seldom apply VI schedules in a planned and systematic way. For example, a teacher might set an electronic countdown timer with varied intervals of time ranging from 1 minute to 10 minutes

Definition: The first response following varying intervals of time produces the reinforcer.

Schedule Effects: VI schedules generate slow to moderate response rates that are constant and stable. There are few, if any, post-reinforcement pauses with VI schedules.

Stylized Graphic Curve of Cumulative Responses:



a = steady response rate; few, if any, postreinforcement pauses
b = reinforcer delivered

Figure 13.5 Summary of VI schedule effects during ongoing reinforcement.

without any prior plan as to which intervals or which order will be used. This set-them-as-you-go selection of intervals approximates the basic requirements for a VI schedule; however, it is not the most effective way of delivering reinforcement on a VI schedule. A planned, systematic application of varied intervals of time should increase the effectiveness of a VI schedule.

For example, applied behavior analysts can select the maximum time interval, whether in seconds or minutes, that will maintain performance and still be appropriate for the situation. Preferably, applied behavior analysts will use data from a direct assessment to guide the selection of the maximum VI interval, or at the least clinical judgment based on direct observation. Analysts can use a table of random numbers to select the varied intervals between 1 and the maximum interval, and then identify the VI schedule by calculating an average value for the VI schedule. The VI schedule may need adjustments following the selection of time intervals. For example, if a larger average interval of time appears reasonable, the teacher can replace some of the smaller intervals with larger ones. Conversely, if the average appears too large, the teachers can replace some of the higher intervals with smaller ones.

Interval Schedules with a Limited Hold

When a **limited hold** is added to an interval schedule, reinforcement remains available for a finite time following the elapse of the FI or VI interval. The participant will miss the opportunity to receive reinforcement if a targeted response does not occur within the time limit. For example, on an FI 5-min schedule with a limited hold of 30 seconds, the first correct response following the elapse of 5 minutes is reinforced, but only if the response occurs within 30 seconds after the end of the 5-minute interval. If no response occurs within 30 seconds, the opportunity for reinforcement has been lost and a new interval begins. The abbreviation LH identifies interval schedules using a limited hold (e.g., FI 5-min LH 30-sec, VI 3-min LH 1-min). Limited holds with interval schedules typically do not change the overall response characteristics of FI and VI schedules beyond a possible increase in rate of response.

Martens, Lochner, and Kelly (1992) used a VI schedule of social reinforcement to increase academic engagement of two 8-year-old boys in a third-grade classroom. The classroom teacher reported that the boys had serious off-task behaviors. The experimenter wore an earphone connected to a microcassette recorder that played a fixed-time cueing tape. During baseline, the cueing tape was programmed for a VI 20-sec schedule of reinforcement with a 0-sec limited hold for the availability of reinforcement. If the boys were not academically engaged when the 20-second interval timed out, they lost that opportunity for reinforcement until the next cue. Following baseline, the experimenter delivered contingent praise on VI 2-min or VI 5-min schedules of reinforcement that alternated daily on a quasi-random basis. Both boys' academic engagement on the VI 5-min schedule resembled their baseline engagement (see Figure 13.6). When the VI 2-min schedule was in effect, both students were academically engaged at consistently higher levels than they were during baseline or the VI 5-min condition.

Figure 13.7 summarizes and compares the four basic intermittent schedules of reinforcement.

THINNING INTERMITTENT REINFORCEMENT

Applied behavior analysts often use one of two procedures for **schedule thinning**. First, they thin an existing schedule by gradually increasing the response ratio or the duration of the time

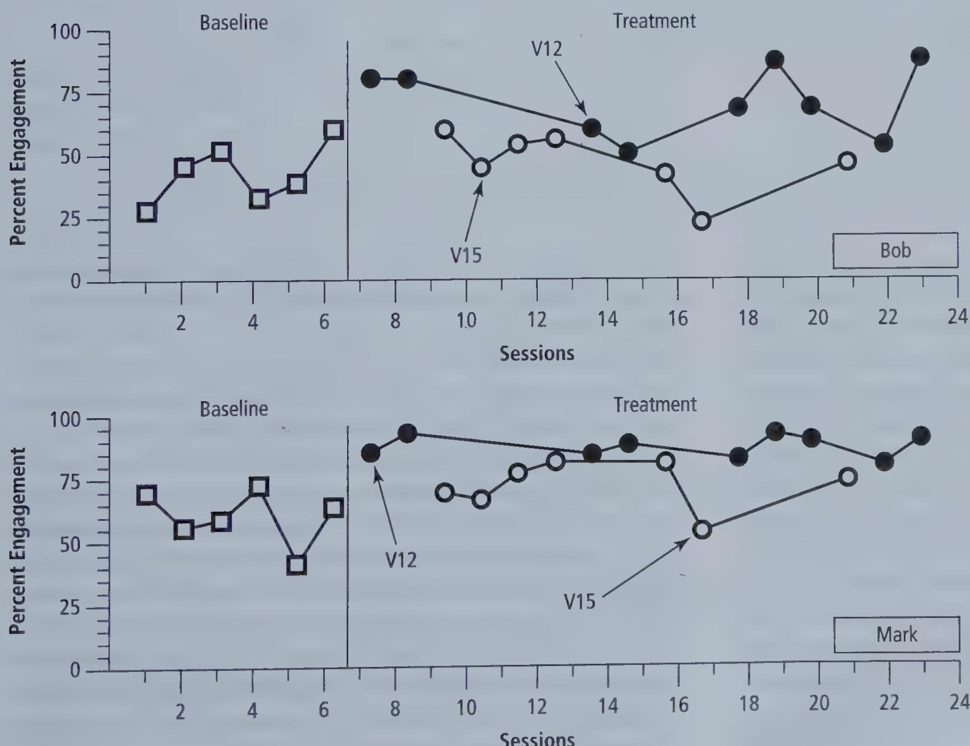


Figure 13.6 Academic engagement for two third-grade boys during baseline (VI 20-sec LH 0-sec) and treatment conditions with VI 2-min and VI 5-min schedules.

"The Effects of Variable-Interval Reinforcement on Academic Engagement: A Demonstration of Matching Theory", B. K. Martens, D. G. Lochner, and S. Q. Kelly, 1992, Reproduced with permission of John Wiley and Sons Inc.

Figure 13.7 Four basic intermittent schedules of reinforcement compared.

Schedule	Schedule Effects	Graphic Depiction
Fixed ratio (FR)—reinforcement follows a fixed number of responses (c)	• High overall rate of responding • Postreinforcement pause (a) • Then a *break-and-run* pattern of responding with little hesitation between responses (b) • Maximum ratio affected by past FR history of reinforcement, motivating operations, reinforcer quality, and changes in ratio requirements • Abrupt, large increases in FR size may generate ratio strain (avoidance, aggression, unpredictable pauses in responding)	Variable ratio (VR)—reinforcement follows a variable number of responses (b)	• High, steady rate of responding (a) • No postreinforcement pause • High VR response requirements can be attained by gradually thinning the schedule	Fixed interval (FI)—reinforcement follows the first response after a fixed amount of time has elapsed since the previous reinforced response (c)	• Low to moderate overall rate of responding • Postreinforcement pause (a) • Response rate accelerates (b) as end of the interval approaches, producing a scallop effect • Longer FI intervals produce the longer postreinforcement pauses and lower overall response rates	Variable interval (VI)—reinforcement follows the first response after a variable amount of time has elapsed since the previous reinforced response (b)	• Consistent, stable rate of responding (a) • No postreinforcement pause • Low to moderate rates of responding • Longer mean intervals produce lower overall response rates	
interval. If a student has answered addition facts effectively and responded well to a CRF schedule for two or three sessions, the teacher might thin the reinforcement contingency slowly from one correct addition fact (CRF) to a VR 2 or VR 3 schedule. The student's performance should guide the progression from a dense schedule (i.e., responses produce frequent reinforcement) to a thin schedule (i.e., responses produce less frequent reinforcement). Applied behavior analysts should use small increments of schedule changes during thinning and ongoing evaluation of the learner's performance to adjust the thinning process and avoid the loss of previous improvements.

Second, teachers often use instructions to clearly communicate the schedule of reinforcement, facilitating a smooth transition during the thinning process. Instructions include rules, directions, and signs. Participants do not require an awareness of environmental contingencies for effective intermittent reinforcement, but instructions may enhance the effectiveness of interventions when participants are told what performances produce reinforcement.

Ratio strain can result from abrupt increases in ratio requirements when moving from denser to thinner reinforcement schedules. Also, ratio strain will occur when the ratio becomes so large that the reinforcement cannot maintain the response level, or the response requirement exceeds the participant's physiological capabilities. Common behavioral characteristics associated with ratio strain include avoidance, aggression, and unpredictable pauses in responding. Applied behavior analysts should reduce the ratio requirement when ratio strain is evident. The analyst can again gradually thin ratio requirements after recovering the behavior. Preemptively, small and gradual increases in ratio requirements help to avoid the development of ratio strain.

VARIATIONS ON BASIC INTERMITTENT SCHEDULES OF REINFORCEMENT

Schedules of Differential Reinforcement of Rates of Responding

Applied behavior analysts frequently encounter behavior problems that result from the rate that people perform certain behaviors. Responding too infrequently, or too often, may be detrimental to social interactions or academic learning. Differential reinforcement provides an intervention for behavior problems associated with rate of response. Differential reinforcement of particular rates of behavior is a variation of ratio schedules. Delivery of the reinforcer is contingent on responses occurring at a rate either higher than or lower than some predetermined criterion. The reinforcement of responses higher than a predetermined criterion is called **differential reinforcement of high rates (DRH)**. When responses are reinforced only when they are lower than the criterion, the schedule provides **differential reinforcement of low rates (DRL)**. DRH schedules produce a higher rate of responding. DRL schedules produce a lower rate of responding.

Applied behavior analysts use three definitions of DRH and DRL schedules. The first definition states that reinforcement is available only for responses that are separated by a given duration of time. This first definition is sometimes called spaced-responding DRH or spaced-responding DRL. An interresponse time (IRT) identifies the duration of time that occurs between two responses. IRT and rate of response are functionally related. Long IRTs produce low rates of responding; short IRTs produce high rates of responding. Responding on a DRH schedule produces reinforcement whenever a response occurs before a time criterion has elapsed. If the time criterion is 30 seconds, the participant's response produces reinforcement only when the IRT is 30 seconds or less.

Under the DRL schedule, a response produces reinforcement when it occurs after a time criterion has elapsed. If the stated DRL time criterion is again 30 seconds, a response produces reinforcement only when the IRT is 30 seconds or greater.

This first definition of DRH and DRL as IRT schedules of reinforcement has been used almost exclusively in laboratory settings. There are two apparent reasons for its lack of application in applied settings: (a) Most applied settings do not have sufficient automated equipment to measure IRT and to deliver reinforcement using an IRT criterion; and (b) reinforcement is delivered usually, but not necessarily, following each response that meets the IRT criterion. Such frequent reinforcement would disrupt student activity in most instructional settings. However, with greater use of computers for tutorial and academic response practice, opportunities should increase for using IRT-based schedules of reinforcement to accelerate or decelerate academic responding. Computers can monitor the pauses between academic responses and provide consequences for each response meeting the IRT criterion, with little disruption in instructional activity.

Based on the laboratory procedures for programming DRL schedules presented previously, Deitz (1977) labeled and described two additional procedures for using differential reinforcement of rates of responding in applied settings: full-session DRH or DRL and interval DRH or DRL. Deitz initially used the full-session and interval procedures as a DRL intervention for problem behaviors. The full-session and interval procedures, however, apply also for DRH.

A DRH full-session schedule provides reinforcement if the total number of responses during the session meets or exceeds a number criterion. If the participant emits fewer than the specified number of responses during the session, the behavior is not reinforced. The DRL full-session schedule is procedurally the same as the DRH schedule, except reinforcement is provided for responding at or below the criterion limit. If the participant emits more than the specified number of responses during the session, reinforcement is not delivered.

The interval definition for DRH and DRL schedules states that reinforcement is available only for responses that occur at a minimum or better rate of response over short durations of time during the session. To apply an interval DRH schedule, the analyst organizes the instructional session into equal intervals of time and dispenses a reinforcer at the end of each interval when the student emits a number of responses equal to, or greater than, a number criterion. The interval DRL schedule is procedurally like the DRH interval schedule, except that reinforcement is provided for responding at or below the criterion limit.

The **differential reinforcement of diminishing rates (DRD)** schedule provides reinforcement at the end of a predetermined time interval when the number of responses is less than a criterion that is gradually decreased across time intervals based on the individual's performance (e.g., fewer than five responses per 5 minutes, fewer than four responses per 5 minutes, fewer than three responses per 5 minutes). Deitz and Repp (1973) used a group DRD contingency to reduce off-task talking of 15 high school senior girls. They set the first DRD criterion limit at five or fewer occurrences of off-task talking during each 50-minute class session. The DRL criterion limits were then gradually reduced to three or fewer, one or fewer, and finally no responses. The students earned a free Friday class when they kept off-task talking at or below the DRD limit Monday through Thursday.

The previous example of a DRD schedule used a procedure identical to that described for the full-session DRL. DRD is also a procedural variation on interval DRL schedules described by Deitz (1977) and Deitz and Repp (1983). The typical procedure for using an interval DRL as an intervention for problem behavior provided reinforcement contingent on emitting one or no responses per brief interval. After the problem behavior stabilizes at the initial criterion, the analyst maintains the maximum criterion of one or no responses per interval, but increases the duration of the session intervals to further diminish the behavior. Increasing the duration of session intervals continues gradually until the problem behavior achieves a terminal low rate of responding.

Deitz and Repp (1983) programmed the interval DRL with a criterion greater than one response per interval, then gradually diminished the maximum number of responses per interval while the duration of the interval remained constant (e.g., fewer than five responses per 5 minutes, fewer than four responses per 5 minutes, fewer than three responses per 5 minutes, etc.). The DRD schedule and the interval DRL schedule that use a

maximum number criterion greater than one per interval are different terms for the same procedure. Full-session and interval DRL have a long history of application in applied behavior analysis. DRD offers applied behavior analysts a new, and perhaps improved, label for the interval DRL procedure. (For a detailed description of differential reinforcement of rates of response, see Chapter 25.)

Increasing Response Variability with Lag Schedules of Reinforcement

Response variability often sets the occasion for expanding important behavior repertoires such as developing problem-solving skills, improving language acquisition and communication behaviors, and facilitating enhanced academic and social behaviors. Behavior analysts consider response variability an operant and therefore sensitive to reinforcement contingencies (Neuringer, 2004; Page & Neuringer, 1985). A **lag schedule** of reinforcement is one method to increase response variability. Reinforcement on a lag schedule is contingent on a response differing in some predetermined way (e.g., different topography, different sequence) from one or more responses that preceded it. With a Lag 1 schedule, each response that differs from the prior response produces reinforcement. Reinforcement on a Lag 2 schedule is contingent on a response being different from the previous 2 responses, a Lag 3 requires a response to differ from the previous 3 responses, and so on. To produce reinforcement on a lag infinity schedule, a response must differ from all prior responses.

Wiskow and Donaldson (2016) used a lag schedule to promote varied naming of items in the categories of vegetable and animal. Three children demonstrating low levels of variability during initial testing served as participants. The children included two typically developing girls 3 and 4 years old, and a 6-year-old boy diagnosed with high-functioning autism.

> Lag 0. The therapist gave the initial instruction, "We are going to play the category game and see how many things you can think of. Wait quietly until it is your turn. When you tell me a correct answer, you will earn a token. Let's start with [category]." The therapist provided general feedback following an incorrect answer (e.g., "Nice try, but a banana is not a vegetable."). The therapist delivered specific praise (e.g., "Great! Lettuce is a vegetable!") and a token following correct responses. If the child did not respond, the therapist said nothing and moved on to the next child.
>
> Lag 1. We arranged a Lag 1 schedule only in the animal category. The therapist gave the following initial instruction in Lag 1 sessions: "We are going to play the category game and see how many things you can think of. Wait quietly until it is your turn. When you tell me an answer that is different than what someone else said, you will earn a token. Let's start with [category]." We did not include the first correct response in the lag schedule because this schedule required that a child's response be different than the immediately prior correct response. That is, in the Lag 1 condition, the first participant could say any correct response and receive praise and a token. Incorrect responses did not reset the schedule or factor into the schedule requirement and were not included when we calculated the percentage of variability (pp. 476–477).

Behavior analysts have increasingly addressed the importance of response variability in the development of verbal behavior (e.g., *intraverbals*, Contreras & Betz, 2016; *tacts*, Heldt & Schlinger, Jr., 2012; *phonemic variability*, Koehler-Platten, Grow, Schulze, & Bertone, 2013; *echoics*, Esch–J.W., Esch–B.E., & Love, 2009; [see also Chapter 18]). These researchers (and others) have demonstrated the effectiveness of Lag schedules on increasing variability with different behaviors, including verbal behavior and with other different categories of participants (e.g., age, gender, disability).

Heldt and Schlinger (2012) investigated the effects of a Lag 3 schedule on increasing variability and, importantly, on maintaining the increased variability. A 13-year-old boy with autism and fragile X syndrome and a 4-year-old boy with mild intellectual disability served as participants. During the Lag 3 schedule, the instructor began the 10 trials per session by (a) saying the participant's name, (b) presenting a picture with an array of images, and (c) saying "What do you see?" Reinforcement was provided when the fourth response differed from the previous three responses. "Therefore, for the first three responses, instructors utilized a reinforcement of different forms procedure, such as the one described by Goetz and Baer (1973). By the fourth response, the instructor implemented the Lag 3 schedule regardless of the prior four responses (i.e., whether they were all novel, all rote, all irrelevant responses, or some combination of those). On this schedule, the instructor ignored incorrect responses, no response within 5 s, or responses that did not differ from the previous three responses, and proceeded to the next trial (p. 133)." The follow-up occurred 3 weeks after termination of the Lag 3 sessions. The results showed that both participants increased variability in tacting during the Lag 3 sessions, and that variability in responding was maintained during a 3-week follow-up. (See also Lag schedule, Chapter 30.)

Progressive Schedules of Reinforcement

A **progressive schedule of reinforcement** systematically thins each successive reinforcement opportunity within the session independent of the participant's behavior. Progressive-ratio and delay to reinforcement (sometimes called *progressive interval, time-based progressive delay, delay fading*) schedules of reinforcement are used for reinforcer assessment and behavioral intervention.

Progressive-ratio Schedule of Reinforcement

In 1961, Hodos introduced a variation of the fixed ratio (FR) schedule of reinforcement that increased the ratio requirements in incremental steps within the session. For example, the participant begins the session on an FR 5 schedule of reinforcement, and receives reinforcement after emitting five responses. Following FR 5 responses and reinforcement, the schedule of reinforcement is now increased by some specified amount (e.g., from FR 5 to FR 10). Following the FR 10 responses

and reinforcement, the ratio would again increase (e.g., from FR 10 to FR 15). This pattern of increasing ratio requirements continues to the session end. Analysts change PR schedule requirements using (a) arithmetic progressions to add a constant number to each successive ratio or (b) geometric progressions to add successively a constant proportion of the preceding ratio (Lattal & Neef, 1996). These within-session changes define the **progressive-ratio (PR) schedule of reinforcement** (Poling, 2010; Roane, 2008; Schlinger et al., 2008).[1,2]

During the PR sessions, the ratios are typically increased to the "breaking point," when the participant stops responding. Comparing the breaking points and corresponding number of responses associated with each PR condition offers an assessment for the potency of a reinforcer. For example, Jerome and Sturmey (2008) had three adults with developmental disabilities complete verbal and pictorial assessments to identify staff preferences. Following the verbal and pictorial assessments, Jerome and Sturmey used a PR schedule to evaluate the reinforcer potency of interactions with preferred staff. The breaking points with the PR schedules were higher for all three adults under responses for positive social interactions with their preferred staff than with their nonpreferred staff.

> In addition to the use of break points as a measure of reinforcer efficacy, PR schedules are also characterized by the omission of a terminal schedule value. That is, PR schedule requirements typically increase throughout the course of a session until responding stops for a period of time (e.g., 5 min) or until a predetermined duration of the observation has been reached (a session cap). Thus, total response output (as opposed to response rate) and break-point values are the primary measures of interest when evaluating behavior with PR schedules. (Roane, 2008, p. 155)

In an article on the applied use of PR schedules, Roane (2008) recommended several areas for future research, including

- The initial ratio size
- The progression of the step-size ratios
- The influence of response topographies on PR schedule performance
- The likely interaction of increasing ratios and the values of reinforcer delivery
- Using PR schedules to evaluate the therapeutic effects of psychopharmacological treatments
- The use of translational research with PR schedules, linking applied and basic research

Words of Caution When Using PR Schedules

Poling (2010) identified the following concerns regarding PR schedules with protected populations and people with special needs.

> In applied research—at least, when *applied* is defined as proposed in Baer, Wolf, and Risley's (1968) seminal article—the potency of a scheduled reinforcer is important primarily with respect to whether or not that reinforcer can be arranged to improve a socially significant target behavior. How it affects behavior in other circumstances, even in the population of concern (e.g., children with autism), is of value only if (a) this information is easily obtained, so there is little cost for people with special needs; and (b) this information allows applied behavior analysts to predict the clinical utility of the scheduled reinforcer. PR schedules are not an especially quick way to scale reinforcer potency. In addition, exposure to long ratios (as when the breaking point is approached) is known to be aversive (e.g., Dardano, 1973). Therefore, members of protected populations should not be exposed to them unless there are clear offsetting benefits. To date, no such benefits have been demonstrated, and no compelling arguments for their existence have been provided. (p. 349).

Delay to Reinforcement Schedules

Applied behavior analysts have used delay to reinforcement schedules to develop self-control (e.g., Binder, Dixon, & Ghezzi, 2000; Dixon & Cummins, 2001). For example, Dixon and Holcomb (2000) used a delay schedule to develop cooperative work behaviors and self-control of six adults dually diagnosed with intellectual disabilities and psychiatric disorders. The adults participated in two groups composed of three men in Group 1 and three women in Group 2. During a natural baseline condition, the groups received instruction to exchange or share cards to complete a cooperative task of sorting playing cards into piles by categories (e.g., hearts with hearts). Dixon and Holcomb terminated a natural baseline session for the group when one of the adults stopped sorting cards.

The groups received points for working on the card-sorting task during the choice baseline condition and the self-control training condition. Groups exchanged their points earned for items such as soda pop or cassette players, ranging in values from 3 points to 100 points.

During the choice baseline conditions, the group's participants could choose an immediate 3 points before doing the card sorting or a delayed 6 points after sorting the cards. Both groups chose the immediate smaller number of points rather than the larger amount following a delay to reinforcement.

During self-control training, the participants were asked while working on a cooperative task, "Do you want 3 points now, or would you like 6 points after sorting the cards for Z minutes and seconds?" (pp. 612–613). The delay was initially 0 seconds for both groups. The progressive delay to reinforcement ranged from an increase of 60 seconds to 90 seconds following each session that the group performance met the exact criterion for number of seconds of task engagement. The terminal goals for the delay to reinforcement were 490 seconds for Group 1 and 772 seconds for Group 2. Both groups achieved these delay-to-reinforcement goals. Following the introduction of the progressive delay procedure, both groups improved their cooperative work engagement and the self-control necessary to select progressively larger delays to reinforcement that resulted in more points earned. Figure 13.8 shows the performance of both groups of adults during natural baselines, choice baselines, and self-control training conditions.

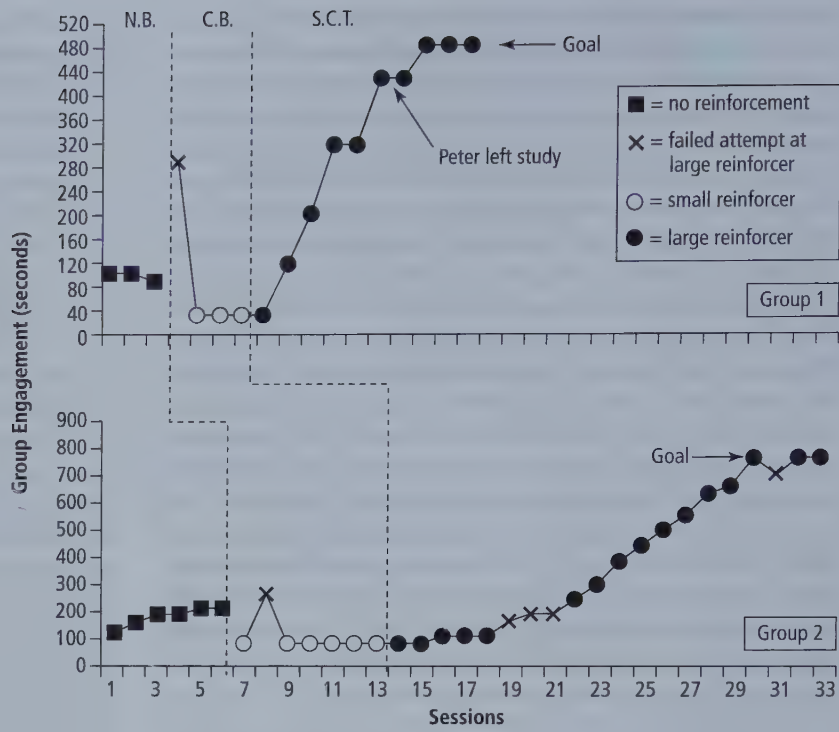

Figure 13.8 Number of seconds of engagement in the concurrent delay activity of cooperative card sorting during natural baseline (N.B.), choice baseline (C.B.), and self-control training (S.C.T.) for each group of participants. Filled circles represent performance at exactly the criterion level, and X data points represent the number of seconds of engagement below the criterion.

Applied behavior analysts often use functional communication training (FCT)—the most prescribed function-based intervention to reduce problem behavior (e.g., aggression, stereotypy, self-injurious behavior [SIB], making threats, elopement) (Greer, Fisher, Saini, Owen, & Jones, 2016). Resurgence may occur when FCT is discontinued (see Chapter 24), or with a rapid thinning of the schedule of reinforcement. If resurgence of a previously reduced problem behavior occurs, applied behavior analysts might apply a delay to reinforcement schedule.

For example, Stevenson, Ghezzi, & Valenton (2016) used FCT (Carr & Durand, 1985) and a delay to reinforcement schedule (called delay fading) to treat the elopement behavior of a 9-year-old boy with autism. The FCT began with a functional behavior assessment (see Chapter 27)—(a) to identify reinforcers and (b) to identify processes for accessing reinforcement with appropriate behavior. During FCT, the boy learned to ask appropriately for the identified reinforcers and his eloping decreased. Stevenson et al. applied the delay fading condition following the boy's behavioral improvements during the FCT condition. The delay fading method used a conjunctive FR 1/VI schedule of reinforcement.

> Throughout these sessions, when Damon [the child] asked for an item or activity (i.e., the FR 1 schedule), the tutor said, "You have to wait for now, so let's keep walking." The VI schedule began timing at this moment, and the first appropriate request that Damon made after the interval elapsed produced the relevant item or activity. The value of the VI component progressed through various phases, when no elopement occurred for three consecutive sessions, from VI 15 s to VI 30 s, VI 45 s, VI 90 s, and finally, VI 300 s. (Stevenson et al., 2016, p. 171)

The results from the FCT and delay fading conditions indicated that the child continued with enduring appropriate communication and low elopements. He learned to wait for desired activity. (See Conjunctive Schedules later in this chapter).

COMPOUND SCHEDULES OF REINFORCEMENT

Applied behavior analysts combine two or more basic schedules of reinforcement—continuous reinforcement (CRF), the four intermittent schedules of reinforcement (FR, VR, FI, VI), differential reinforcement of various rates of responding (DRH, DRL), and extinction (EXT)—to form **compound schedules of reinforcement**. The basic component schedules:

- can occur simultaneously or successively;
- can occur with or without discriminative stimuli; and
- make reinforcement contingent on meeting the response requirements of each component schedule independently, or contingent on meeting the response requirements of the combination of the compound schedules (Ferster & Skinner, 1957).

Concurrent Schedules

A **concurrent schedule (conc)** of reinforcement occurs when (a) two or more contingencies of reinforcement (b) operate independently and simultaneously (c) for two or more behaviors. Each schedule is correlated with a discriminative stimulus. People in the natural environment have opportunities for making choices among concurrently available events. For example, Sharon receives a weekly allowance from her parents, contingent on doing daily homework and cello practice. After school she can choose when to do homework and when to practice the cello, and

she can distribute her responses between these two simultaneously available schedules of reinforcement. Applied behavior analysts use concurrent schedules for reinforcer assessment and for behavioral interventions.

Using Concurrent Schedules for Reinforcer Assessment

Applied behavior analysts have used concurrent schedules extensively to provide choices during the assessment of consequence preferences and the assessment of response quantities (e.g., rate, latency, magnitude) and reinforcer quantities (e.g., rate, duration, immediacy, amount). Responding to concurrent schedules provides a desirable assessment procedure because (a) the participant makes choices, (b) making choices during assessment approximates the natural environment, (c) the schedule is effective in producing hypotheses about potential reinforcers operating in the participant's environment, and (d) these assessments require the participant to choose between stimuli rather than indicating a preference for a given stimulus (Adelinis, Piazza, & Goh, 2001; Neef, Bicard, & Endo, 2001; Piazza et al., 1999).

Roane, Vollmer, Ringdahl, and Marcus (1998) presented 10 items to a participant, 2 items at a time. The participant had 5 seconds to select 1 item by using a reaching response to touch the selected item. As a consequence for the selection, the participant received the item for 20 seconds. The analyst verbally prompted a response if the participant did not respond within 5 seconds, waiting another 5 seconds for the occurrence of a prompted response. Items were eliminated from the assessment (a) if they were not chosen during the first five presentations or (b) if they were chosen two or fewer times during the first seven presentations. The participant made a total of 10 choices among the remaining items. The number of selections out of the 10 opportunities served as a preference index. (See also "Concurrent Schedule Reinforcer Assessment" in Chapter 11.)

Using Concurrent Schedules for Intervention

Applied behavior analysts have used concurrent schedules extensively for improving vocational, academic, and social skills in applied settings (e.g., Cuvo, Lerch, Leurquin, Gaffaney, & Poppen, 1998; Reid, Parsons, Green, & Browning, 2001; Romaniuk et al., 2002). For example, Hoch, McComas, Johnson, Faranda, and Guenther (2002) arranged two concurrent response alternatives for three boys with autism. The boys could play in one setting with a peer or sibling, or play alone in another area. Hoch and colleagues manipulated the duration of access to toys (i.e., reinforcer magnitude) and preference (i.e., reinforcer quality). In one condition, the magnitude and quality of the reinforcer were equal in both settings. In the other condition, the magnitude and quality of the reinforcer were greater for play in the setting with a peer or sibling than in the play-alone setting. With the introduction of the condition with greater magnitude and quality of the reinforcer, the boys allocated more play responses to the setting with the peer or sibling, rather than playing alone. The magnitude and quality of the reinforcer influenced choices made by the three boys. Figure 13.9 reports the percentage of responses allocated to the concurrent play areas.

Concurrent Schedule Performances: Formalizing the Matching Law

Cuvo et al. (1998) reported that concurrent schedules typically produce two response patterns. With concurrent interval schedules (conc VI/VI, conc FI/FI), participants "typically do not allocate all of their responses exclusively to the richer schedule [i.e., the schedule producing the higher rate of reinforcement]; rather, they distribute their responding between the two schedules to match or approximate the proportion of reinforcement that is actually obtained on each independent schedule" (p. 43). Conversely, with concurrent ratio schedules (conc VR/VR, conc FR/FR), participants are sensitive to the ratio schedules and tend to maximize reinforcement by responding primarily to the ratio that produces the higher rate of reinforcement.

Williams (1973) identified three types of interactions found with concurrent schedules. First, when similar reinforcement is scheduled for each of the concurrent responses, the response receiving the higher frequency of reinforcement will increase in rate, whereas a corresponding decrease will occur in the response rate of the other behavior. Second, when one response produces reinforcement and the other produces punishment, responses associated with punishment will decrease in occurrence. That decrease may produce a higher rate of response for the behavior producing reinforcement. Third, with a concurrent schedule programmed for one response to produce reinforcement and the other response to produce avoidance of an aversive stimulus, the rate of avoidance responding will accelerate with an increase in the intensity or the frequency of the aversive stimulus. As avoidance responding accelerates, typically responding on the reinforcement schedule will then decrease.

The **matching law** addresses response allocation to choices available with concurrent schedules of reinforcement. Typically, the rate of responding is proportional to the rate of reinforcement received from each choice alternative. The characteristics of performance on concurrent schedules are consistent with the relationships formalized by Herrnstein (1961, 1970) and as detailed by Cuvo et al. (1998) and Williams (1973).

Discriminated Compound Schedules of Reinforcement

A discriminative stimulus (S^D) signals the presence of each component schedule in a discriminated compound schedule of reinforcement.

Multiple Schedules

A **multiple schedule (mult)** presents two or more basic schedules of reinforcement in an alternating, usually random, sequence. The basic schedules within the multiple schedule occur successively and independently. A discriminative stimulus is correlated with each basic schedule, and that stimulus is present as long as the schedule is in effect. Applied behavior analysts have used multiple schedules of reinforcement for diverse treatment conditions—for example, thinning dense schedules of reinforcement (Greer, Fisher, Saini, Owen, & Jones, 2016), facilitating the verbal skill of children with autism (e.g., Sidener, Shabani, Carr, &

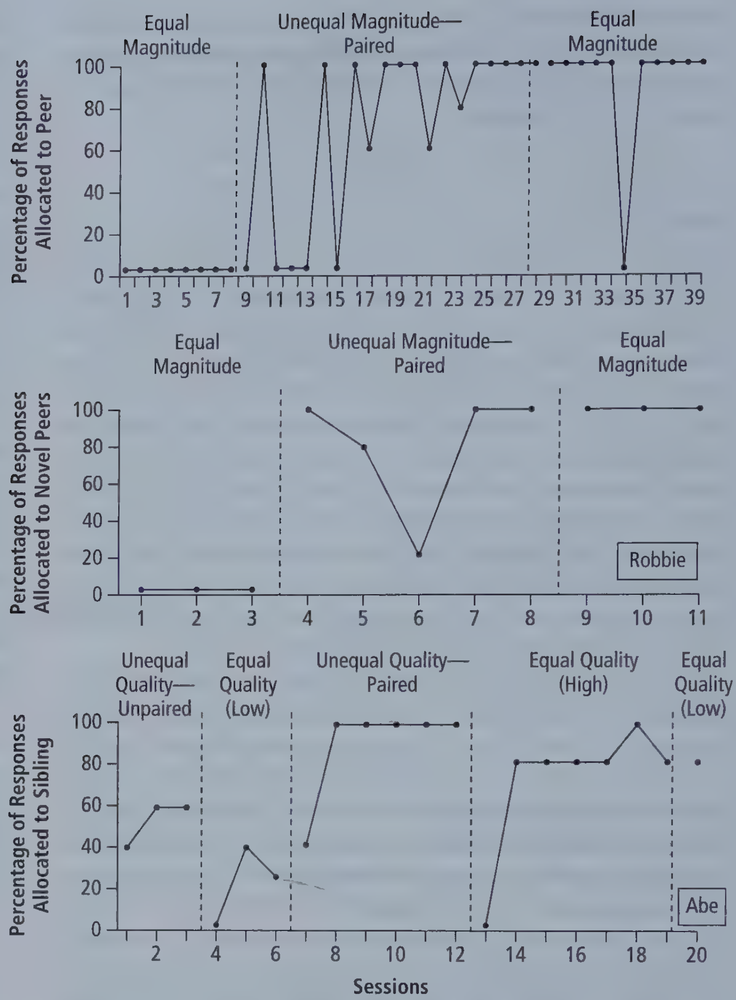

Figure 13.9 Percentage of responses allocated to the play area with the peer across experimental sessions (top panel) and in natural-setting probes with different peers in the classroom (middle panel) for analyzing the magnitude of reinforcement with Robbie, and the percentage of responses allocated to the play area with the sibling across experimental sessions for analyzing the quality of reinforcement with Abe (bottom panel).

"The Effects of Magnitude and Quality of Reinforcement on Choice Responding During Play Activities" by H. Hoch, J. J. McComas, L. Johnson, N. Faranda, and S. L. Guenther, 2002, Journal of Applied Behavior Analysis, Reproduced with permission of John Wiley and Sons Inc.

Roland, 2006), and reducing severe problem behavior (Neidert, Iwata, & Dozier, 2005). Academic behaviors also can become sensitive to the control of multiple schedules of reinforcement. For example, a student might respond to basic arithmetic facts with her teacher, and also with her tutor. With the teacher, the student responds to arithmetic facts during small-group instruction. The tutor then provides individual instruction and practice on the facts. This situation follows a multiple schedule because there is one class of behavior (i.e., math facts), a discriminative stimulus for each contingency in effect (i.e., teacher/tutor, small group/individual), and different conditions for reinforcement (i.e., reinforcement is less frequent in group instruction).

Tiger and Hanley (2005) used a three-component multiple schedule of reinforcement ($SR+/EXT_1/EXT_2$) to teach two preschool children how and when to recruit teacher attention at appropriate times. The children sat at individual tables with access to materials such as blocks and string beads. The analyst looked down except for giving contingent attention to one child's approach responses (SR+), while the other child's approach experienced extinction (EXT_1), and both children's approaching the analyst produced extinction (EXT_2). The analyst wore a red lei (discriminative stimulus) when attention was available for one child, a blue lei when attention was available to the other child, and a white lei when attention was not available to either child. "The purpose of the MULT condition was to determine if correlating stimuli with the availability (SR+) and unavailability (EXT_1 and EXT_2) of attention was sufficient to bring children's social approaches under stimulus control." (p. 502) The children demonstrated discriminated performances when—prior to the session—they received verbal reminders of the multiple schedule arrangements (cf. Tiger & Hanley, 2004; Tiger, Hanley, & Heal, 2006).

Torelli, Lloyd, Diekman, and Wehby (2016) extended Tiger and colleagues' (2004, 2005, 2006) line of research from preschool to elementary school classrooms. In the words of Torelli and colleagues, "The purpose of the current study was to evaluate the effects of a class-wide multiple schedule on differentiated rates of student recruitment of teacher attention in two public elementary classrooms. General education teachers implemented the multiple schedule intervention in the context of a common instructional routine (i.e., small group rotations among reading centers). Results indicated that the multiple schedule intervention was effective at decreasing disruptive bids for attention when teacher attention was not available" (p. 1).

To learn more about the use of multiple schedules in clinical assessment and treatment, see Saini, Miller, and Fisher (2016) and "Multiple Schedule Reinforcer Assessment" in Chapter 11.

Reynolds (1961) introduced the term **behavioral contrast** to describe the effects of (a) a schedule change that increases or decreases the rate of responding in one component of a multiple schedule of reinforcement, which is accompanied by (b) a change in the response rate in the opposite direction on another, unaltered component. That is, changing schedule requirements in one component may affect responding in other unaltered components (e.g., changing a mult FR 3/FI 30-sec to a mult FR 3/EXT may result in an increased rate of response in the FR component, the unaltered component).

For example, an analyst used the following intervention to decrease a student's disruptive behavior in the classroom and on the playground. She established an interval of time and delivered reinforcement at the end of the interval if the student had emitted no disruptive classroom behavior during the interval. With the occurrence of a disruptive behavior, the analyst immediately reset a timer, starting a new interval. The analyst introduced no intervention on playground behavior. This procedure effectively decreased the student's disruptive classroom behavior, and the number of playground disruptions remained low as well. With the effectiveness of differential reinforcement of other behavior (DRO; see Chapter 25), the analyst began to thin the classroom reinforcement schedule by extending the interval of time (e.g., 25-, 35-, and 45-min intervals). Schedule thinning effectively maintained the appropriate classroom behavior. However, the behavioral contrast of the increased occurrences of disruptive behavior on the playground surprised the analyst.

Although most research on behavioral contrast has been conducted with nonhuman subjects, Pierce and Epling (1995) concluded the phenomenon likely occurs in humans. We concur and advise applied behavior analysts to be aware of behavioral contrast effects in their practice.

Chained Schedules

A **chained schedule (chain)** is similar to a multiple schedule. The multiple and chained schedules have two or more basic schedule requirements that occur successively, and have a discriminative stimulus correlated with each independent schedule. A chained schedule differs from a multiple schedule in three ways. First, the basic schedules in a chain schedule always occur in a specific order, never in the random or unpredictable order of multiple schedules. Second, the behavior may be the same for all elements of the chain, or different behaviors may be required for different elements in the chain. Third, conditioned reinforcement for responding in the first element in a chain is the presentation of the second element; conditioned reinforcement for responding in the second element is presentation of the third element, and so on until all elements in the chain have been completed in a specific sequence. The last element normally produces unconditioned reinforcement in a laboratory setting, or unconditioned or conditioned reinforcement in applied settings.

Tarbox, Madried, Aguilar, Jacobo, and Schiff (2009) used two-component chain schedules (e.g., "mun" & "day" for "Monday"; "b" and "all" for "ball") to develop the echoic behavior of two children with autism and one child with developmental delay.

> During each chaining session, the therapist presented one echoic in three sequential trials as rapidly as feasible (i.e., the therapist presented a trial immediately after the completion of reinforcement for the previous trial). On the first trial, the therapist modeled the first component (e.g., "say 'mun'"). If the participant correctly imitated this component within 5 s, the therapist delivered reinforcement and immediately modeled the second component (e.g., "say 'day'"). If the participant imitated the second component correctly, the therapist delivered reinforcement, modeled the entire target echoic (e.g., "say 'Monday'"), and provided reinforcement for correct imitation. An incorrect response on any of the three trials resulted in a single repetition of that trial, after which the therapist resumed the sequence. (p. 903)

The following example shows an elaborate sequence of different behaviors that must occur in a specific order. To service a bicycle headset, the mechanic will complete a chain with 13 components: (1) Disconnect the front brake cable; (2) remove handlebar and stem; (3) remove front wheel; (4) remove locknut; (5) unscrew adjusting race; (6) take fork out of frame; (7) inspect races; (8) grease and replace bearing balls for lower stack; (9) grease and replace bearing balls for upper race; (10) grease threads of steering column; (11) put fork into frame and thread the screwed race; (12) return lock washer; (13) adjust and lock the headset. The final outcome (i.e., a clean, greased, and adjusted bicycle headset) is contingent on the completion of all 13 components. (For a detailed description of behavior chains and how applied behavior analysts help individuals learn new and more complex chains of behavior, see Chapter 23.)

Nondiscriminated Schedules of Reinforcement

Unlike with discriminated compound schedules of reinforcement, the presence of each component schedule in a nondiscriminated compound schedule of reinforcement is not associated with an S^D.

Mixed Schedules

A **mixed schedule of reinforcement (mix)** uses a procedure identical to that of the multiple schedules, except no discriminative stimuli signal the presence of the independent component schedules. For example, with a mix FR 10/FI 1 schedule, reinforcement sometimes occurs after the completion of 10 responses and sometimes occurs with the first response after a 1-minute interval from the preceding reinforcement.

The research of Tiger and Hanley (2005), presented in the section on multiple schedules, used a three-component mult schedule of reinforcement (SR+, EXT_1 and EXT_2) to teach preschool children how to recruit teacher attention at appropriate times. They also used a time-based rotation of those components without discriminative stimuli. This mix schedule (SR+, EXT_1, and EXT_2) "served as a baseline from which the influence of schedule-correlated stimuli on children's social approaches would be assessed." (p. 501)

Tandem Schedules

The **tandem schedule (tand)** operates like the chained schedule, except that discriminative stimuli are not used with the elements in the chain. In a tand FR 15/FI 2 schedule, after a participant makes 15 responses (FR 15), the first correct response following an elapse of 2 minutes (FI 2) produces reinforcement.

Jeffries et al. (2016) assessed the effectiveness of a CRF/FR 4 tandem schedule of reinforcement with children using an iPad platform. Essentially, a child examined a number (e.g., 7, 2) embedded within simulated eyes on the iPad with the direction to pick the matching number on a corresponding grid. If the number matched, a piece of coal appeared on the screen and a praise statement was emitted by the [iPad] narrator (CFR). After the child received four pieces of coal (FR 4), an interactive *Steam Train* game appeared, which the child was allowed to play for 1 min.

Although basic researchers have produced considerable data on the effects of mixed and tandem schedules, there is little applied research on these schedules. As applied behavior analysts continue to improve the science's knowledge base, how nondiscriminated compound schedules of reinforcement might contribute to assessment and intervention may become more apparent.

Schedules Combining Number of Responses and Time

Alternative Schedules

An **alternative schedule (alt)** provides an opportunity for reinforcement on two or more simultaneously available basic schedules of reinforcement. The first schedule completed provides reinforcement, regardless of which schedule component is met first. All schedule requirements start over following reinforcement. With an alt FR 50/FI 5-min schedule, reinforcement is delivered whenever either of these two conditions has been met: (a) 50 correct responses, provided the 5-minute interval of time has not elapsed; or (b) the first response after the elapse of 5 minutes, provided that fewer than 50 responses have been emitted.

For instance, a teacher using an alt FR 25/FI 3-min schedule of reinforcement assigns 25 math problems and assesses the student's correct and incorrect answers following the elapse of 3 minutes. If the student completes the 25 problems before the elapse of 3 minutes, the teacher checks the student's answers and provides a consequence consistent with the FR 25 schedule. However, if the ratio requirement of 25 math problems has not been completed after an elapse of 3 minutes, the first correct answer following the 3 minutes produces reinforcement. The alternative schedule offers the advantage of a second chance for reinforcement if the student has not met the FR requirement in a reasonable amount of time. The FI provides reinforcement for one response, and that one reinforced response might encourage continued responding with the new start of the FR requirement.

Conjunctive Schedules

A **conjunctive schedule (conj)** of reinforcement is in effect whenever reinforcement follows the completion of response requirements for two or more schedules of reinforcement. For example, a student behavior produces reinforcement when at least 2 minutes have elapsed and 50 responses have been made. This arrangement is a conj FI 2/FR 50 schedule of reinforcement. With the conjunctive schedule of reinforcement, the first response following the conclusion of the time interval produces reinforcement if the criterion number of responses has been completed.

A 14-year-old boy with autism had higher rates of aggression with two of his four therapists during instruction. The higher rates of aggression were directed toward the two therapists who previously worked with the boy at a different treatment facility. Progar et al. (2001) intervened to reduce the levels of aggression with the therapists from the different facility to the levels that occurred with the other two therapists in the current setting. The boy's aggression occurred in demand situations (e.g., making his bed) and was escape maintained. The initial intervention used three consequences: (1) a 10-minute chair time-out for attempts to choke, (2) escape extinction (see Chapter 24), and (3) differential reinforcement other behavior (DRO; see Chapter 25) for the omission of aggression during the 10-minute sessions. This intervention was identical to the treatment used with the boy at the other facility. It was ineffective in reducing the boy's aggression in the current setting.

Because of the ineffectiveness of the initial intervention, Progar and colleagues added a conj FR/VI-DRO schedule of reinforcement to their initial intervention. They delivered edible reinforcers contingent on completing a three-component task, such as dusting or straightening objects (i.e., an FR 3 schedule), and the omission of aggression for an average of every 2.5 minutes (i.e., a VI-DRO 150-sec). An occurrence of aggression reset the conj schedule. (*Note*: Resetting this conj schedule used a standard procedure because any occurrence of the problem behavior during a DRO interval immediately reset the time to the beginning of the interval.) Progar and colleagues demonstrated that the conj FR VI-DRO schedule produced a substantial reduction in aggression directed toward the two therapists previously from the other treatment facility.

Duvinsky and Poppen (1982) found that human performance on a conjunctive schedule is influenced by the ratio and interval requirements. When task requirements are high in relation to the interval requirements, people are likely to work steadily on the task throughout the time available. However, people are likely to engage in behaviors other than the task requirements when a large time interval and a low ratio requirement are present.

Table 13.1 describes and provides examples of the compound schedules of reinforcement presented above. Table 13.2 compares the defining dimensions of these schedules.

TABLE 13.1 Descriptions and Examples of Compound Schedules of Reinforcement

Discriminated Compound Schedules of Reinforcement

SCHEDULE	DESCRIPTION	EXAMPLE
Concurrent (conc)	Two or more schedules of reinforcement, each with a correlated S^D, operate independently and simultaneously for two or more behaviors.	A student is given two math worksheets, one blue with addition problems, one white with subtraction problems. The student can work on either or both types of problems, and earns a reinforcer for every 10 correct answers to addition problems and every 5 correct answers to subtraction problems. [conc FR 10/FR 5]
Multiple (mult)	Two or more basic schedules of reinforcement for the same behavior operate successively, usually in random sequence. An S^D is correlated with each component schedule. Reinforcement is delivered each time the response requirements are met for the schedule in effect.	During daily math practice activity, a student is given a blue worksheet or a white worksheet. Which color worksheet is assigned each day varies randomly. Regardless of color, each worksheet contains a mix of 100 addition problems. On blue worksheet days, the student earns a reinforcer for each 10 correct answers. On white worksheet days, the student receives a reinforcer each time he correctly answers a variable number (average, 5) of problems. [mult FR 10/VR 5]
Chained (chain)	Two or more basic schedules, each correlated with an S^D, operate in a specified sequence. The component schedules may require the same behavior or different behaviors. Meeting the response requirement in the first component presentation of the S^D for the second component must be accomplished, and so on until all elements in the chain have been completed. Completing the last element normally produces unconditioned or conditioned reinforcement in applied settings.	A student receives a worksheet containing 20 addition problems. When the student has correctly answered all of the problems, he receives a second worksheet, this one with 10 subtraction problems. After correctly answering the 10 subtraction problems, the student receives a reinforcer. [chain FR 20/FR 10]

Nondiscriminated Compound Schedules of Reinforcement

SCHEDULE	DESCRIPTION	EXAMPLE
Mixed (mix)	Two or more basic schedules are presented successively, usually in random sequence. Unlike with a multiple schedule, however, each component schedule is not signaled by an S^D.	A student is assigned daily math worksheets always of the same color. Sometimes the student receives a reinforcer after 10 correct answers; sometimes reinforcement follows the first correct answer after a 1-min interval has elapsed from the preceding reinforcement. [mix FR 10/FI 1]
Tandem (tand)	Two or more basic schedules operate in a specified sequence like a chained schedule. Unlike with a chained schedule, however, an S^D is not associated with each component schedule.	A student receives a worksheet with math problems. She earns a reinforcer for completing 15 problems, and then, the first problem completed after an elapse of 2 min also produces a reinforcer. [tand FR 15/FI 2]

Compound Schedules of Reinforcement Combining Number of Responses and Time

SCHEDULE	DESCRIPTION	EXAMPLE
Alternative (alt)	Reinforcement is obtained by meeting the response requirements of any of two or more simultaneously available component schedules. Reinforcement is delivered regardless of which schedule component is met. All component schedule requirements are reset following reinforcement.	A student receives a worksheet with math problems and is instructed to begin. If 15 correct answers are emitted prior to the elapse of 3 min, a reinforcer is delivered. If the FR requirement is not met after 3 min, the first correct answer from that time forward is reinforced. [FI 3-min/FR 15]
Conjunctive (conj)	Reinforcement follows the completion of response requirements for two or more simultaneously operating schedules of reinforcement.	A student receives a worksheet with math problems. After 15 problems have been answered correctly, the first correct answer after an elapse of 2 min produces reinforcement. [conj FR 15/FI 2]

TABLE 13.2 Defining Dimensions of Compound Schedules of Reinforcement

Dimension	Concurrent	Multiple	Chained	Mixed	Tandem	Alternative	Conjunctive
Number of component schedules	2 or more	2 or more	2 or more	2 or more	2 or more	2 or more	2 or more
Number of response classes involved	2 or more	1	1 or more	1	1 or more	1	1
Discriminative stimuli or cues for each component schedule	Possible	Yes	Yes	No	No	Possible	Possible
Successive presentation of component schedules	No	Yes	Yes	Yes	Yes	No	No
Simultaneous presentation of component schedules	Yes	No	No	No	No	Yes	Yes
Reinforcement limited to final component schedule	No	No	Yes	No	Yes	No	Yes
Must meet response requirements of each component schedule for reinforcement	Yes	Yes	No	Yes	No	Yes	No

PERSPECTIVES ON USING SCHEDULES OF REINFORCEMENT IN APPLIED SETTINGS

Applied Research with Intermittent Schedules

Basic researchers have systematically analyzed the effects of intermittent schedules of reinforcement on behavior (e.g., Ferster & Skinner, 1957). Their results have produced well-established schedule effects. These schedule effects have strong generality across many species, response classes, and laboratories. However, a review of the applied literature on schedule effects (e.g., *Journal of Applied Behavior Analysis*, 1968 to 2016) will show that applied behavior analysts have not embraced the analysis of schedule effects with enthusiasm, as have basic researchers. Consequently, schedule effects have not been documented clearly in applied settings. Uncontrolled variables in applied settings, such as the following, influence a participant's sensitivity and insensitivity to the schedule of reinforcement:

1. Instructions given by the applied behavior analyst, self-instructions, and environmental aids (e.g., calendars, clocks) make human participants resistant to temporal schedule control.
2. Past histories of responding to intermittent schedules of reinforcement can affect current schedule sensitivity or insensitivity.
3. Immediate histories from schedules of reinforcement may affect current schedule performances more than remote past histories.
4. Sequential responses required in many applied applications of intermittent schedules of reinforcement (e.g., work leading to the paycheck, studying for a pop quiz) are uncommon applications of schedules of reinforcement, particularly with interval schedules.
5. Uncontrolled establishing operations in conjunction with schedules of reinforcement in applied settings will confound schedule effects.

Some well-established schedule effects found in basic research were presented earlier in this chapter. Applied behavior analysts, however, should use caution in extrapolating these effects to applied settings, for the following reasons:

1. Most applied applications of schedules of reinforcement only approximate true laboratory schedules of reinforcement, especially the interval schedules that may occur rarely in natural environments (Nevin, 1998).
2. Many uncontrolled variables in applied settings will influence a participant's sensitivity and insensitivity to the schedule of reinforcement (Madden, Chase, & Joyce, 1998).

Applied Research with Compound Schedules

Although a considerable body of applied research on multiple, concurrent, and chained schedules has been reported, scant research exists on the effects of nondiscriminated compound schedules of reinforcement in applied settings. We encourage applied behavior analysts to explore the use of mixed, tandem, alternative, and conjunctive schedules. Doing so will reveal the effects of these compound schedules in applied settings and their interactions with other environmental variables (e.g., antecedent stimuli, motivating operations) (Lattal & Neef, 1996).

Applied Research with Adjunctive Behavior

This chapter has stressed the effects of schedules of reinforcement on the specific behaviors that produce reinforcement. Other behaviors can occur when an individual responds to a given contingency of reinforcement. These other behaviors occur independently of schedule control. Typical examples of such behaviors include normal time fillers, such as doodling, smoking, idle talking, and

drinking. Such behaviors are called **adjunctive behaviors**, or schedule-induced behaviors, when the frequency of these time-filling behaviors increases as a side effect of other behaviors maintained by a schedule of reinforcement (Falk, 1961, 1971).

A substantial body of experimental literature is available on many types of adjunctive behaviors with nonhuman subjects (see reviews: Staddon, 1977; Wetherington, 1982) and some basic research with human subjects (e.g., Kachanoff, Leveille, McLelland, & Wayner 1973; Lasiter, 1979). Common diverse examples of adjunctive behaviors observed in laboratory experiments include aggression, defecation, pica, and wheel running. Some common excessive human problem behaviors might develop as adjunctive behaviors (e.g., the use of drugs, tobacco, caffeine, and alcohol; overeating; nail biting; self-stimulation; and self-abuse). These potentially excessive adjunctive behaviors are socially significant, but the possibility that such excesses are developed and maintained as adjunctive behaviors has been essentially ignored in applied behavior analysis.

Foster (1978), in an extended communication to the readership of the *Journal of Applied Behavior Analysis*, reported that applied behavior analysts have neglected the potentially important area of adjunctive behavior. He stated that applied behavior analysis does not have a data or knowledge base for adjunctive phenomena. Similarly, Epling and Pierce (1983) called for applied behavior analysts to extend the laboratory-based findings in adjunctive behavior to the understanding and control of socially significant human behavior. To our knowledge, Lerman, Iwata, Zarcone, and Ringdahl's (1994) article provides the only research on adjunctive behavior published in the *Journal of Applied Behavior Analysis* from 1968 through 2016. Lerman and colleagues provided an assessment of stereotypic and self-injurious behavior as adjunctive responses. Data from this preliminary study suggest that intermittent reinforcement did not induce self-injury, but with some individuals, stereotypic behavior showed characteristics of adjunctive behavior.

Foster (1978) and Epling and Pierce (1983) cautioned that many teachers and therapists may apply interventions directly to adjunctive behaviors rather than to the variables functionally related to their occurrence. These direct interventions may be futile and costly in terms of money, time, and effort because adjunctive behaviors appear resistant to interventions using operant contingencies.

The condition under which adjunctive behaviors are developed and maintained is a major area for future research in applied behavior analysis. Applied research directed to adjunctive behaviors will advance the science of applied behavior analysis and will provide an important foundation for improved practices in therapy and instruction.

SUMMARY

Intermittent Reinforcement

1. A schedule of reinforcement is a rule that establishes the probability that a specific occurrence of a behavior will produce reinforcement.
2. Continuous reinforcement and extinction provide the boundaries for all other schedules of reinforcement.
3. Only selected occurrences of behavior produce reinforcement with an intermittent schedule of reinforcement.
4. Continuous reinforcement (CRF) is used to strengthen behavior, primarily during the initial stages of learning new behaviors.
5. Intermittent reinforcement (INT) is used to maintain an established behavior, especially during maintenance stages of learning.

Defining Basic Intermittent Schedules of Reinforcement

6. Ratio schedules require a number of responses before one response produces reinforcement.
7. Interval schedules require an elapse of time before a response produces reinforcement.

Schedule Effects and Consistency of Performance

8. A fixed ratio (FR) schedule requires the completion of a specified number of responses before a response produces reinforcement.
9. FR schedules produce a typical pattern of responding: (a) After the first response of the ratio requirement, the participant completes the required responses with little hesitation between responses; and (b) a postreinforcement pause follows reinforcement.
10. The size of the ratio and the reinforcement magnitude can influence the duration of the postreinforcement pause.
11. A variable ratio (VR) schedule of reinforcement requires the completion of a variable number of responses before a response produces reinforcement. A number representing the average (e.g., mean) number of responses required for reinforcement identifies the VR schedule.
12. VR schedules produce consistent, steady rates of response. They typically do not produce a postreinforcement pause, as do FR schedules.
13. A fixed interval (FI) schedule provides reinforcement for the first response following the elapse of a specific, constant duration of time since the last reinforced response. The reinforcer is available after the fixed time interval has elapsed, and it remains available until the first response is emitted.
14. FI schedules typically produce a postreinforcement pause in responding during the early part of the interval. An initially slow, but accelerating, rate of response is evident toward the end of the interval, usually reaching a maximum rate just before delivery of the reinforcer. This gradually accelerating rate of response toward the

end of the interval is called an FI scallop because of the rounded curves that are shown on a cumulative graph.

15. A variable interval (VI) schedule provides reinforcement for the first response following the elapse of a variable duration of time.

16. A VI schedule of reinforcement tends to produce a low to moderate stable rate of response. On a cumulative graph, the slope of the VI schedule appears uniform with few pauses in responding.

17. When a limited hold is added to an interval schedule, reinforcement remains available for a finite time following the elapse of the FI or VI interval.

Thinning Intermittent Reinforcement

18. Two procedures are used commonly for schedule thinning. First, the response ratio or the duration of the time interval is gradually increased. Instructions can be used to clearly communicate the schedule of reinforcement, facilitating a smooth transition during the thinning process. Instructions include rules, directions, and signs.

19. To adjust the thinning process, and to avoid the loss of previous improvements, use small increments of schedule changes.

20. Ratio strain can result from abrupt increases in ratio requirements when moving from denser to thinner reinforcement schedules.

Variations on Basic Intermittent Schedules of Reinforcement

21. Differential reinforcement of high rates (DRH) and differential reinforcement of low rates (DRL) are variations of ratio schedules that make reinforcement contingent on responses occurring above or below criterion response rates.
    - DRH schedules produce higher rates of responding.
    - DRL schedules produce lower rates of responding.

22. The differential reinforcement of diminishing rates schedule provides reinforcement at the end of a predetermined time interval when the number of responses is less than a criterion that is gradually decreased across time intervals based on the individual's performance.

23. A lag schedule of reinforcement is one method to increase response variability. Reinforcement on a lag schedule is contingent on a response differing in some predetermined way (e.g., different topography, different sequence) from one or more responses that preceded it.

24. A progressive ratio schedule of reinforcement is a variation of the fixed ratio (FR) schedule in which the ratio requirements increase incrementally within the session.

Compound Schedules of Reinforcement

25. Continuous reinforcement, the four basic intermittent schedules of reinforcement, differential reinforcement of rates of responding, and extinction, when combined, produce compound schedules of reinforcement.

26. The basic component schedules within a compound schedule (a) can occur successively or simultaneously; (b) can occur with or without discriminative stimuli; and (c) make reinforcement contingent on meeting the response requirements of each component schedule independently, or in combination with compound schedules.

27. A multiple schedule (mult) presents two or more basic schedules of reinforcement in an alternating, usually random, sequence. The basic schedules within the multiple schedule occur successively and independently. A discriminative stimulus is correlated with each basic schedule, and that stimulus is present as long as the schedule is in effect.

28. Behavioral contrast describes the effects of (a) a schedule change that increases or decreases the rate of responding in one component of a multiple schedule of reinforcement, which is accompanied by (b) a change in the response rate in the opposite direction on another unaltered component.

29. A concurrent schedule (conc) of reinforcement occurs when (a) two or more contingencies of reinforcement (b) operate independently and simultaneously (c) for two or more behaviors. Each schedule is correlated with a discriminative stimulus.

30. A chained schedule (chain) is similar to a multiple schedule. The multiple and chained schedules have two or more basic schedule requirements that occur successively, and have a discriminative stimulus correlated with each independent schedule.

31. A mixed schedule of reinforcement (mix) uses a procedure identical to that of the multiple schedules, except no discriminative stimuli signal the presence of the independent component schedules.

32. A tandem schedule (tand) operates like the chained schedule, except that discriminative stimuli are not used with the elements in the chain.

33. An alternative schedule (alt) provides an opportunity for reinforcement on two or more simultaneously available basic schedules of reinforcement. The first schedule completed provides reinforcement, regardless of which schedule component is met first. All schedule requirements start over following reinforcement.

34. A conjunctive schedule (conj) of reinforcement is in effect whenever reinforcement follows the completion of response requirements for two or more schedules of reinforcement.

Perspectives on Using Schedules of Reinforcement in Applied Settings

35. Well-established schedule effects found in basic research were presented in this chapter. Applied behavior analysts, however, should use caution in extrapolating these effects to applied settings.

36. Applied behavior analysts should include an analysis of the basic intermittent schedules and the compound schedules in their research agendas. A better understanding of the schedule effects in applied settings will advance the development of applied behavior analysis and its applications.

37. The conditions under which adjunctive behaviors (e.g., time fillers, such as doodling, smoking, idle talking, and drinking) are developed and maintained are important areas for future research in applied behavior analysis.

KEY TERMS

adjunctive behaviors
alternative schedule (alt)
behavioral contrast
chained schedule (chain)
compound schedule of reinforcement
concurrent schedule (conc)
conjunctive schedule (conj)
continuous reinforcement (CRF)
differential reinforcement of diminishing rates (DRD)
differential reinforcement of high rates (DRH)
differential reinforcement of low rates (DRL)
fixed interval (FI)
fixed ratio (FR)
intermittent schedule of reinforcement (INT)
lag schedule
limited hold
matching law
mixed schedule of reinforcement (mix)
multiple schedule (mult)
postreinforcement pause
progressive schedule of reinforcement
progressive-ratio (PR) schedule of reinforcement
ratio strain
schedule of reinforcement
schedule thinning
tandem schedule (tand)
variable interval (VI)
variable ratio (VR)

MULTIPLE-CHOICE QUESTIONS

1. Every time Baxter raised his hand in class, Mrs. Tulley called on him. What schedule of reinforcement is Baxter's hand raising on?

a. Intermittent reinforcement

b. Fixed-interval

c. Continuous reinforcement

d. Fixed-ratio 2

Hint: (See "Continuous Reinforcement")

2. Timmy has just recently begun clearing his plate after he finishes his meal. Timmy's mother really likes this new behavior and would like to see more of it. Which schedule of reinforcement should Timmy's mother use to strengthen Timmy's new behavior of clearing his plate?

a. Variable-ratio 8

b. Intermittent reinforcement

c. Fixed-ratio 10

d. Continuous reinforcement

Hint: (See "Intermittent Reinforcement")

3. Which schedule of reinforcement occurs when two or more contingencies of reinforcement operate independently and simultaneously for two or more behaviors?

a. Variable-ratio schedules of reinforcement

b. Concurrent schedules of reinforcement

c. Fixed-interval schedules of reinforcement

d. Multiple schedules of reinforcement

Hint: (See "Compound Schedules of Reinforcement")

4. Which schedule of reinforcement presents two or more basic schedules of reinforcement in an alternating (usually random) sequence usually occurring successively and independently with no correlated discriminative stimuli?

a. Multiple schedules of reinforcement

b. Alternative schedules of reinforcement

c. Variable-interval schedules of reinforcement

d. Mixed schedules of reinforcement

Hint: (See "Discriminated Compound Schedules of Reinforcement")

5. Which schedule of reinforcement produces a post-reinforcement pause?
   a. Fixed ratio
   b. Continuous reinforcement schedule
   c. Tandem schedules of reinforcement
   d. Variable-interval schedules of reinforcement

   Hint: (See "Defining Basic Intermittent Schedules of Reinforcement")

6. To gradually reduce a high-frequency behavior, which schedule of reinforcement is the most appropriate?
   a. Differential reinforcement of high rates of responding
   b. Differential reinforcement of low rates of responding
   c. Fixed-ratio schedules of reinforcement
   d. Concurrent schedules of reinforcement

   Hint: (See "Schedules of Differential Reinforcement of Rates of Responding")

7. Schedule thinning refers to:
   a. Gradually decreasing the response ratio or the duration of the time interval
   b. Quickly increasing the response ratio or the duration of the time interval
   c. Gradually increasing the response ratio or the duration of the time interval
   d. Moving gradually from an intermittent schedule to a continuous reinforcement schedule.

   Hint: (See "Thinning Intermittent Reinforcement")

8. Common behavioral characteristics associated with ________ include avoidance, aggression, and unpredictable pauses in responding.
   a. Ratio strain
   b. Post-reinforcement pause
   c. Scallop effect
   d. Fixed interval

   Hint: (See "Thinning Intermittent Reinforcement")

9. Which schedule of reinforcement is identical to the chained schedule except it does not use discriminative stimuli with the elements in the chain?
   a. Mixed schedule of reinforcement
   b. Fixed-ratio schedule of reinforcement
   c. Tandem schedule of reinforcement
   d. Chained schedule of reinforcement

   Hint: (See "Discriminated Compound Schedules of Reinforcement"; "Nondiscriminated Schedules of Reinforcement")

10. When the frequency of a time-filling behavior increases as a side effect of some other behavior maintained by a schedule of reinforcement, this is referred to as:
    a. Ratio strain
    b. Post-reinforcement pause
    c. Schedule induced
    d. Schedule thinning

    Hint: (See "Applied Research with Adjunctive Behavior")

ESSAY-TYPE QUESTIONS

1. Discuss the term schedules of reinforcement. In your discussion, be sure to describe what it is, and discuss the "boundaries for all other schedules of reinforcement" identified in the chapter.

   Hint: (See "Defining Basic Intermittent Schedules of Reinforcement")

2. Explain in detail how you would utilize schedules of reinforcement for teaching a student a new skill and, once acquired, what schedule you would use to maintain it.

   Hint: (See "Defining Basic Intermittent Schedules of Reinforcement")

3. Compare and contrast the four basic intermittent schedules of reinforcement.

   Hint: (See "Defining Basic Intermittent Schedules of Reinforcement")

4. Identify and describe the schedule of effects, specifically the issues of consistency of performance and rate of response, for each of the four basic intermittent schedules of reinforcement.

   Hint: (See "Defining Basic Intermittent Schedules of Reinforcement")

5. Describe the process of how you would use a ratio schedule to (1) teach a student a new skill and (2) move the skill into maintenance.

   Hint: (See "Thinning Intermittent Reinforcement")

6. During the treatment condition, a student became avoidant of work, began engaging in physical aggression and random pauses in responding. Upon inquiry, you discover that the staff was in the process of thinning the schedule of reinforcement the student was on. Identify the term that describes these phenomena and discuss how it occurred. How can it be remedied?

   Hint: (See "Thinning Intermittent Reinforcement")

7. Julia is a 9-year-old student at Blackmore Elementary. You have been asked by your professor to help her teacher reduce the frequency of Julia's hand raising in class using a differential reinforcement strategy. The teacher has recorded Julia raising her hand an average of 57 times an hour. Discuss which differential reinforcement procedure you would use, why you would use it and how it would work.

   Hint: (See "Schedules of Differential Reinforcement of Rates of Responding")

8. Identify and discuss the discriminated schedules of reinforcement.

Hint: (See "Discriminated Compound Schedules of Reinforcement")

9. Identify and discuss the nondiscriminated schedules of reinforcement.

Hint: (See "Nondiscriminated Schedules of Reinforcement")

10. Discuss and explain two different ways applied behavior analysts use progressive schedules of reinforcement.

Hint: (See "Progressive Schedules of Reinforcement")

NOTES

1. While we define the PR schedule of reinforcement as increasing response requirements within the session, as introduced by Hodos (1961), we recognize that applied behavior analysts may increase response requirements over successive sessions rather than within the session (e.g., DeLeon, Iwata, Goh, & Worsdell, 1997; Wilson & Gratz, 2016). Jarmolowizc and Lattal (2010) suggested the label progressive fixed-ratio (PFR) for schedules in which response requirements are increased from one session to the next.
2. An escalating schedule of reinforcement, in which consecutive responses produce an ever-increasing magnitude of reinforcement (e.g., Romanowich & Lamb, 2010, 2015), should not be confused with a PR schedule of reinforcement.

PART 5

Punishment

Punishment is a basic principle of learning. Although often considered bad—the unfortunate evil twin to reinforcement—punishment has as much importance to learning as reinforcement does. Learning from consequences that produce pain, discomfort, or the loss of reinforcers has survival value for the individual and for the species.

As with reinforcement, stimulus changes that function as consequences in punishment contingencies can be described by two types of operations: A new stimulus is presented or an existing stimulus is removed. Chapter 14 begins by defining the basic principle of punishment and distinguishes positive punishment and negative punishment based on the operation of the response-suppressing consequence. The remainder of the chapter focuses on the side effects and limitations of punishment, factors that influence the effectiveness of punishment, examples of interventions involving positive punishment, guidelines for using punishment effectively, and ethical considerations related to using punishment in applied settings. Chapter 15 describes two behavior change tactics based on negative punishment: time-out from positive reinforcement and response cost. Examples show how time-out and response cost reduce or eliminate undesired behavior, and guidelines provide direction for effectively implementing these tactics.

CHAPTER 14

Positive Punishment

LEARNING OBJECTIVES

- Define and discuss the definitions of positive and negative punishment.
- Define and discuss factors that influence the effectiveness of punishment.
- Identify and explain the potential side effects of punishment use.
- List examples of positive punishment and describe their respective procedures.
- Discuss the guidelines for the use of punishment as an intervention.
- Identify and discuss ethical considerations regarding the use of punishment.
- Explain the current state of knowledge regarding the use of punishment as a treatment intervention.

Have you ever stubbed your toe while walking too fast in a darkened room and then walked slowly the rest of the way to the light switch? Have you ever smashed your finger with a hammer and then refrained from holding the nail in quite the same way before swinging the hammer again? Have you ever left a sandwich unattended at a beach party, watched a seagull fly away with it, and then did not turn your back on the next treat you pulled from the picnic basket? If you have had these or similar experiences, you have been the beneficiary of punishment.

It may seem strange to refer to people who stubbed their toe, smashed a finger, or lost a tasty sandwich as benefiting from the experience, as opposed to referring to that person as a "victim" of punishment. Although many people consider punishment a bad thing—reinforcement's evil counterpart—punishment is as important to learning as reinforcement. Learning from consequences that produce pain, discomfort, or the loss of reinforcers has survival value for the individual organism and for our species. Punishment teaches us not to repeat behaviors that cause harm. Fortunately, it usually does not take too many stubbed toes or smashed fingers to reduce the occurrence of the behaviors that produced those outcomes.

Although punishment is a natural phenomenon and one of the basic principles of operant conditioning, it is poorly understood and frequently misapplied, and its application is controversial. At least some of the misunderstandings and controversy surrounding the use of punishment in behavior change programs can be attributed to practitioners who, on the one hand, confuse punishment as an empirically derived principle of behavior with its commonplace usage and its legal connotations; and, on the other hand, misapply punishment altogether.

Punishment is generally understood to be the application of aversive consequences—such as physical pain, psychological hurt, and the loss of privileges, or fines—for the purpose of teaching a lesson to a person who has misbehaved so she will not repeat the misdeed. Punishment is sometimes used as an act of retribution on the part of the person or agency administering the punishment, or to provide "a lesson for others" on how to behave. Punishments meted out by the legal system, such as jail time and fines, are often considered a process by which convicted lawbreakers must repay their debt to society.

These everyday and legal notions of punishment, although having various degrees of validity and utility within their own contexts, have little, if anything, to do with punishment as a principle of behavior. In the everyday connotation of punishment, most people would agree that a teacher who sends a student to the principal's office for misbehaving in class, or a police officer who issues a ticket to a speeding motorist, has punished the offender. However, as a principle of behavior, punishment is not about *punishing the person*; punishment is a *response → consequence contingency* that suppresses the future frequency of similar responses. From the perspective of both the science and the practice of behavior analysis, the trip to the principal's office did not punish fooling around in class unless the future rate at which the student fools around in class decreases as a function of his trip to the principal's office, and the police officer's ticket did not punish speeding unless the motorist drives above the speed limit less often than she did before receiving the ticket.

In this chapter, we define punishment, identify factors that influence the effectiveness of punishment, discuss its side effects and limitations, describe examples of several behavior change tactics that incorporate punishment, present guidelines for using punishment effectively, and discuss ethical considerations in the use of punishment. In the chapter's concluding section, we remind behavior analysts of punishment's natural and necessary role in learning and underscore the need for more basic and applied research on punishment, and state that a wide variety of differential reinforcement options, stimulus control procedures, time-out from positive reinforcement, response blocking, and contingent restraint, be employed in lieu of treatments featuring unconditioned punishers as default technologies.

DEFINITION AND CHARACTERISTICS OF PUNISHMENT

This section presents the functional relation that defines punishment, describes the two operations by which punishment can be implemented, identifies the types of consequences that function as punishers, explains the discriminative effect of punishment, and describes the recovery from the punishment effect.

Operation and Defining Effect of Punishment

Like reinforcement, punishment is a two-term functional relation defined by its effects on the frequency of behavior. **Punishment** has occurred when a response is followed immediately by a stimulus change that decreases the future frequency of that type of behavior.

An early study by Hall and colleagues (1971) provides a straightforward example of punishment. Andrea, a 7-year-old girl with hearing impairments, "pinched and bit herself, her peers, the teacher, and visitors to the classroom at every opportunity and was so disruptive the teacher reported that academic instruction was impossible" (p. 24). During an initial 6-day baseline period, Andrea bit or pinched an average of 71.8 times per day. Whenever Andrea bit or pinched anyone during the intervention condition, her teacher immediately pointed at her with an outstretched arm and shouted "No!" On the first day of intervention, the frequency of Andrea's biting and pinching decreased substantially (see Figure 14.1). Her aggressive behavior followed a downward trend during the initial intervention phase, ending in an average of 5.4 incidents per day. A 3-day return to baseline conditions resulted in Andrea's biting and pinching at a mean rate of 30 times per day. When the teacher reinstated the intervention, pointing her finger and stating "No!" each time Andrea pinched or bit, Andrea's problem behavior dropped to 3.1 incidents per day. During the second intervention phase, the teacher reported that Andrea's classmates were no longer avoiding her, perhaps because their behavior of being near Andrea was punished less often by bites and pinches.

It is important to point out that punishment is defined neither by the actions of the person delivering the consequences (in the case of socially mediated punishment) nor by the nature of those consequences.[1] A decrease in the future occurrence of the behavior must be observed before a consequence-based intervention qualifies as punishment. The intervention that proved successful in reducing the frequency of Andrea's biting and pinching—her teacher's pointed finger and "No!"—is classified as a punishment-based treatment only because of its suppressive effects. If Andrea had continued to bite and pinch at the baseline level of responding when the intervention was applied, her teacher's pointing and "No!" would not have been punishment.

Because the presentation of punishers often evokes behavior incompatible with the behavior being punished, the immediate suppressive effects of punishment can easily be overestimated. Michael (2004) explained and provided a good example:

> The decreased frequency of the punished response that is due to its having been followed by punishment will not be seen until after behavior evoked by the punishing stimulus changes has ceased. Because the evocative effect of the punishment stimulus change (as a respondent unconditioned or conditioned elicitor or as operant S^D or MO) is in the same direction as the future change due to punishment as a response consequence (weakening of the punished behavior), the former can be easily misinterpreted as the latter. For example, when a small child's misbehavior is followed by a severe reprimand, the misbehavior will cease immediately, but primarily because the reprimand controls behavior incompatible with the misbehavior—attending to the adult who is doing the reprimanding, denying responsibility for the misbehavior, emotional behavior such as crying, etc. This sudden and total cessation of the misbehaver does not imply, however, that the future frequency of its occurrence has been reduced, which would be the true effect of punishment. (pp. 36–37)

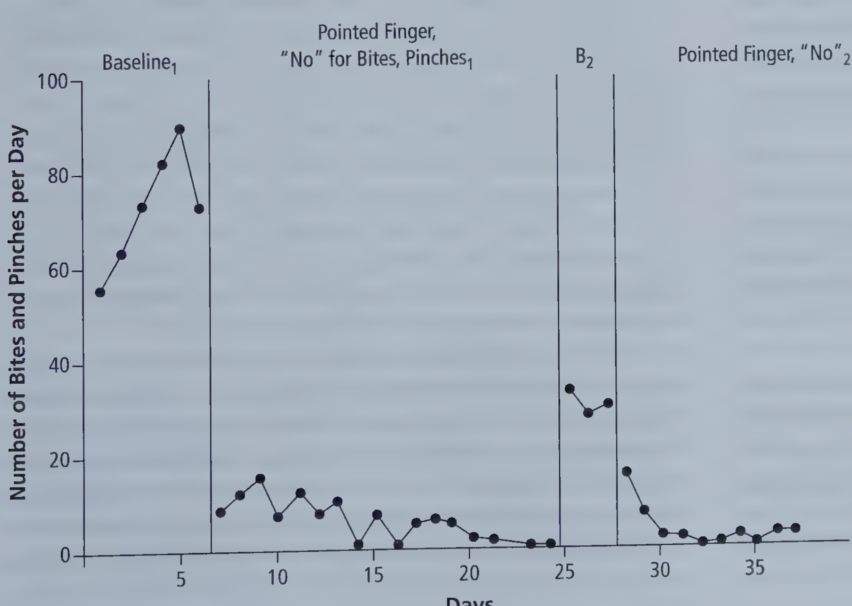

Figure 14.1 Number of bites and pinches by a 7-year-old girl during baseline and punishment ("No" plus pointing) conditions.

From "The Effective Use of Punishment to Modify Behavior in the Classroom," by R. V. Hall, S. Axelrod, M. Foundopoulos, J. Shellman, R. A. Campbell, and S. S. Cranston, 1971, *Educational Technology, 11*(4), p. 25. Copyright 1971 by Educational Technology. Used by permission.

Extinction effects caused by withholding reinforcement for the problem behavior (a procedure that should be included in punishment-based interventions whenever possible) contribute to the difficulty of determining the effectiveness of punishment—or even whether the punishment contingency is responsible for reductions in responding. However, rapid reductions in responding characteristic of punishment can usually be distinguished from gradual reductions in responding typical of extinction. Compare the immediate decrease in Andrea's biting and pinching from baseline to punishment condition in Figure 14.1 with the gradual decrease in responding typical of extinction shown in Figure 24.4.

Positive Punishment and Negative Punishment

Like reinforcement, punishment can be accomplished by either of two types of stimulus change operations. **Positive punishment** occurs when the presentation of a stimulus (or an increase in the intensity of an already present stimulus) immediately following a behavior results in a decrease in the frequency of the behavior. Stubbing one's toe on a chair leg is an example of positive punishment—if it suppresses the frequency of the behavior that preceded the toe stub—because the painful stimulation is best described as the presentation of a stimulus. Behavior change tactics based on positive punishment involve the contingent presentation of a stimulus immediately following occurrences of the target behavior. Andrea's teacher constituted positive punishment; the teacher's pointed finger and "No!" were stimuli presented or added to Andrea's environment.

Negative punishment has occurred when the removal of an already present stimulus (or a decrease in the intensity of an already present stimulus) immediately following a behavior results in a decrease in the future frequency of the behavior. The beach party attendee's behavior of turning his back on his food was negatively punished when the seagull flew off with his sandwich. For a stimulus change to function as negative punishment, which amounts to the removal of a positive reinforcer, a "motivating operation for the reinforcer must be in effect, otherwise removing it will not constitute punishment" (Michael, 2004, p. 36). A seagull's flying off with a hungry person's sandwich would function as punishment for his inattentiveness, but perhaps have little effect on the behavior of a person who has eaten his fill and set the sandwich down.

Behavior change tactics based on negative punishment involve the contingent loss of available reinforcers immediately following a behavior (i.e., response cost, a procedure akin to a fine) or the removal of the opportunity to acquire additional reinforcers for a period of time (i.e., time-out from reinforcement, a procedure akin to being sidelined during a game). Negative punishment is the focus of Chapter 15.

As with reinforcement, the modifiers *positive* and *negative* when used with *punishment* connote neither the intention nor the desirability of the behavior change produced; they specify only that the stimulus change that functioned as the punishing consequence is best described as the presentation of a new stimulus (positive punishment) or the termination (or reduction in intensity or amount) of an already present stimulus (negative punishment). As Michael (2004) noted, positive punishment and negative punishment are susceptible to misunderstanding.

> Assuming that you must receive either positive or negative punishment, which would you prefer? As with reinforcement, you should certainly not decide until you know specifically what each consists of. Would you prefer negative reinforcement or positive punishment? Of course, negative reinforcement. (p. 37)

Positive punishment and negative reinforcement are frequently confused as well. Because aversive events are associated with positive punishment and with negative reinforcement, the umbrella term *aversive control* is often used to describe interventions involving either or both of these two principles. Distinguishing between the two principles is difficult when the same aversive event is involved in concurrent positive punishment and negative reinforcement contingencies. For example, Baum (2017) described how the application and threat of physical beatings might condition the behavior of people living in a police state.

> If speaking out results in a beating, then speaking out is positively punished. If lying avoids a beating, then lying is negatively reinforced. The two tend to go hand-in-hand, because if one activity is punished, some alternative action will avoid punishment. (p. 163)

The keys to identifying and distinguishing concurrent positive punishment and negative reinforcement contingencies involving the same aversive stimulus event are (a) recognizing the opposite effects the two contingencies have on the future frequency of behavior and (b) realizing that two different behaviors must be involved because the same consequence (i.e., stimulus change) cannot serve as positive punishment and negative reinforcement for the same behavior. In a positive punishment contingency, the stimulus is absent prior to a response and is presented (or increased in intensity) as a consequence; in a negative reinforcement contingency, the stimulus is present prior to a response and is removed (or decreased in intensity) as a consequence. For example, positive punishment and negative reinforcement contingencies operated concurrently in a study by Azrin, Rubin, O'Brien, Ayllon, and Roll (1968) in which adults wore an apparatus throughout the normal working day that automatically produced a 55-dB tone contingent on slouching (sustained rounding of the shoulders or upper back for 3 seconds) and immediately terminated the tone when they straightened their shoulders. Slouching produced a tone (positive punishment), straightening the shoulders escaped the tone (negative reinforcement), and nonslouching avoided a tone (negative reinforcement).

Threatening a person with punishment if she engages in a behavior should not be confused with punishment. Punishment is a behavior → consequence relation, and a threat of what will happen if a person behaves in a certain way is an antecedent event to the behavior. When the threat of punishment suppresses behavior, it may be due to the threat functioning as an establishing operation that evokes alternative behaviors that avoid the threatened punishment.

Types of Punishers

A **punisher** is a stimulus change that immediately follows a response and decreases future occurrences of that type of behavior. The stimulus change in a positive punishment contingency may be called a *positive punisher* or, more simply, a *punisher*. Likewise the term *negative punisher* can be applied to a stimulus change involved in negative punishment. Though technically accurate, the term *negative punisher* is clumsy because it refers to a positive reinforcer that is removed contingent on occurrences of the target behavior. Therefore, when most behavior analysts use the term *punisher*, they are referring to a stimulus whose presentation functions as punishment (i.e., a positive punisher). As with reinforcers, punishers can be classified as unconditioned or conditioned.

Unconditioned Punishers

An **unconditioned punisher** (also called *primary punisher* or *unlearned punisher*) is a stimulus whose presentation functions as punishment without having been paired with any other punishers. Because unconditioned punishers are the product of the evolutionary history (phylogeny) of a given species, all biologically intact members of that species are susceptible to punishment by the same unconditioned punishers. Painful stimulation such as that caused by physical trauma to the body, certain odors and tastes, physical restraint, loss of bodily support, and extreme muscular effort are examples of stimulus changes that typically function as unconditioned punishers for humans (Michael, 2004). Like unconditioned reinforcers, unconditioned punishers are "phylogenetically important events that bear directly on fitness" of the organism (Baum, 2017, p. 67).

However, virtually any stimulus to which an organism's receptors are sensitive—light, sound, and temperature, to name a few—can be intensified to the point that its delivery will suppress behavior even though the stimulus is below levels that cause tissue damage (Bijou & Baer, 1965). Unlike unconditioned reinforcers, such as food and water, whose effectiveness depends on a relevant establishing operation, under most conditions many unconditioned punishers will suppress any behavior that precedes their onset. An organism does not have to be "deprived of electric stimulation" for the onset of electric shock to function as punishment. (However, the behavior of an organism that has just received many shocks at a specified voltage level in a short period, particularly shocks of mild intensity, may be relatively unaffected by another shock at a similar intensity.)

Conditioned Punishers

A **conditioned punisher** (also called *secondary punisher* or *learned punisher*) is a stimulus change whose presentation functions as punishment as a result of a person's conditioning history. A conditioned punisher acquires the capability to function as a punisher through stimulus–stimulus pairing with one or more unconditioned, or previously conditioned, punishers. For example, as a result of its onset at or very near the same time as an electric shock, a previously neutral stimulus change, such as an audible tone, will become a conditioned punisher capable of suppressing behavior that immediately precedes the tone when it occurs later without the shock (Hake & Azrin, 1965).[2] If a conditioned punisher is repeatedly presented without the punisher(s) with which it was initially paired, its effectiveness as punishment will wane until it is no longer a punisher.

Previously neutral stimuli can also become conditioned punishers for humans without direct physical pairing with another punisher through a pairing process Alessi (1992) called *verbal analog conditioning*. This is similar to the example of verbal pairing described in Chapter 11 for the conditioning of a conditioned reinforcer in which Engelmann (1975) showed cut-up pieces of yellow construction paper to a group of preschool children and told them, "These pieces of yellow paper are what big kids work for" (pp. 98–100). From that point on, many children began working extra hard for yellow pieces of paper. Miltenberger (2016) gave the example of a carpenter telling his apprentice that if the electric saw starts to make smoke, the saw motor may become damaged or the blade may break. The carpenter's statement establishes smoke from the saw as a conditioned punisher capable of decreasing the frequency of any behaviors that immediately precede the smoke (e.g., pushing too forcefully on the saw, holding the saw at an inappropriate angle).

A stimulus change that has been paired with numerous forms of unconditioned and conditioned punishers becomes a **generalized conditioned punisher**. Reprimands ("No!" "Don't do that!") and disapproving gestures (e.g., scowls, head shakes, frowns) are generalized conditioned punishers for many people because they have been paired repeatedly with a wide range of unconditioned or conditioned punishers (e.g., burned finger, loss of privileges). As with generalized conditioned reinforcers, generalized conditioned punishers are independent of specific motivating conditions and will function as punishment under most conditions.

To restate a critical point, punishers are defined by their function (a decrease in the future occurrence of behavior), not by their physical properties. Even stimulus changes that would function as unconditioned reinforcers or punishers can have the opposite effect under certain conditions. For example, a bite of food will function as a punisher for a person who has eaten too much, and an electric shock may function as a reinforcer if it signals the availability of food for a food-deprived organism (e.g., Holz & Azrin, 1961). If a student receives a smiley face sticker and praise while completing math problems and his productivity decreases as a result, smiley face stickers and praise are punishers for that student. A consequence that might serve as a punisher at work might not do so at home. Although common experiences mean that many of the same stimulus events function as conditioned punishers for most people, a punisher for one person may be a powerful reinforcer for another. Remember the cartoon described in Chapter 11 of two students cleaning erasers after school: The activity was punishment for one and reinforcement for the other.

Discriminative Effects of Punishment

Punishment does not operate in a contextual vacuum. The environmental situation in which punishment occurs plays an

important role in determining the antecedent stimulus conditions in which punishment's suppressive effects will be observed. The three-term contingency for "the operant functional relation involving punishment can be stated much like that involving reinforcement: (1) In a particular stimulus situation (S), (2) some kinds of behavior (R), when followed immediately by (3) certain stimulus changes (S^P), show a decreased future frequency of occurrence in the same or in similar situations" (Michael, 2004, p. 36).

If punishment occurs only in some stimulus conditions and not in others (e.g., a child gets scolded for reaching into the cookie jar before dinner only when an adult is in the room), the suppressive effects of punishment will be most prevalent under those conditions. A discriminated operant for punishment is the product of a conditioning history in which responses in the presence of a certain stimulus have been punished and similar responses in the absence of that stimulus have not been punished (or have resulted in a reduced frequency or intensity of punishment). Highway speeding is a discriminated operant in the repertoire of many motorists who drive within the speed limit in and around locations where they have been pulled over by the police for speeding but continue to drive over the speed limit on roads where they have never seen a police cruiser.

There is no standard term or symbol in the behavior analysis literature for an antecedent stimulus that acquires stimulus control related to punishment. Some authors have modified the shorthand symbol for a discriminative stimulus for reinforcement (S^D) to indicate the antecedent stimulus in a three-term punishment contingency, such as the S^{D-} used by Sulzer-Azaroff and Mayer (1977). Other authors refer to an antecedent stimulus correlated with the presence of a punishment contingency as a *punishment-based* S^D (e.g., Malott & Shane, 2016; Michael, 2004). We have adopted S^{Dp} as the symbol for the **discriminative stimulus for punishment**, as proposed by O'Donnell (2001). "An S^{Dp} can be defined as a stimulus condition in the presence of which a response has a lower probability of occurrence than it does in its absence as a result of response-contingent punishment delivery in the presence of the stimulus" (p. 262). Figure 14.2 shows three-term contingency diagrams for discriminated operants for positive punishment and negative punishment.

A study by McKenzie, Smith, Simmons, and Soderlund (2008) illustrates the stimulus control of a client's problem behavior by a stimulus associated with punishment. Diane, a woman with profound intellectual disabilities, had engaged in chronic eye poking that impaired her vision and on two occasions dislodged one of her eyes from the socket. Several reinforcement-based interventions had failed to produce clinically meaningful reductions in the behavior.

During an initial *no-wristbands baseline* phase, Diane was observed through a one-way mirror and the duration of her eye poking measured. In the *wristbands (no reprimands)* condition that followed, the therapist entered the room at the first occurrence of eye poking, placed two red tennis wristbands on Diane's wrists, and then left the area and remained out of Diane's sight for the remainder of the session. When eye poking was first observed during the *wristbands (reprimands)* condition, the therapist immediately entered the room and delivered a verbal reprimand (e.g., "Diane, stop poking!"). After presenting the reprimand and observing that Diane had stopped eye poking, the therapist left the room. The plan "was to repeat the reprimand at 3-s intervals until eye poking ceased, but it was never necessary to deliver more than one reprimand" (McKenzie et al., 2008, p. 257).

Data from a phase in which wristbands (reprimands) and no-wristbands (baseline) sessions were alternated showed that the wristbands rapidly acquired and maintained stimulus control

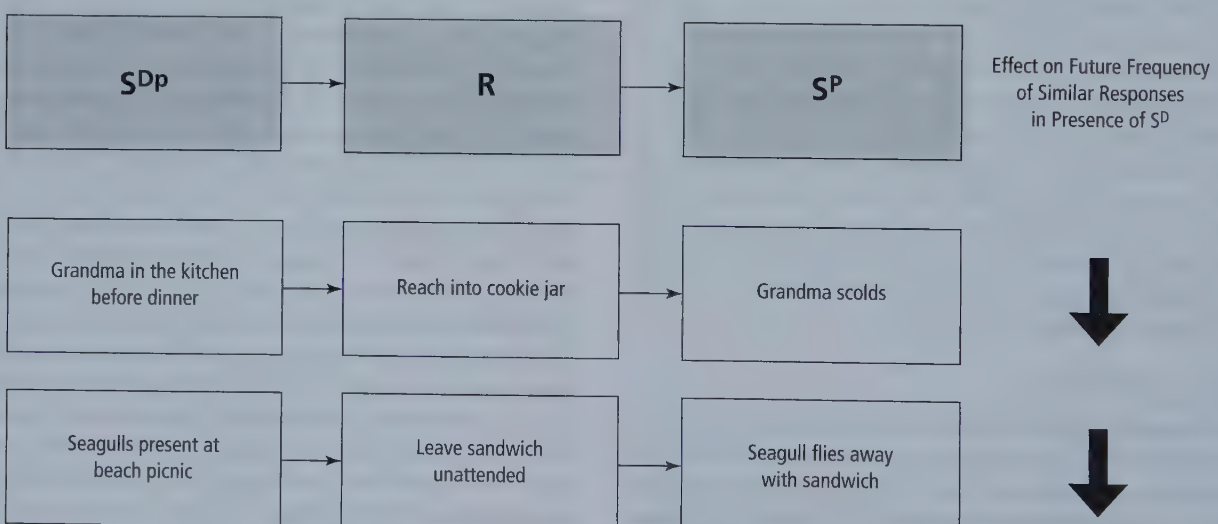

Figure 14.2 Three-term contingencies illustrating positive and negative punishment of discriminated operants: A response (R) emitted in the presence of a discriminative stimulus (S^{Dp}) is followed closely in time by a stimulus change (S^P) and results in a decreased frequency of similar responses in the future when the S^{Dp} is present. A discriminated operant for punishment is the product of a conditioning history in which responses in the presence of the S^{Dp} have been punished and similar responses in the absence of the S^{Dp} have not been punished (or have resulted in a reduced frequency or intensity of punishment than in the presence of the S^{Dp}).

over eye poking (see Figure 14.3). During wristbands (reprimands) sessions, Diane poked her eyes for a mean of 2 seconds (range, 0 to 7 sec) compared to a mean of 133 seconds (range, 2 sec to 402 sec) during no-wristbands sessions. Discriminative control of the wristbands was replicated in a delayed multiple baseline across settings analysis. Results showed reprimands in the treatment setting had acquired stimulus control. Notably, no reprimands were ever delivered when Diane wore the wristbands in the canteen or at home.

Recovery from Punishment

Punishment's suppressive effects on behavior are usually not permanent. This phenomenon, called **recovery from punishment**, is especially likely when the behavior being punished also obtains reinforcement. Figure 14.4 shows the results from one of a series of basic laboratory experiments by Azrin (1960) that demonstrated recovery from punishment. The top set of data paths is the cumulative record of a pigeon's key pecking during a 1-hr session of food reinforcement on a variable interval (VI) 6-min schedule prior to any punishment. The data paths on the lower part of the figure show responding during punishment and reinforcement. Beginning on the 1st day, and for each daily 1-hr session thereafter for 35 consecutive sessions, every key peck was followed immediately by a brief electric shock of moderate intensity (5 milliamperes for 100 milliseconds). Contingent shock suppressed pecking on the 1st day of punishment, but responding gradually recovered over the next 20 sessions and stabilized at about 900 responses per session, compared with 2800 responses prior to punishment.

"Using a stimulus correlated with reprimands to suppress automatically maintained eye poking," by S. D. McKenzie, R. G., Smith, J. N. Simmons, and M. J. Soderlund, 2008, *Journal of Applied Behavior Analysis*, *41*, p. 258. Reproduced with permission of John Wiley & Sons Inc.

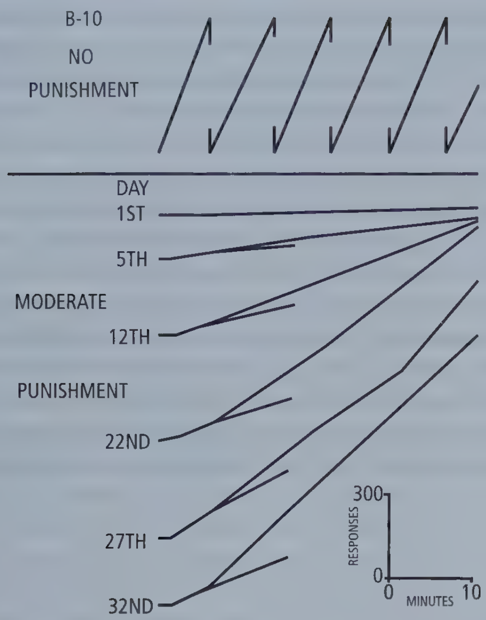

Figure 14.4 Partial recovery of responding by a pigeon during punishment of every response concurrent with reinforcement on a variable interval schedule.

"Effects of Punishment Intensity during Variable-Interval Reinforcement," By N. H. Azrin, 1960, *Journal of Experimental Analysis of Behavior, 3*, p. 127. Reproduced with permission of John Wiley & Sons Inc.

Recovery of responding to prepunished levels is more likely to occur when the punishment was mild or when the person can discriminate that the punishment contingency is no longer active. Sometimes responding after punishment is discontinued will not only recover but also briefly exceed the level at which it was occurring prior to punishment (Azrin, 1960; Holz & Azrin, 1962). Although the response-weakening effects of punishment often wane when punishment is discontinued, so, too, do the response-strengthening effects of reinforcement, which are often fleeting when previously reinforced behavior is placed on extinction (Vollmer, 2002). Michael (2004) noted that

> Recovery from punishment is sometimes given as an argument against the use of punishment to cause a decrease in behavior. "Don't use punishment because the effect is only temporary." But of course the same argument could be made for reinforcement. The strengthening effect of reinforcement decreases when the behavior occurs without the reinforcement. The weakening effect of punishment decreases when the behavior occurs without the punishment. (p. 38)

FACTORS THAT INFLUENCE THE EFFECTIVENESS OF PUNISHMENT

Reviews of basic and applied research identify several variables as keys to the effectiveness of punishment: immediacy, intensity, schedule or frequency, inadvertent reinforcement of the target behavior, and the availability of reinforcement for an alternative behavior (Axelrod, 1990; Azrin & Holz, 1966; Hineline & Rosales-Ruiz, 2013; Lerman & Vorndran, 2002).

Immediacy

Maximum suppressive effects are obtained when the onset of the punisher occurs immediately after the occurrence of the target response. Even small time delays can decrease the effectiveness of punishment.[3]

> Basic studies with humans and nonhumans indicate that punishment procedures can fail to suppress responding when the consequence is delayed by just 10–30 seconds. . . . When a punisher is delayed, other responses or multiple occurrences of the targeted behavior are likely to intervene before the consequence is delivered, weakening the contingency between the response and its consequence. (Lerman & Toole, 2011, p. 359)

Intensity of Punishment

Basic researchers examining the effects of punishers of varying intensity have reported three reliable findings: (1) A positive correlation exists between the intensity of the punishing stimulus and response suppression; (2) a negative correlation exists between the intensity of the punishing stimulus and recovery from punishment (described above and illustrated in Figure 14.4); and (3) a high-intensity stimulus that was previously presented at low intensity and gradually increased in intensity for subsequent responses may be ineffective as punishment (e.g., Azrin & Holz, 1960; Hake, Azrin, & Oxford, 1967; Holz & Azrin, 1962; Terris & Barnes, 1969).

Data from another of Azrin's (1960) early laboratory experiments on the effects of different intensities of punishment illustrate the first two findings (see Figure 14.5). Each curve is the cumulative record of a pigeon pecking an illuminated key during a 1-hr period of concurrent food reinforcement on a VI 1-min schedule and punishment of each response by shocks of various intensities. Results for two subjects show the more intense the punishing stimulus, the more immediately and thoroughly it suppresses behavior.

Data from other studies demonstrated that recovery from punishment varies inversely with the intensity of punishment (e.g., Azrin, 1960; Hake, Azrin, & Oxford, 1967). Responding by subjects that received very mild punishment recovered more rapidly and completely than did responding by subjects that received more intense punishment. Virtually permanent response suppression may occur when complete suppression of behavior to a zero rate of responding has been achieved with intense punishment. In their review of basic research on punishment, Azrin and Holz (1966) noted that:

> Intense punishment did not merely reduce responses to the unconditioned or operant level, but reduced them to an absolute level of zero. Since punishment is delivered only after a response occurs, there is

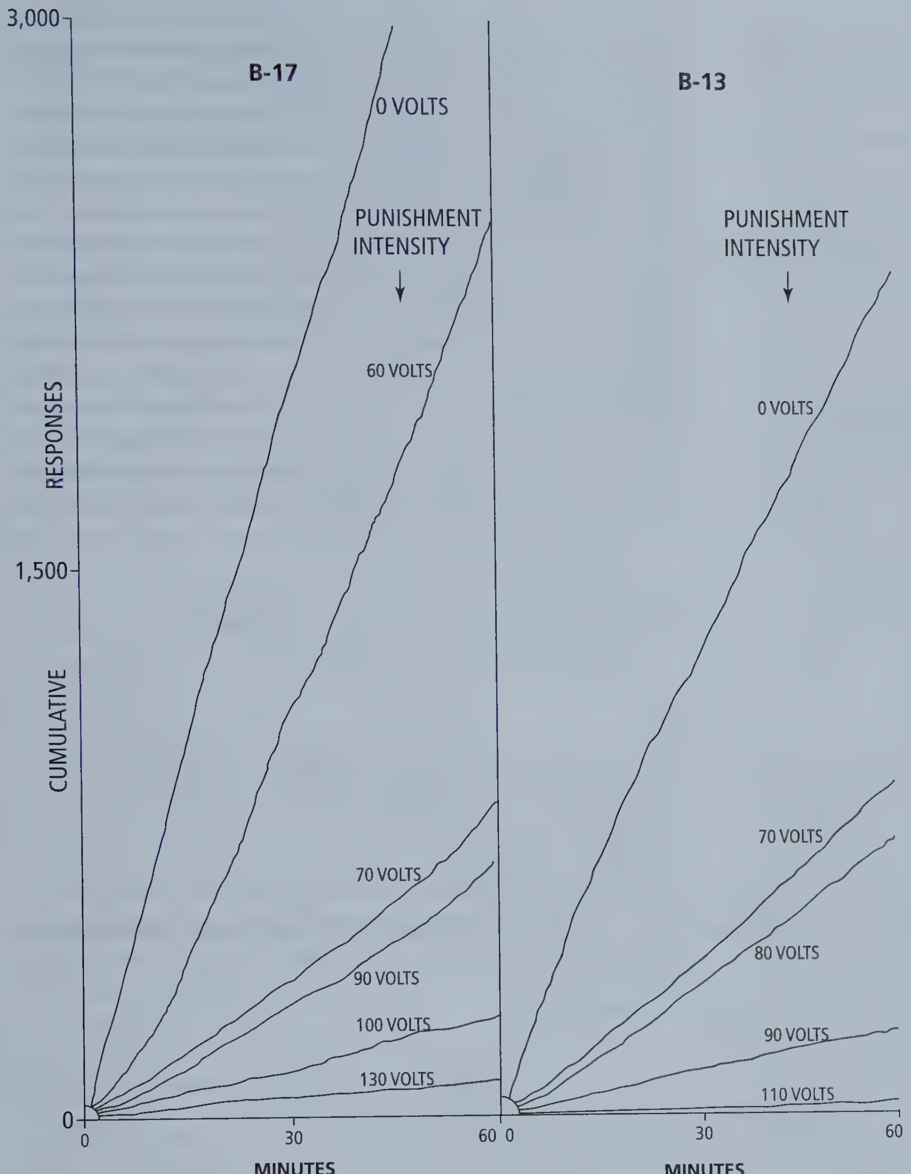

Figure 14.5 Response rate for two pigeons as a function of punishment intensity. Each curve is the cumulative record of pecking an illuminated key during a 1-hr period of concurrent reinforcement on a VI 1-min schedule and in which punishment of each response occurs.

"Effects of Punishment Intensity during Variable-Interval Reinforcement," by N. H. Azrin, 1960, *Journal of Experimental Analysis of Behavior*, *3*, p. 138. Reproduced with permission of John Wiley & Sons Inc.

> no opportunity for the subject to detect the absence of punishment unless he responds. If punishment is so severe as to completely eliminate the responses then the opportunity for detecting the absence of punishment no longer exists. (p. 410)

A high-intensity stimulus may be ineffective as a punisher if that stimulus was initially presented at low intensity and the intensity is increased gradually (Hineline & Rosales-Ruiz, 2013). Recovery of responding to pre-punished levels is more likely to rebound when (a) the punishment was mild, (b) habituation to the punisher occurred, (c) the person can discriminate that the punishment contingency is no longer active, (d) the punished behavior is reinforced inadvertently, or (e) staff training (or the lack of it) militates against treatment integrity (Lerman & Toole, 2011).

However, as Lerman and Vorndran (2002) pointed out, relatively few applied studies have examined the relation between punishment intensity and treatment efficacy, and that research has yielded inconsistent and sometimes contradictory results (Cole, Montgomery, Wilson, & Milan, 2000; Singh, Dawson, & Manning, 1981; Williams, Kirkpatrick-Sanchez, & Iwata, 1993). When selecting the intensity of a punishing stimulus, the practitioner should ask: Will this degree of the punisher suppress occurrences of the problem behavior? Lerman and Vorndran (2002) recommended, "While the punishing stimulus needs to be intensive enough for an effective application, it should not be more intense than necessary." (p. 443)

Schedule and Consistency of Punishment

The suppressive effects of a punisher are maximized by a continuous schedule of punishment (FR 1) in which each occurrence of the behavior is followed by the punishing consequence. In general, the greater the proportion of responses that are followed by the punisher, the greater the response reduction

(Azrin, Holz, & Hake, 1963; Zimmerman & Ferster, 1962). Azrin and Holz (1966) summarized the comparative effects of punishment on continuous and intermittent schedules as follows:

> Continuous punishment produces more suppression than does intermittent punishment for as long as the punishment contingency is maintained. However, after the punishment contingency has been discontinued, continuous punishment allows more rapid recovery of the responses, possibly because the absence of punishment can be more rapidly discriminated. (p. 415)

Intermittent punishment, however, may be partially effective under some conditions (Cipani, Brendlinger, McDowell, & Usher, 1991; Clark, Rowbury, Baer, & Baer, 1973; Romanczyk, 1977). Lerman, Iwata, Shore, and DeLeon (1997) demonstrated that a gradual thinning of the punishment schedule might maintain the suppressive effects of punishment that was initially delivered on a continuous schedule (FR 1). Participants were five adults with profound intellectual disabilities and histories of chronic self-injurious behavior (SIB) in the form of hand mouthing or head hitting. Treatment by punishment (time-out from reinforcement for one participant and contingent restraint for the other four) delivered on a continuous (FR 1) schedule produced marked reductions in SIB from baseline levels for all five participants. (Figure 14.6 shows the results for three of the five participants.) The participants were then exposed to intermittent schedules of punishment (FI 120-sec or FI 300-sec). On the FI 120-sec schedule, the therapist delivered punishment contingent on the first SIB response after 120 seconds had elapsed since the previous application of punishment or the start of the session. The frequency of SIB under the intermittent schedule of punishment for all but

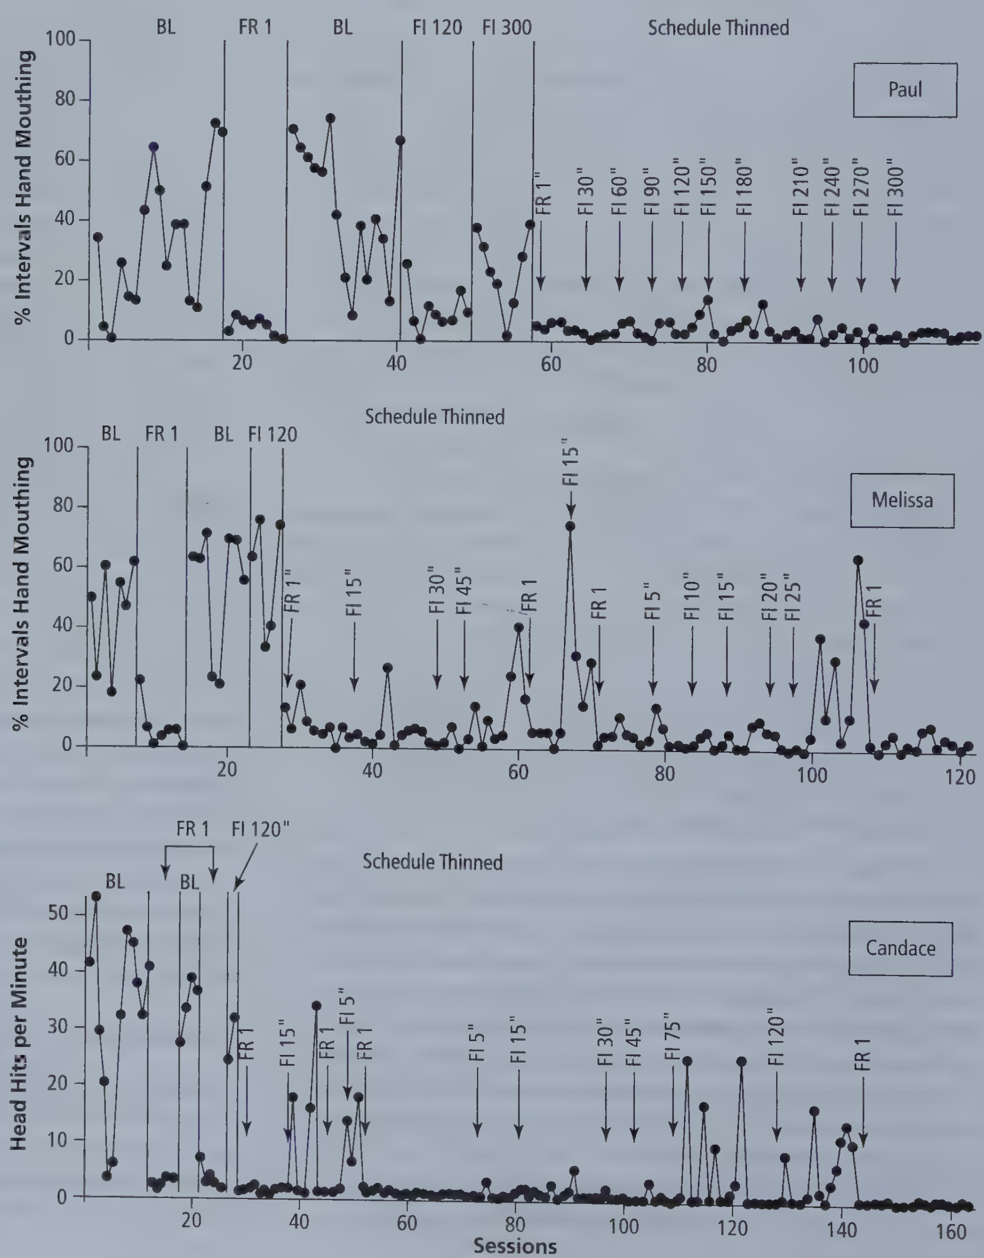

Figure 14.6 Self-injurious behavior (SIB) by three adults with profound intellectual disabilities during baseline and punishment delivered on continuous (FR 1) and various fixed interval schedules.

"Effects of Intermittent Punishment on Self-Injurious Behavior: An Evaluation of Schedule Thinning," by D. C. Lerman, B. A. Iwata, B. A. Shore, and I. G. DeLeon, 1997, *Journal of Applied Behavior Analysis, 30*, p. 194. Reproduced with permission of John Wiley & Sons Inc.

one participant (Wayne, not shown in Figure 14.6) increased to baseline levels.

After re-establishing low levels of SIB for each participant with FR 1 punishment, the researchers gradually thinned the punishment schedules. For example, schedule thinning for Paul consisted of increasing the duration of the fixed interval duration by 30-sec increments to FI 300-sec (i.e., FR 30-sec, FR 60-sec, FR 90-sec, etc.). With the exception of a few sessions, Paul's SIB remained at low levels as the punishment schedule was progressively thinned over 57 sessions. During the final 11 sessions, in which punishment was delivered on an FI 300-sec schedule, his SIB occurred at a mean of 2.4% of observed intervals (compared to 33% in baseline). A similar pattern of success with a gradually thinning punishment schedule was obtained for another subject, Wendy (not shown in Figure 14.6).

The effectiveness of punishment on an FI 300-sec schedule for three of the five participants—Paul, Wendy, and Wayne (whose SIB remained low even though punishment was abruptly changed from FR 1 to FI 120-sec and then FI 300-sec)—enabled infrequent application of punishment. In practice, this would free therapists or staff from continuous monitoring of behavior.

For Melissa and Candace, however, repeated attempts to gradually thin the punishment schedule proved unsuccessful in maintaining the frequency of their SIB at levels attained by FR 1 punishment. Lerman and colleagues (1997) speculated that one explanation for the ineffectiveness of punishment on a fixed interval schedule was that after a person has experienced an FI schedule for some time, the delivery of punishment could function "as a discriminative stimulus for punishment-free periods, leading to a gradual overall increase in responding under FI punishment" (p. 198).

Reinforcement for the Target Behavior

The effectiveness of punishment is modulated by the reinforcement contingencies maintaining the problem behavior. If a problem behavior occurs at a frequency sufficient to cause concern, it is presumably producing reinforcement. If the target response is never reinforced, then "punishment would scarcely be possible since the response would rarely occur" (Azrin & Holz, 1966, p. 433).

To the extent that the reinforcement maintaining the problem behavior can be reduced or eliminated, punishment will be more effective. Of course, if *all* reinforcement for the problem behavior was withheld—a condition difficult to achieve in many settings—the resulting extinction schedule would decrease the behavior independent of the presence of a punishment contingency. However, as Azrin and Holz (1966) pointed out:

> The physical world often provides reinforcement contingences that cannot be eliminated easily. The faster we move through space, the quicker we get to where we are going, whether the movement be walking or driving an auto. Hence, running and speeding will inevitably be reinforced. Extinction of running and speeding could be accomplished only by the impossible procedure of eliminating all reinforcing events that result from movement through space. Some other reductive method, such as punishment, must be used. (p. 433)

Reinforcement for Alternative Behaviors

Holz, Azrin, and Ayllon (1963) found that punishment was ineffective in reducing psychotic behavior when that behavior was the only means by which patients could attain reinforcement. However, when patients could emit an alternative response that resulted in reinforcement, punishment was effective in reducing their inappropriate behavior. Summing up laboratory and applied studies that have reported the same finding, Millenson (1967) stated:

> If punishment is employed in an attempt to eliminate certain behavior, then whatever reinforcement the undesirable behavior had led to must be made available via a more desirable behavior. Merely punishing school children for "misbehavior" in class may have little permanent effect. . . . The reinforcers for "misbehavior" must be analyzed and the attainment of these reinforcers perhaps permitted by means of different responses, or in other situations. . . . But for this to happen, it appears important to provide a rewarded alternative to the punished response. (p. 429)

A study by Thompson, Iwata, Conners, and Roscoe (1999) provides an excellent illustration of how the suppressive effects of punishment can be enhanced by reinforcement for an alternative response. Four adults with developmental disabilities who had been referred to a day treatment program for self-injurious behavior (SIB) participated in the study. Twenty-eight-year-old Shelly, for example, expelled saliva and then rubbed it onto her hands and other surfaces (e.g., tables, windows), which led to frequent infections; and Ricky, a 34-year-old man with deaf-blindness, frequently hit his head and body, resulting in bruises (contusions). Previous interventions such as differential reinforcement of appropriate behavior, response blocking, and protective equipment had been ineffective in reducing the SIB of all four participants.

A functional behavior analysis (see Chapter 27) with each participant suggested that SIB was maintained by automatic reinforcement. Reinforcer assessments were conducted to identify materials that produced the highest levels of contact with the lowest levels of SIB (e.g., wooden stringing beads, a mirrored microswitch that produced vibration and music, a balloon). The researchers then conducted a punisher assessment to determine the least intrusive consequences that produced a 75% reduction in SIB for each participant.

Using an experimental design that combined reversal, alternating treatments, and multiple baseline components, Thompson and colleagues (1999) analyzed the effects of punishment with and without reinforcement of alternative behavior on participants' SIB. During the no-punishment condition, the therapist was present in the room, but did not interact with the participant or provide any consequences for SIB. During the punishment condition, immediately following each occurrence of SIB the therapist delivered the consequence previously identified as a punisher for the participant. For example:

> Each time Shelly expelled saliva, the therapist delivered a reprimand ("no spitting") and briefly dried each of her

hands (and any other wet surfaces) with a cloth. Ricky's hands were held in his lap for 15 s each time he engaged in SIB. Donna and Lynn both received a verbal reprimand and had their hands held across their chests for 15 s following SIB. (p. 321)

Within each no-punishment and punishment phase, sessions of reinforcement and no-reinforcement conditions were alternated. During reinforcement sessions, participants had continual access to leisure materials or activities previously identified as highly preferred; during no-reinforcement sessions, participants had no access to leisure materials.

The study's results are shown in Figure 14.7. During the no-punishment baseline phase, only Shelly's SIB was consistently lower during the reinforcement sessions than during the no-reinforcement sessions. Although the introduction of punishment reduced SIB from baseline levels for all four participants, punishment was more effective during those sessions in which reinforcement for alternative behaviors was available. Also, fewer punishers were delivered during the punishment condition sessions when reinforcement was available.

Thompson and colleagues (1999) concluded that the effects of punishment can be improved when reinforcement is applied for alternative behaviors, and that practitioners need not increase the aversiveness of the punishing stimulus to increase the effectiveness of punishment. Adding a reinforcement component to the punishment procedure may be sufficient to achieve desired results, while simultaneously implementing a less restrictive approach.

"Effects of Reinforcement for Alternative Behavior during Punishment for Self-Injury," by R. H. Thompson, B. A. Iwata, J. Conners, and E. M. Roscoe, 1999, *Journal of Applied Behavior Analysis*, *32*, p. 323. Reproduced with permission of John Wiley & Sons Inc.

POSSIBLE SIDE EFFECTS AND PROBLEMS WITH PUNISHMENT

A variety of side effects are often correlated with punishment, including the elicitation of undesirable emotional responses and aggression, escape and avoidance, and an increased rate of the problem behavior under nonpunishment conditions (Azrin & Holz, 1966; Hutchinson, 1977; Linscheid & Meinhold, 1990). Other problems noted include modeling undesirable behavior and overusing punishment because reductions in problem behavior can function as negative reinforcement for caregivers.

Emotional and Aggressive Reactions

Punishment, especially positive punishment in the form of aversive stimulation, may evoke aggressive behavior with respondent and operant components (Azrin & Holz, 1966). For example, electric shock elicited reflexive forms of aggression and fighting in laboratory animals (Azrin, Hutchinson, & Hake, 1963; Ulrich & Azrin, 1962; Ulrich, Wolff, & Azrin, 1962). Such pain-elicited, or *respondent aggression*, is directed toward any nearby person or object. A student who is punished severely may begin to throw and destroy materials within her reach, and attack other students or the person delivering the punishment. Aggressive behavior following punishment that occurs because it has enabled the person to escape the aversive stimulation in the past is referred to as *operant aggression* (Azrin & Holz, 1966).

Escape and Avoidance

Escape and avoidance are expected reactions to aversive stimulation. Escape and avoidance behaviors take a wide variety of forms, some of which may be a greater problem than the target behavior being punished. For example, a student who is admonished repeatedly for sloppy work or coming to class unprepared may stop coming to class altogether. A person may lie, cheat, hide, or exhibit other undesirable behaviors to avoid punishment. Mayer, Sulzer, and Cody (1968) indicated that escape and avoidance do not always occur in the literal sense of those terms. Individuals may escape punishing environments by consuming drugs or alcohol, or by simply "tuning out."

As the intensity of a punisher increases, so, too, does the likelihood of escape and avoidance. For example, in a study evaluating the effectiveness of a specially designed cigarette holder that delivered an electric shock to the user when it was opened as an intervention for reducing cigarette smoking, Powell and Azrin (1968) found the following: "As the punishment intensity increased, the duration decreased for which the subjects would remain in contact with the contingency; ultimately, an intensity was reached at which they refused to experience it altogether" (p. 69).

Escape and avoidance as side effects to punishment, like emotional and aggressive reactions, can be minimized or prevented altogether by providing desirable alternative responses to the problem behavior that both avoid the delivery of punishment and provide reinforcement.

Behavioral Contrast

Reynolds (1961) introduced the term **behavioral contrast** to refer to the phenomenon in which a change in one component of a multiple schedule that increases or decreases the rate of responding on that component is accompanied by a change in the response rate in the opposite direction on the other, unaltered component of the schedule.[4] Behavioral contrast can occur as a function of a change in reinforcement or punishment density on one component of a multiple schedule (Brethower & Reynolds, 1962; Lattal & Griffin, 1972). For example, behavioral contrast for punishment takes the following general form: (a) Responses are occurring at similar rates on two components of a multiple schedule (e.g., a pigeon pecks a backlit key, which alternates between blue and green, reinforcement is delivered on the same schedule on both keys, and the bird pecks at roughly the same rate regardless of the key's color); (b) responses on one component of the schedule are punished, whereas responses on the other component continue to go unpunished (e.g., pecks on the blue key are punished, and pecks on the green key continue to produce reinforcement at the prior rate); (c) rate of responding decreases on the punished component and increases on the unpunished component (e.g., pecks on the blue key are suppressed and pecks on the green key increase even though pecks on the green key produce no more reinforcement than before).

Here is a hypothetical example to further illustrate the contrast effect of punishment. A child is eating cookies before dinner from the kitchen cookie jar at equal rates in the presence and absence of his grandmother. One day, Grandma scolds the child for eating a cookie before dinner, which suppresses his rate of pre-dinner cookie eating when she is in the kitchen (see Figure 14.2); but when Grandma's not in the kitchen, the boy eats cookies from the jar at a higher rate than he did when unsupervised prior to punishment. Contrast effects of punishment can be minimized, or prevented altogether, by consistently punishing occurrences of the target behavior in all relevant settings and stimulus conditions, withholding or at least minimizing the person's access to reinforcement for the target behavior, and providing alternative desirable behaviors. (With respect to our hypothetical case of the child eating cookies before dinner, we recommend simply removing the cookie jar!)

Punishment May Involve Modeling of Undesirable Behavior

Most readers are familiar with the example of the parent who, while spanking a child, says, "This will teach you not to hit your playmates!" Unfortunately, the child may be more likely to imitate the parent's actions, not the parent's words. More than three decades of research have found a strong correlation between young children's exposure to harsh, excessive punishment and antisocial behavior and conduct disorders in adolescents and adults (Patterson, 1982; Patterson, Reid, & Dishion, 1992; Sprague & Walker, 2000). Although the appropriate use of behavior change tactics based on the punishment principle need not involve harsh treatment or negative personal interactions, practitioners should heed Bandura's (1969) valuable counsel in this regard:

> Anyone attempting to control specific troublesome responses should avoid modeling punitive forms of behavior that not only counteract the effects of direct training but also increase the probability that on future occasions the individual may respond to interpersonal thwarting in an imitative manner. (p. 313)

Punishment May Be Overused due to Negative Reinforcement of the Punishing Agent's Behavior

Negative reinforcement may be a reason for the widespread use of, and reliance upon, punishment in child rearing, education, and society. When Person A delivers a reprimand or other aversive consequence to Person B for misbehaving, the immediate effect is often the temporary cessation of the troubling behavior. The termination of this aversive stimulus serves as negative reinforcement for Person A's behavior. Reese (1966) stated the case succinctly: "Punishment reinforces the punisher" (p. 37).

Alber and Heward (2000) described how the natural contingencies at work in a typical classroom could strengthen a teacher's use of reprimands for disruptive behavior while undermining her use of contingent praise and attention for appropriate behavior.

> Paying attention to students when they are behaving inappropriately (e.g., "Carlos, you need to sit down right now!") is negatively reinforced by the immediate cessation of the inappropriate behavior (e.g., Carlos stops running around and returns to his seat). As a result, the teacher is more likely to attend to student disruptions in the future. . . . Although few teachers must be taught to reprimand students for misbehavior, many teachers need help increasing the frequency with which they praise student accomplishments. Teacher-praising behavior is usually not reinforced as effectively as teacher-reprimanding behavior. Praising a student for appropriate behavior usually produces no immediate effects—the child continues to do his work when praised. Although praising a student for working productively on an assignment may increase the future likelihood of that behavior, there are no immediate consequences for the teacher. By contrast, reprimanding a student often produces an immediate improvement in the teacher's world (if only temporary)—that functions as effective negative reinforcement for reprimanding. (pp. 178–179)

POSITIVE PUNISHMENT INTERVENTIONS

Interventions featuring positive punishment interventions can take a wide variety of forms. We describe five in this section: reprimands, response blocking, response interruption and redirection (RIRD), contingent exercise, and overcorrection.

Reprimands

It may seem strange that immediately following a discussion of teachers' overreliance on reprimands, our first example of a positive punishment intervention focuses on reprimands. The delivery of verbal reprimands following the occurrence of misbehavior is perhaps the most common form of *attempted* positive punishment. However, a number of studies have shown that a firmly said "No!" or "Stop! Don't do that!" delivered immediately on the occurrence of a behavior can function as effective punishment (e.g., Hall et al., 1971; Thompson et al., 1999; Van Houten, Nau, Mackenzie-Keating, Sameoto, & Colavecchia, 1982).

In spite of the widespread use of reprimands in an effort to suppress undesired behavior, surprisingly few studies have examined their effectiveness as punishers. Results of a series of experiments by Van Houten, Nau, Mackenzie-Keating, Sameoto, and Colavecchia (1982) designed to identify variables that increased the effectiveness of reprimands as punishers for disruptive behavior in the classroom revealed that reprimands delivered with eye contact and in close proximity to the student were more effective than reprimands delivered from across the room. An interesting study by O'Leary, Kaufman, Kass, and Drabman (1970) found that quiet reprimands that were audible only to the child being reprimanded were more effective in reducing disruptive behavior than loud reprimands that could be heard by other children in the classroom.

If being reprimanded is the only way a child receives adult attention, it should not be surprising that reprimands function as reinforcement for that child rather than as punishment. Indeed, Madsen, Becker, Thomas, Koser, and Plager (1968) found that the repeated use of reprimands while students were out of seat served to increase, rather than reduce, the behavior. Consistent with research on other punishing stimuli, reprimands are more effective as punishers when motivation for the problem behavior has been minimized and the availability of an alternative behavior maximized (Van Houten & Doleys, 1983).

A parent or teacher does not want to adopt a pattern of constant reprimanding. Reprimands should be used thoughtfully and sparingly in combination with frequent praise and attention contingent on appropriate behavior. O'Leary and colleagues (1970) recommended:

> An ideal combination would probably be frequent praise, some soft reprimands, and very occasional loud reprimands. . . . Combined with praise, soft reprimands might be very helpful in reducing disruptive behaviors. In contrast, it appears that loud reprimands lead one into a vicious cycle of more and more reprimands resulting in even more disruptive behavior. (p. 155)

Response Blocking

Response blocking—physically intervening as soon as the person begins to emit the problem behavior, to prevent the completion of the response—has shown effectiveness in reducing the frequency of some problem behaviors, such as chronic hand mouthing, eye poking, and pica (e.g., Lalli, Livezey, & Kates, 1996; Lerman & Iwata, 1996; Reid, Parsons, Phillips, & Green, 1993). In addition to preventing the response from occurring by using the least amount of physical contact and restraint possible, the therapist might issue a verbal reprimand or prompt to stop engaging in the behavior (e.g., Hagopian & Adelinis, 2001).

Lerman and Iwata (1996) used response blocking in treating the chronic hand mouthing (contact between any part of the

hand and the lips or mouth) of Paul, a 32-year-old man with profound intellectual disabilities. Following a baseline condition, in which Paul was seated in a chair with no one interacting with him and no leisure materials were available, response blocking on an FR 1 schedule was implemented. A therapist sat behind Paul and blocked his attempts to put his hand in his mouth. "Paul was not prevented from bringing his hand to his mouth; however, the therapist blocked the hand from entering the mouth by placing the palm of her hand about 2 cm in front of Paul's mouth" (p. 232). Response blocking produced an immediate and rapid decrease in hand-mouthing attempts to near-zero levels (see Figure 14.8).

Response blocking is often implemented as a treatment for SIB or self-stimulatory behavior when functional analysis reveals consistent responding in the absence of socially mediated consequences, which suggests the possibility that the behavior is maintained by automatic reinforcement from sensory stimuli produced by the response. Because response blocking prevents the learner from contacting the sensory stimuli that are normally produced by completing the response, subsequent decreases in responding could be due to extinction. Lerman and Iwata (1996) presented their study as a potential method for distinguishing whether the suppressive effects of response blocking are due to punishment or extinction mechanisms. They explained their reasoning, in part, as follows:

> Depending on the mechanism through which behavior is reduced (extinction vs. punishment), different schedules of reinforcement or punishment are in effect when a given proportion of responses is blocked. . . . Thus, as larger proportions of responses are blocked, the reinforcement schedule becomes leaner and the punishment schedule becomes richer. If response blocking produces extinction, response rates should increase or be maintained as more responses are blocked (i.e., as the reinforcement schedule is thinned), until [the effects of] extinction [i.e., reduced response rate] occurs at some point along the progression. Conversely, if the procedure functions as punishment, response rates should decrease as more responses are blocked (i.e., as the punishment schedule becomes richer). (pp. 231–232, words in brackets added)

A condition in which all responses are blocked might function as an extinction schedule (i.e., reinforcement in the form of sensory stimuli is withheld for all responses) or as a continuous (FR 1) schedule of punishment (i.e., all responses are followed by physical contact). As Lerman and Iwata (1996) explained, if only some responses are blocked, the situation may function as an intermittent schedule of reinforcement or as an intermittent schedule of punishment. Therefore, comparing response rates among conditions in which different proportions of responses are blocked should indicate whether the effects are due to extinction or to punishment.

If response blocking functioned as extinction for Paul's hand mouthing, an initial increase in response rate would be expected when the blocking procedure was implemented for every response; however, no such increase was observed.[5] If response blocking functioned as punishment, blocking every response would constitute a continuous schedule of punishment and a rapid decrease in responding would be expected; and that is exactly what the results showed (see data for the first response block [1.0] phase in Figure 14.8).

Conversely, if response blocking functioned as extinction for Paul's hand mouthing, then blocking some, but not all, responses would place the hand mouthing on an intermittent schedule of reinforcement and responding would be expected to increase from baseline levels. And blocking an ever-larger proportion of responses thins the reinforcement schedule further, causing the response rate to rise even higher. Instead, as a greater proportion of responses were blocked, the suppressive effects on Paul's SIB became more pronounced, a result expected as a punishment schedule becomes denser. Overall, therefore, the results of the experiment indicated that response blocking functioned as punishment for Paul's hand mouthing.

Smith, Russo, and Le (1999) conducted a systematic replication of Lerman and Iwata's (1996) experiment and found that the frequency of eye poking by a 41-year-old woman treated

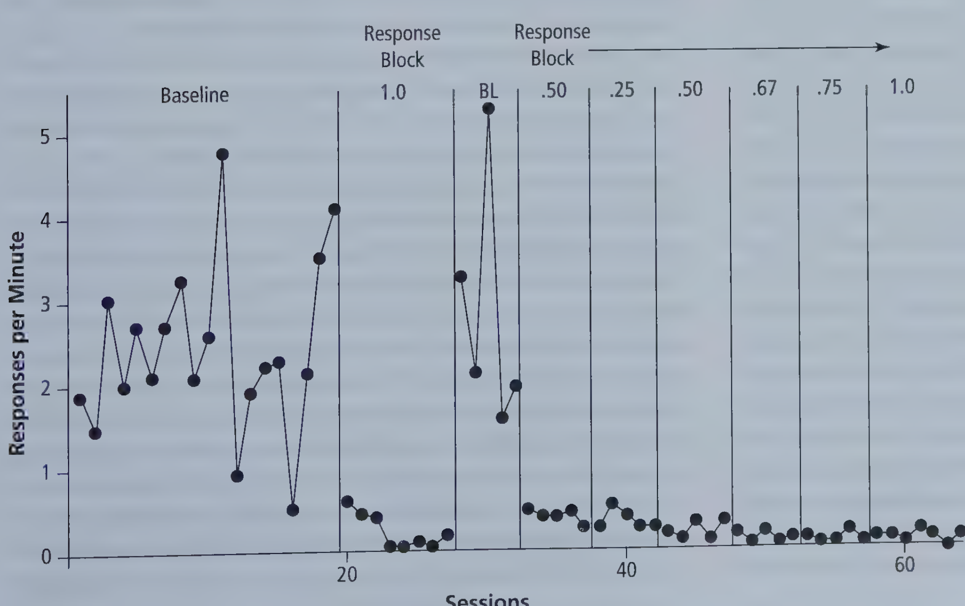

Figure 14.8 Rates of hand mouthing during baseline and varying schedules of response blocking.

"A Methodology for Distinguishing between Extinction and Punishment Effects Associated with Response Blocking," by D. C. Lerman and B. A. Iwata, 1996, *Journal of Applied Behavior Analysis, 29*, p. 232. Reproduced with permission of John Wiley & Sons Inc.

with response blocking decreased gradually—a response pattern indicative of extinction. The authors concluded that "whereas blocking may reduce one participant's behavior via punishment, it may extinguish another participant's behavior" (p. 369).

If response blocking occurs *before* the response is emitted, its suppressive effects cannot be due to punishment or extinction. Punishment and extinction are both behavior → consequence relations. Any procedure that prevents the target behavior from occurring in its entirety eliminates the behavior → consequence contingency and should be considered an antecedent intervention. However, if the problem behavior is a progression of movements or a response chain, then blocking the initial movement or response in the chain before the sequence produces the presumed reinforcer would alter the behavior → consequence contingency. For example, blocking a client's open hand *after* he begins to move it toward contact with his head is a consequence whose suppressive effects can be analyzed in terms of punishment and/or extinction.

Although response blocking may be viewed as a less restrictive and more humane intervention than delivering aversive stimulation after a response has occurred, it must be approached with great care. Side effects such as aggression and resistance to the response-blocking procedure have occurred (Hagopian & Adelinis, 2001; Lerman, Kelley, Vorndran, & Van Camp, 2003). Providing prompts and reinforcement for an alternative response can minimize resistance and aggression. For example, the aggressive behavior by a 26-year-old man with moderate intellectual disabilities and bipolar disorder during treatment with response blocking for pica (ingesting paper, pencils, paint chips, and human feces) was reduced by supplementing response blocking with a prompt and redirection to engage in an alternative behavior, in this case moving to an area of the room where popcorn was available (Hagopian & Adelinis, 2001).

Response Interruption and Redirection (RIRD)

Response interruption and redirection (RIRD) is a procedural variation of response blocking that includes interrupting stereotypic behavior at its onset and redirecting the individual to complete high-probability behaviors instead. Two types of RIRD have been identified and evaluated in the literature: motor RIRD and vocal RIRD (Ahearn, Clark, MacDonald, and Chung, 2007; Cassella, Sidener, Sidener, & Progar, 2011; Shawler & Miguel, 2015; Wunderlich & Vollmer, 2015). Both types have been used primarily with individuals with autism who emitted high levels of repetitive, stereotypic, nonfunctional behaviors. Procedurally, RIRD is employed when, at the onset of a stereotypic behavior, the therapist immediately presents a series of instructions, or demands, requiring high-probability vocal or motor responses (e.g., "What am I holding?" "Tell me your name." "Clap your hands."). RIRD is usually terminated upon a set criterion of successful responses (e.g., three correct in a row), although Saini, Gregory, Uran, and Fantetti (2015) found that one correct demand response was effective. RIRD has been used alone and combined with other procedures to reduce stereotypy so that students could engage in more interpersonal or socially appropriate behaviors. Practitioners who consider using RIRD procedures should have sufficient time, resources, and trained staff before implementation. RIRD can be labor- and time-intensive, and may extend teaching sessions beyond what can be accommodated in some educational or therapeutic settings.

Contingent Exercise

Contingent exercise is an intervention in which the client is required to perform a response that is not topographically related to the problem behavior. Contingent exercise has been found effective as punishment for various self-stimulatory, stereotypic, disruptive, aggressive, and self-injurious behaviors (e.g., DeCatanzaro & Baldwin, 1978; Kern, Koegel, & Dunlap, 1984; Luce & Hall, 1981; Luiselli, 1984).[6] In perhaps the most frequently cited example of contingent exercise as a punisher, Luce, Delquadri, and Hall (1980) found that the repetition of mild exercise contingent on aggressive behavior by two boys with severe disabilities reduced it to near-zero levels. Figure 14.9 shows the results for Ben, a 7-year-old who frequently hit other children at school. Each time Ben hit someone, he was required to stand up and sit down 10 times. Initially, Ben had to be physically prompted to stand; an assistant held the child's hand while pulling his upper body forward. Physical prompts were accompanied by verbal prompts of "stand up" and "sit down." Soon, whenever hitting occurred, the nearest adult simply said, "Ben, no hitting. Stand up and sit down 10 times" and the verbal prompts alone were sufficient for Ben to complete the exercise. If a hitting episode occurred during the contingent exercise, the procedure was reinstated.

Overcorrection

Overcorrection is a behavior reduction tactic in which, contingent on each occurrence of the problem behavior, the learner is required to engage in effortful behavior that is directly or logically related to the problem behavior. Originally developed by Foxx and Azrin (1972, 1973; Foxx & Bechtel, 1983) as a method for decreasing disruptive and maladaptive behaviors of adults with intellectual disabilities in institutional settings, overcorrection combines the suppressive effects of punishment and the educative effects of positive practice. Overcorrection includes either or both of two components: restitution and positive practice.

In **restitutional overcorrection**, contingent on the problem behavior, the learner is required to repair the damage caused by the problem behavior by returning the environment to its original state and then to engage in additional behavior that brings the environment to a condition better than it was prior to the misbehavior. A parent applying restitutional overcorrection with a child who repeatedly tracks mud onto the kitchen floor might require the child to first wipe up the mud and clean his shoes and then to *over* correct the effects of his misbehavior by mopping and waxing a portion of the floor and polishing his shoes.

Azrin and Foxx (1971) used restitutional overcorrection in their toilet training program by requiring a person who had an accident to undress, wash her clothes, hang them up to dry, shower, dress in clean clothing, and then clean up a portion of the lavatory. Azrin and Wesolowki (1974) eliminated stealing of food by hospitalized adults with intellectual disabilities by requiring residents to return not only the stolen food, or the

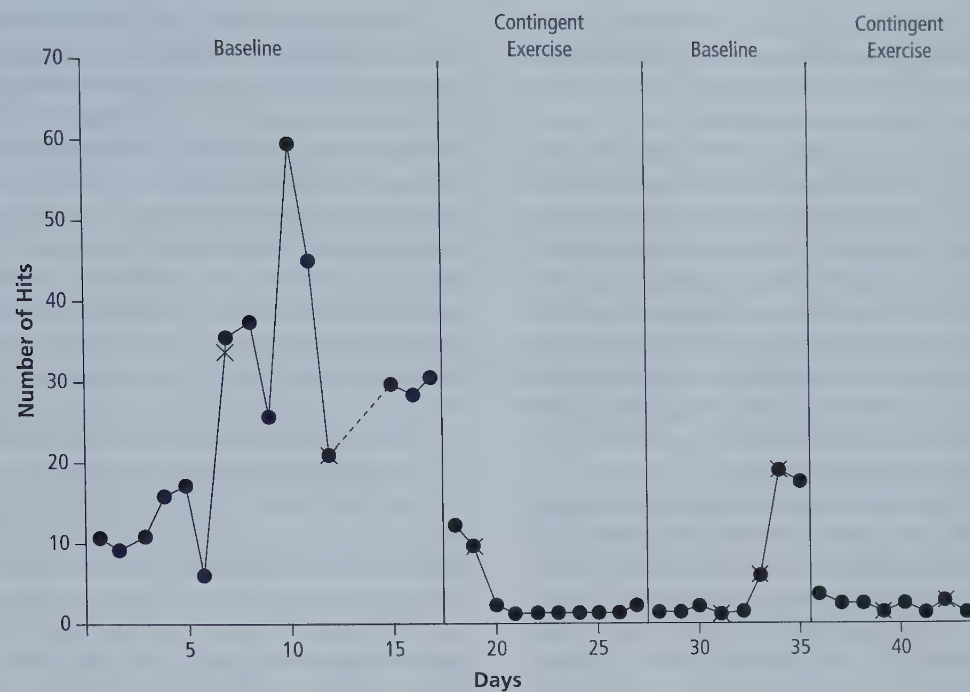

Figure 14.9 Number of times a 7-year-old boy hit other children during 6-hour school days during baseline and contingent exercise. X's represent response measures recorded by a second observer.

"Contingent Exercise: A Mild but Powerful Procedure for Suppressing Inappropriate Verbal and Aggressive Behavior," by S. C. Luce, J. Delquadri, and R. V. Hall, 1980, *Journal of Applied Behavior Analysis, 13*, p. 587. Reproduced with permission of John Wiley & Sons Inc.

portion that remained uneaten, but also to purchase an additional item of that food at the commissary and give it to the victim.

Azrin and Besalel (1999) differentiated a procedure they called *simple correction* from overcorrection. With simple correction, the learner is required, subsequent to the occurrence of an inappropriate behavior, to restore the environment to its previous state. For example, a simple correction procedure is in effect when requiring a student who cuts to the head of the lunch line to go to the back of the line. Requiring the student to wait until all others get in line and are served before re-entering the line would constitute a form of overcorrection in this instance. Azrin and Besalel recommended that simple correction be used to reduce behaviors that are not severe, occur infrequently, are not deliberate, and do not severely interfere with or annoy other people.

Correction is not possible if the problem behavior produces an irreversible effect (e.g., a one-of-a-kind dish is broken) or if the corrective behavior is beyond the person's means or skills. In such instances, Azrin and Besalel (1999) recommended that the person be required to correct as much of the damage his behavior caused as possible, be present at all points in the correction, and assist with any parts of the correction that he is able to perform. For example, a child who breaks a neighbor's window might be required to clean up the pieces of glass, measure the window, contact the store for a replacement pane, and be present and assist with each step when the new window pane is installed.

In **positive practice overcorrection**, contingent on an occurrence of the problem behavior, the learner is required to repeatedly perform a correct form of the behavior, or a behavior incompatible with the problem behavior, for a specified duration of time or number of responses. Positive practice overcorrection entails an educative component in that it requires the person to engage in an appropriate alternative behavior. The parent whose son tracks mud into the house could add a positive practice component by requiring him to practice wiping his feet on the outside door mat and then to enter the house for 2 minutes or 5 consecutive times. Overcorrection that includes restitution and positive practice helps teach what to do in addition to what not to do. The child who breaks an irreplaceable dish could be required to gently and slowly wash a number of dishes, perhaps with an exaggerated carefulness.

Researchers and practitioners have used positive practice overcorrection to reduce the frequency of problem behaviors such as toilet training (Azrin & Foxx, 1971), self-stimulation and stereotypic behavior (Azrin, Kaplan, & Foxx, 1973; Foxx & Azrin, 1973b), pica (Singh & Winton, 1985), bruxism (Steuart, 1993), sibling aggression (Adams & Kelley, 1992), and classroom disruptions (Azrin & Powers, 1975). Positive practice overcorrection has also been used for academic behaviors (Lenz, Singh, & Hewett, 1991), most often to decrease oral reading and spelling errors (e.g., Ollendick, Matson, Esveldt-Dawson, & Shapiro, 1980; Singh & Singh, 1986; Singh, Singh, & Winton, 1984; Stewart & Singh, 1986).

Positive practice overcorrection can also be applied to reduce or eliminate behaviors that do not create permanent response products that can be repaired or restored to their original state. For example, Heward, Dardig, and Rossett (1979) described how parents used positive practice overcorrection to

help their teenage daughter stop making a grammatical error in her speech. Eunice frequently used the contraction "don't" instead of "doesn't" with the third person singular (e.g., "He don't want to go."). A positive reinforcement program in which Eunice earned points she could redeem for preferred activities each time she used "doesn't" correctly had little effect on her speech. Eunice agreed with her parents that she should speak correctly but claimed the behavior was a habit. Eunice and her parents then decided to supplement the reinforcement program with a mild punishment procedure. Each time Eunice or her parents caught her using "don't" incorrectly in her speech, she was required to say the complete sentence she had just spoken 10 times in a row, using correct grammar. Eunice wore a wrist counter that reminded her to listen to her speech and to keep track of the number of times she employed the positive practice procedure.

When positive practice effectively suppresses the problem behavior, it is not clear what behavioral mechanisms are responsible for the behavior change. Punishment may result in decreased frequency of responding, because the person engages in effortful behavior as a consequence of the problem behavior. A reduction in the frequency of the problem behavior as an outcome of positive practice may also be a function of an increased frequency of an incompatible behavior, the correct behavior that is strengthened in the person's repertoire as the result of the intensive, repeated practice. Azrin and Besalel (1999) suggested that positive practice may be effective because it provides additional positive learning opportunities that have been absent in prior environments, and also requires "extra effort" that discourages future misbehaviors.

Specific procedures for implementing overcorrection vary greatly. Factors such as the type and severity of the problem behavior, its effects on the environment, the setting, the desired alternative behavior, and the learner's current skills should be considered. Figure 14.10 provides general guidelines for implementing overcorrection (Azrin & Besalel, 1999; Foxx & Bechtel, 1983; Kazdin, 2001; Miltenberger & Fuqua, 1981).

Although rapid and long-lasting therapeutic effects have been reported after corrective training, practitioners should be aware of several potential problems and limitations associated with overcorrection. First, overcorrection is a labor-intensive, time-consuming procedure that requires the full attention of the practitioner implementing it. Implementing overcorrection usually requires the practitioner to monitor the learner directly throughout the overcorrection process. Second, for overcorrection to be effective as punishment, the time that the learner spends with the person monitoring the overcorrection sequence must not be reinforcing. "If it is, it just might be worth waxing the entire kitchen floor if Mom chats with you and provides a milk and cookies break" (Heward et al., 1979, p. 63).

Third, a child who misbehaves frequently may not execute a long list of "cleanup" behaviors just because he was told to do so. Azrin and Besalel (1999) recommended three strategies to minimize the likelihood of refusal to perform the overcorrection sequence: (1) remind the learner what the more severe disciplinary action will be and, if the refusal persists, then impose that discipline; (2) discuss the need for correction before the problem behavior occurs; and (3) establish correction as an expectation and routine habit for any disruptive behavior. If the child resists too strongly or becomes aggressive, overcorrection may not be a viable treatment. Adult learners must voluntarily make the decision to perform the overcorrection routine.

GUIDELINES FOR USING PUNISHMENT

Assuming that habituation, treatment integrity, reinforcement, and training issues can be addressed, punishment can yield rapid, long-lasting suppression of problem behavior. Unfortunately, however, agency policies, human subject review procedures, and historical practices have limited the use of punishment for research and treatment in clinic-based settings (Grace, Kahng, & Fisher, 1994). Still, punishment may be a treatment of choice when (a) the problem behavior produces serious physical harm

Figure 14.10 Guidelines for implementing overcorrection.

1. Immediately upon the occurrence of the problem behavior (or the discovery of its effects), in a calm, unemotional tone of voice, tell the learner that he has misbehaved and provide a brief explanation for why the behavior must be corrected. Do not criticize or scold. Overcorrection entails a logically related consequence to reduce future occurrences of the problem behavior; criticism and scolding do not enhance the tactic's effectiveness and may harm the relationship between the learner and practitioner.
2. Provide explicit verbal instructions describing the overcorrection sequence the learner must perform.
3. Implement the overcorrection sequence as soon as possible after the problem behavior has occurred. When circumstances prevent immediately commencing the overcorrection sequence, tell the learner when the overcorrection process will be conducted. Several studies have found that overcorrection conducted at a later time can be effective (Azrin & Powers, 1975; Barton & Osborne, 1978).
4. Monitor the learner throughout the overcorrection activity. Provide the minimal number of response prompts, including gentle physical guidance, needed to ensure that the learner performs the entire overcorrection sequence.
5. Provide the learner with minimal feedback for correct responses. Do not give too much praise and attention to the learner during the overcorrection sequence.
6. Provide praise, attention, and perhaps other forms of reinforcement to the learner each time he "spontaneously" performs the appropriate behavior during typical activities. (Although technically not part of the overcorrection procedure, reinforcing an alternative behavior is a recommended complement to all punishment-based interventions.)

and must be suppressed quickly, (b) reinforcement-based treatments have not reduced the problem behavior to socially acceptable levels, or (c) the reinforcer maintaining the problem behavior cannot be identified or withheld (Lerman & Vorndran, 2002).

If the decision is made to use a punishment-based intervention, steps should be taken to ensure that the intended punisher actually works. The guidelines that follow will help practitioners apply punishment with optimal effectiveness while minimizing undesirable side effects and problems. We based these guidelines on the assumption that the analyst has conducted a functional behavior assessment to identify the variables that maintain the problem behavior, that the problem behavior has been defined clearly, and that the participant cannot avoid or escape the punisher.

Select Effective and Appropriate Punishers

Conduct Punisher Assessments

Aversive stimulus assessments are conducted to identify stimuli that function as punishers. Fisher and colleagues (1994) identified two advantages of conducting punisher assessments. First, the sooner an ideal punisher can be identified, the sooner it can be applied to the problem behavior. Second, data from punisher assessments might reveal the magnitude or intensity of the punisher necessary for behavioral suppression, enabling the practitioner to deliver the lowest intensity punisher to achieve socially significant response suppression.

Punisher assessment mirrors reinforcement assessment, except that instead of measuring engagement or duration of contact with each stimulus, the behavior analyst measures overall response suppression, negative verbalizations, avoidance movements, escape attempts, or disruptions associated with each potential punishing stimulus. Data from the punisher assessments are then used to develop a hypothesis on the relative comparative effects of each stimulus change as a punisher.

The decision of which among several potential punishers to choose should be based on the relative degree of punisher intrusiveness, the ease with which the punisher can be consistently and safely delivered, and data on potential response suppression. Subsequent observation might reveal that a consequence that is less intrusive, time-consuming, or difficult to apply might produce a significant decrease in the targeted behavior (Thompson et al., 1999).

Use Varied Punishers of Sufficient Quality and Intensity

The quality of a punisher is relative to a number of past and current variables that affect the participant. For example, Thompson and colleagues found that 15 seconds of physical restraint was a high-quality punisher for Ricky, Donna, and Lynn, but the physical restraint was not as ideal for Shelly. Although stimuli that reliably evoke escape and avoidance behaviors often function as high-quality punishers, practitioners should recognize that a stimulus change that effectively suppresses some behaviors may not affect other behaviors and that highly motivated problem behaviors may only be suppressed by a particularly high-quality punisher.

Generally, basic and applied researchers have found that the greater the intensity, magnitude, or amount of a punishing stimulus, the greater the suppression of behavior. This finding is conditional on delivering the punishing stimulus at its optimum level of magnitude initially, rather than gradually increasing the level over time (Azrin & Holtz, 1966). For example, Thompson and colleagues (1999) used the previously described punisher assessment procedure to determine an optimum magnitude or duration level for a punishing stimulus: a level and duration that produced a 75%, or greater, decrease in self-injurious behaviors (SIB) from baseline. Specifically, they determined that to meet the criterion of a punishing stimulus, one participant had his hands held in his lap for 15 seconds when SIB occurred, whereas two other participants received a verbal reprimand and their hands were held against their body for 15 seconds following SIB.

Beginning with a punishing stimulus of sufficient intensity is important, because participants may adapt to the punishing stimulus when levels of magnitude are increased gradually. It is possible that 15 seconds of movement restriction would have been a poor punisher for the participants if Thompson et al. (1999) had begun with a punishing stimulus of 3 seconds and gradually increased its magnitude from 3- to 6- to 9- to 15-sec intervals. Hineline and Rosales-Ruiz (2013) advise practitioners to begin "with an intense but safe, practical, and accepted punisher and then withhold further increases in intensity until the other variables are ruled out" (p. 488).

Use Varied Punishers

The effectiveness of a punishing stimulus can decrease with repeated presentations of that stimulus. Using a variety of punishers may help to reduce habituation effects. In addition, using various punishers may increase the effectiveness of less intrusive punishers. For example, Charlop, Burgio, Iwata, and Ivancic (1988) compared various punishers to a single presentation of one of the punishers (i.e., a stern "No!", overcorrection, time-out with physical restraint, a loud noise). Three-, 5-, and 6-year-old children with developmental disabilities served as participants. Their problem behaviors included aggression (Child 1), self-stimulation and destructive behavior (Child 2), and aggression and out-of-seat behavior (Child 3). The varied-punisher condition was slightly more effective than the single-presentation condition and enhanced the sensitivity of the behavior to less intrusive punishing stimuli (see Figure 14.11). Charlop and colleagues concluded, "It appears that by presenting a varied format of commonly used punishers, inappropriate behaviors may further decrease without the use of more intrusive punishment procedures" (p. 94).

Deliver the Punisher at the Beginning of a Behavioral Sequence

Punishing an inappropriate behavior as soon as it begins is more effective than waiting until the chain of behavior has been completed (Solomon, 1964). Once the sequence of responses that make up the problem behavior is initiated, powerful secondary reinforcers associated with completing each step of the chain may prompt its continuation, thereby counteracting the inhibiting or suppressing effects of the punishment that occurs at the end of the sequence. Therefore, whenever practical, the punishing stimulus should be presented early in the behavioral

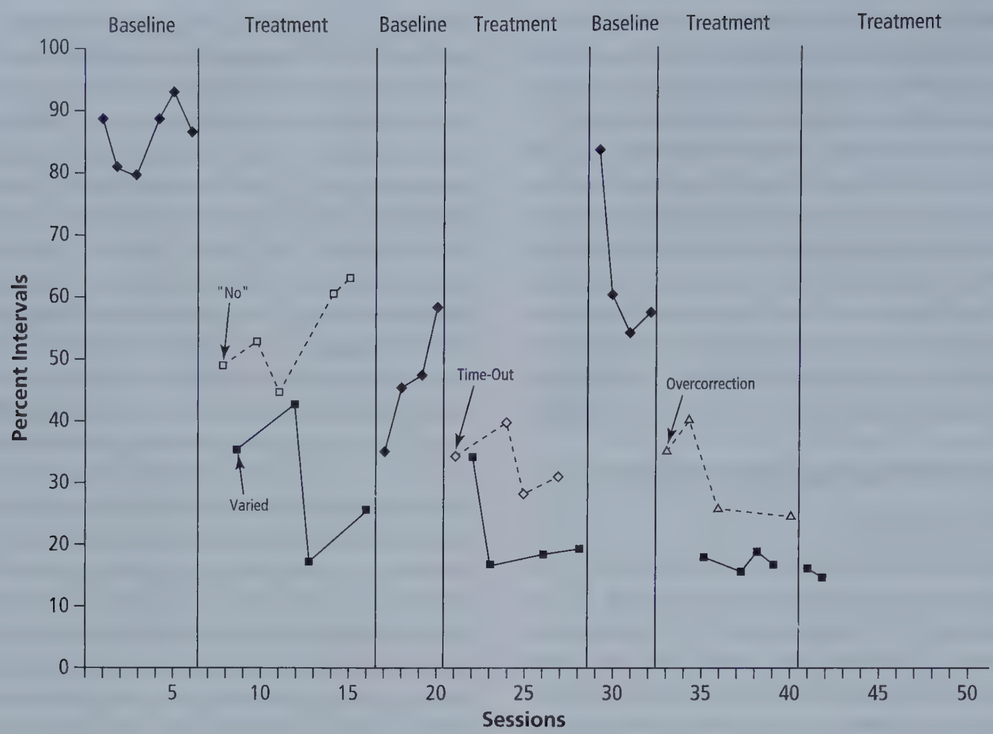

Figure 14.11 Percentage of intervals of occurrence of self-stimulation and destructive behavior for a 6-year-old girl with autism.

"Stimulus Variation as a Means of Enhancing Punishment Effects," by M. H. Charlop, L. D. Burgio, B. A. Iwata, and M. T. Ivancic, 1988, *Journal of Applied Behavior Analysis, 21*, p. 92. Reproduced with permission of John Wiley & Sons Inc.

sequence rather than later (Heron, 1978). For example, if violent arm swinging is a reliable precursor to self-injurious eye poking, then punishment (e.g., response blocking, restraint) should be delivered as soon as arm swinging starts.

Punish Each Instance of the Behavior Initially

Punishment is most effective when the punisher follows each response. This consistency is especially important when a punishment intervention is first implemented. Consistency goes beyond just programming an effective punishment schedule, that is, *when* punishment is delivered. Consistency refers to whether the punisher itself, its application as a behavior → consequence functional relation, and its procedural elements are being implemented as intended. Consistency, therefore, relates to treatment integrity. One can easily imagine the situation in which the disruptive behavior of an adolescent high school student with multiple teachers is supposedly being addressed with a plan whereby contingent on a disruptive behavior, each teacher will point his or her finger toward the student and emit a sharp reprimand, "No!". However, in reality some of the teachers follow the plan, but others do not. Or, a few teachers say "Noooo" with a semi-joking intonation, while others issue a firm reprimand. When these inconsistent situations occur, treatment integrity is at risk. Consequently, it becomes difficult to determine if the failure to suppress the disruptive behavior is the result of a stimulus that does not serve as a punisher, or if the punishment procedure is compromised by one or more treatment implementation failures.

Gradually Shift to an Intermittent Schedule of Punishment

Although punishment is most effective when the punisher immediately follows each occurrence of the problem behavior (Hineline & Rosales-Ruiz, 2013), practitioners may find a continuous schedule of punishment impractical because they lack the resources and time to attend to each occurrence of the behavior (O'Brien & Karsh, 1990). Several studies have found that, after responding has been reduced by a continuous schedule of punishment, an intermittent schedule of punishment may be sufficient to maintain the behavior at a socially acceptable frequency (Clark, Rowbury, Baer, & Baer, 1973; Lerman et al., 1997; Romanczyk, 1977).

We recommend two guidelines for using intermittent punishment. First—and this is especially important—a continuous (FR 1) schedule of punishment should be used to diminish the problem behavior to a clinically acceptable level before gradually thinning to an intermittent schedule of punishment. Second, combine intermittent punishment with extinction. It is unlikely that reduced responding will continue under intermittent punishment if the reinforcer that maintains the problem behavior cannot be identified and withheld. If these two guidelines for intermittent punishment are met and the frequency of the problem behavior increases to an unacceptable level, return to a continuous schedule of punishment and then, after recovery of acceptably low rates of responding, gradually shift to an intermittent schedule of punishment that is denser than the one used previously (e.g., VR 2 rather than VR 4).

Mediate Unavoidable Response-to-Punishment Delay

Consequences intended to serve as punishers for problem behavior are frequently delayed in the natural environment. Realistically, delays may occur because caregivers are not able to monitor behaviors continuously and may miss them, the individual may escape the delivery of the punisher, or the misbehavior may go undetected (Lerman & Vorndran, 2002). When punishers cannot be delivered immediately, applied behavior analysts should strive to mediate response-to-punishment delay.

For example, before administering a delayed punisher, Rolider and Van Houten (1985) played audiotapes of the child's tantrums earlier in the day. Explaining the tape recorder's purpose to the child and leaving it in sight while the recordings were collected might have resulted in the tape recorder bridging the temporal gap between inappropriate behavior and its consequence (i.e., by functioning as discriminative stimuli for punishment) (Lerman & Vorndran, 2002).

Supplement Punishment with Complementary Interventions

Applied behavior analysts typically do not use punishment as a single intervention: They combine punishment with other interventions, primarily differential reinforcement, extinction, and a variety of antecedent interventions. Basic and applied researchers consistently find that the effectiveness of punishment is enhanced when the learner can make other responses for reinforcement. In most circumstances, applied behavior analysts should incorporate differential reinforcement of alternative behavior (DRA), differential reinforcement of incompatible behavior (DRI), or differential reinforcement of other behaviors (DRO) (see Chapter 25) into a treatment program to supplement a punishment. When used as a reductive procedure for problem behavior, differential reinforcement consists of two components: (1) providing reinforcement contingent on the occurrence of a behavior other than the problem behavior and (2) withholding reinforcement for the problem behavior (i.e., extinction). The study by Thompson and colleagues (1999) presented previously provides an excellent example of how reinforcement of an alternative behavior can enhance the suppressive effects of punishment and enable relatively benign punishment procedures to be effective even for chronic problem behaviors that have been resistant to change.

We recommend that practitioners reinforce alternative behaviors copiously. Additionally, the more reinforcement the learner obtains by emitting appropriate behaviors, the less motivated he will be to emit the problem behavior. In other words, heavy and consistent doses of reinforcement for alternative behaviors function as an abolishing operation that weakens (abates) the frequency of the problem behavior.

There is still another important reason for recommending the reinforcement of alternative behaviors. Applied behavior analysts are in the business of building repertoires by teaching the clients and students they serve new skills and more effective ways of controlling their environments and achieving success. Punishment (with the exception of some overcorrection procedures) eliminates behaviors from a person's repertoire. Although the person will be better off without those behaviors in her repertoire, punishment only teaches her what *not* to do—it does not teach her what to do instead.

The effectiveness of antecedent interventions such as functional communication training (FCT), high-probability request sequence (high-*p*), and noncontingent reinforcement (NCR), which diminish the frequency of problem behaviors by decreasing the effectiveness of the reinforcers that maintain the problem behaviors (see Chapter 26), can be made more effective when combined with punishment. For instance, Fisher and colleagues (1993) found that, although FCT did not reduce to clinically significant levels the destructive behaviors of four participants with severe intellectual disabilities and communication deficits, a combination of FCT and punishment produced the largest and most consistent reductions in problem behaviors.

Watch and Prepare for Negative Side Effects

It is difficult to predict the side effects that may result from punishment. The suppression of one problem behavior by punishment may lead to an increase in other undesirable behaviors. For example, punishment of self-injurious behavior may produce increased levels of noncompliance or aggression. Punishing one problem behavior may lead to a parallel decrease in desirable behaviors. For example, requiring that a student rewrite an ill-conceived paragraph may result in his ceasing to produce any academic work. Although punishment may produce no undesirable side effects, practitioners should be alert to problems such as escape and avoidance, emotional outbursts, and behavioral contrast, and have a plan for dealing with such events should they occur.

Record, Graph, and Evaluate Data Daily

Data collection in the initial sessions of a punishment-based intervention is especially critical. Unlike some behavior reduction procedures whose suppressive effects are often gradual (e.g., extinction, differential reinforcement of alternative behavior), the suppressive effects of punishment are usually quick and abrupt. In their classic review of the basic research on punishment, Azrin and Holz (1966) wrote:

> Virtually all studies of punishment have been in complete agreement that the reduction of responses by punishment is immediate if the punishment is at all effective. When the data have been presented in terms of the number of responses per day, the responses have been drastically reduced or eliminated on the very first day in which punishment was administered. When the data have been presented in terms of moment-to-moment changes, the reduction of responses has resulted within the first few deliveries of punishment . . . or within a few minutes. (p. 411)

The first data points from the punishment conditions in all of the graphs presented in this chapter provide additional empirical evidence for Azrin and Holz's statement of the immediate effects of punishment. Because of the abrupt effect of punishment, the practitioner should pay particular attention to the data from the first session or two of intervention. If a noticeable reduction of the problem behavior has not occurred within two

sessions of a punishment-based intervention, we recommend that the practitioner make adjustments to the intervention.

Frequent inspection of the data from a punishment perspective reminds those involved of the purpose of the intervention and reveals whether the problem behavior is being reduced or eliminated as intended. When the data indicate that a clinically or socially significant change has occurred and has been maintained, punishment can be shifted to an intermittent schedule or perhaps terminated altogether.

ETHICAL CONSIDERATIONS REGARDING THE USE OF PUNISHMENT

Ethical considerations regarding the use of punishment revolve around three major issues: the client's right to safe and humane treatment, the professional's responsibility to use least restrictive procedures, and the client's right to effective treatment.[7]

Right to Safe and Humane Treatment

Dating from the Hippocratic Oath (Hippocrates, 460 BC–377 BC), the first ethical canon and responsibility for any human services provider is to do no harm. So, any behavior change program, be it a punishment-based intervention to reduce life-threatening self-injurious behavior or an application of positive reinforcement to teach a new academic skill, must be physically safe for all involved and contain no elements that are injurious, degrading, or disrespectful to participants.

Treatments are deemed safe when they put neither the caregiver nor the target individual at physical, psychological, or social risk (Favell & McGimsey, 1993). Although there exists no universally accepted definition of what constitutes humane treatment, a reasonable case could be made that humane treatments are (a) designed for therapeutic effectiveness, (b) delivered in a compassionate and caring manner, (c) assessed formatively to determine effectiveness and terminated if effectiveness is not demonstrated, and (d) sensitive and responsive to the overall physical, psychological, and social needs of the person.

Least Restrictive Alternative

A second canon of ethics for human services professionals is not to intrude on a client's life any more than necessary to provide effective intervention. The *doctrine of the least restrictive alternative* holds that less intrusive procedures should be tried and found to be ineffective before more intrusive procedures are implemented. Interventions can be viewed as falling along a continuum of restrictiveness from least to most. The more a treatment procedure affects a person's life or independence, such as her ability to go about daily activities in her normal environment, the greater its restrictiveness. A completely unrestrictive intervention is a logical fallacy. Any treatment must affect the person's life in some way to qualify as an intervention. At the other end of the continuum, absolute restrictiveness exists during solitary confinement, where personal independence is unavailable. All behavior change interventions developed and implemented by applied behavior analysts fall within these extremes.

Selecting any punishment-based intervention essentially rules out as ineffective all positive or positive reductive approaches based on their demonstrated inability to improve the behavior. For example, Gaylord-Ross (1980) proposed a decision-making model for reducing aberrant behavior that would have practitioners rule out assessment considerations, inappropriate or ineffective schedules of reinforcement, ecological variables, and curriculum modifications *before* punishment is implemented.

Some authors and professional organizations have advanced the position that all punishment-based procedures are inherently intrusive and should never be used (e.g., LaVigna & Donnellen, 1986; Mudford, 1995). Others have advanced the counter-position that punishment-based procedures, because of their inherent level of intrusiveness, should be used only as a last resort (Gaylord-Ross, 1980; Iwata, 1988).

Most people would rate interventions based on positive reinforcement as less restrictive than interventions based on negative reinforcement; reinforcement interventions as less restrictive than punishment interventions; and interventions using negative punishment as less restrictive than those using positive punishment. However, the intrusiveness or restrictiveness of an intervention cannot be determined by the principles of behavior on which it is based. Restrictiveness is a relative concept that depends on the procedural details and ultimately rests at the level of the person with whom it is applied. A positive reinforcement intervention that requires deprivation may be more restrictive than a positive punishment procedure in which a buzzer sounds each time an incorrect response is made, and what one person considers intrusive may pose no discomfort for another person. Horner (1990) suggested that most people accept punishment interventions to reduce challenging behavior as long as those interventions: "(a) do not involve the delivery of physical pain, (b) do not produce effects that require medical attention, and (c) are subjectively judged to be within the typical norm of how people in our society should treat each other" (pp. 166–167).

In their review of response-reduction interventions based on the principle of punishment, Friman and Poling (1995) pointed out that punishment-based tactics, such as those requiring the person to make an effortful response contingent on the occurrence of target behavior, meet Horner's (1990) criteria for acceptable response-reduction interventions. They stated: "None of the procedures caused pain or required medical attention, nor did they contrast with societal norms. For example, coaches often require disobedient players to run laps, and drill instructors make misbehaving recruits do pushups" (p. 585).

Although least restrictive alternative practices assume that the less intrusive procedures are tried and found ineffective before a more restrictive intervention is introduced, practitioners must balance that approach against an effectiveness standard. Gast and Wolery (1987) suggested that, if a choice must be made between a less intrusive but ineffective procedure and a more intrusive but effective procedure, the latter should be chosen. A Task Force on the Right to Effective Treatment appointed by the Association for Behavior Analysis International provided, in part, the following perspective on the importance of judging

the ultimate restrictiveness of treatment options on the basis of their degree of proven effectiveness:

> Indeed, a slow-acting but nonrestrictive procedure could be considered highly restrictive if prolonged treatment increases risk, significantly inhibits or prevents participation in needed training programs, delays entry into a more optimal social or living environment, or leads to adaptation and the eventual use of a more restrictive procedure. Thus, in some cases, a client's right to effective treatment may dictate the immediate use of quicker-acting, but temporarily more restrictive, procedures. (Van Houten et al., 1988, p. 114).

Right to Effective Treatment

Ethical discussions regarding the use of punishment revolve most often around its possible side effects and how experiencing the punisher may cause unnecessary pain and possible psychological harm for the person. Although each of these concerns deserves careful consideration, the right to effective treatment raises an equally important ethical issue, especially for persons who experience chronic, life-threatening severe problem behaviors. Some maintain that failing to use a punishment procedure that research has shown to be effective in suppressing self-destructive behavior similar to their client's is unethical because doing so withholds a potentially effective treatment and risks maintaining a dangerous or uncomfortable state for the person. For example, Baer (1971) stated: "[Punishment] is a legitimate therapeutic technique that is justifiable and commendable when it relieves persons of the even greater punishments that result from their own habitual behavior" (p. 111).

As Iwata (1988) explained, if all other less intrusive treatments with a sufficient research base to provide a legitimate chance of success have failed, the use of punishment procedures is the only ethical option:

> In the ideal world, treatment failures do not occur. But in the actual world failures do occur, in spite of our best efforts, leaving us with these options: continued occurrence of the behavior problem toward some devastating endpoint, restraint, sedating drugs, or aversive contingencies. I predict that if we apply our skills to maximize the effectiveness of positive reinforcement programs, we will succeed often. After following such a course, my further prediction is that if we reach the point of having to decide among these ultimate default options, the client's advocate, the parent, or, if necessary, the courts will select or use the option of aversive contingencies. Why? Because under such circumstances it is the only ethical action. (pp. 152–153)

Balancing the least restrictive alternative, the right to effective treatment, and Baer's (1971) vision to relieve a person of greater punishments if his severe behavior problem remains untreated or ineffective treatments are allowed to continue, is a difficult challenge. However, behavior analysts are not without relief. In the intervening 40-plus years since the 1980s, and in light of more recent successful developments using least restrictive alternative interventions informed by functional behavior analysis, even the most serious life-threatening behaviors can be treated effectively and humanely without resorting to the use of noxious or painful unconditioned punishers (e.g., water mist, aromatic ammonia, electric shock). Research has shown that the judicious use of stimulus control procedures (McKenzie et al., 2008), time-out and contingent restraint (Lerman et al., 1997), adding a significant reinforcement component (DRA) to a punishment regimen (Thompson et al., 1999), effectively manipulating reprimands (McKenzie et al., 2008), response blocking (Lalli, Lizevey, & Kates, 1996), contingent exercise (Luce et al., 1980), varying commonly used punishers (Charlop et al., 1988), and overcorrection (Steuart, 1993) can reduce problem behaviors for which unconditioned punishers were often applied. The application of unconditioned punishers no longer meets the standards of least restrictive alternative or best practice.

Applied behavior analysts who conduct functional behavior analyses, perform comprehensive punisher assessments, vary antecedent and consequence methods, and apply these methods alone or in combination will achieve as much, or more, success in reducing self-injurious and other dangerous behaviors than previously considered possible. In doing so, they will fulfill their mission of improving clients' quality of life by ensuring the right to effective treatment, providing best practice, and using the least restrictive alternative.

Punishment Policy and Procedural Safeguards

Armed with knowledge from the experimental literature, real-world variables and contingencies with which to contend (i.e., chronic, life-threatening problems), and practices and procedures rooted in ethical codes of conduct, practitioners can consider punishment approaches, when necessary, to provide meaningful programs for the persons in their care. One mechanism for ensuring that best practice approaches are used (Peters & Heron, 1993) is to adopt and use dynamic policies and procedures that provide clear guidelines and safeguards to practitioners.

Agencies can protect and ensure their clients' rights to safe, humane, least restrictive, and effective treatment by developing policy and procedural guidelines that must be followed when any punishment-based intervention is implemented (Favell & McGimsey, 1993; Griffith, 1983; Wood & Braaten, 1983). Figure 14.12 provides an outline and examples of the kinds of components that might be included in such a document.

Best practice dictates that practitioners consult their local, state, or national professional association policy statements regarding the use of punishment. For example, the Association for the Advancement of Behavior Therapy (AABT) provides guidelines that address treatment selection, including punishment (Favell et al., 1982). The Association for Behavior Analysis International adheres to the American Psychological Association's Ethics Code (2004), which, in turn, addresses treatment issues. Collectively, policy statements address implementation requirements, procedural guidelines and precautions, and evaluation methods that an agency should use when implementing any punishment-based intervention. Chapter 31 provides additional information on ethical standards for applied

Figure 14.12 Suggested components in an agency's policy and procedural guidelines to help ensure the ethical, safe, and effective use of punishment.

Policy Requirements

- Intervention must conform to all local, state, and federal statutes.
- Intervention must conform to the policies and codes of ethical conduct of relevant professional organizations.
- Intervention should include procedures for strengthening and teaching alternative behaviors.
- Intervention must include plans for generalization and maintenance of behavior change and criteria for eventual termination or reduction of punishment.
- Informed consent must be obtained from the client or a parent or legal advocate before intervention begins.

Procedural Safeguards

- Before intervention begins, all relevant staff must be trained in (a) the technical details of properly administering the punishment procedure; (b) procedures for ensuring the physical safety of the client and staff and the humane treatment of the client; and (c) what to do in the event of negative side effects, such as emotional outbursts, escape and avoidance aggression, and noncompliance.
- Supervision and feedback of staff administering the punishment intervention must be provided and, if necessary, booster-training sessions provided.

Evaluation Requirements

- Each occurrence of the problem behavior must be observed and recorded.
- Each delivery of the punisher must be recorded and the client's reactions noted.
- Periodic review of the data (e.g., daily, weekly) by a team of parent/advocates, staff, and technical consultants must be conducted to ensure that ineffective treatment is not prolonged or effective treatment terminated.
- Social validity data must be obtained from the client, significant others, and staff on (a) treatment acceptability and (b) the real and likely impact of any behavior change on the client's current circumstances and future prospects.

behavior analysts and procedures for securing informed consent, protecting clients' rights, and ensuring safe and humane interventions.

CONCLUDING PERSPECTIVES

We conclude this chapter with brief comments on our perspectives regarding the principle of punishment, and especially applications featuring unconditioned punishers as default technologies. We believe that applied behavior analysis would be a stronger, more competent discipline, and its practitioners would be more effective, if (a) punishment's natural role and contributions to survival and learning are recognized and valued within their limitations, (b) focused basic and applied research on punishment is conducted, and (c) treatments featuring differential reinforcement options, stimulus control procedures, time-out from positive reinforcement, response blocking, and contingent restraint, be employed in lieu of treatments featuring unconditioned punishers as default technologies.

Punishment's Natural and Necessary Role in Survival and Learning Should Be Recognized

Behavior analysts ought not dismiss punishment out of hand as a possible therapeutic intervention. Positive and negative punishment contingencies occur naturally in everyday life as part of a complex mix of concurrent reinforcement and punishment contingencies, as Baum (2017) illustrated so well in this example:

> Life is full of choices between alternatives that offer different mixes of reinforcement and punishment. Going to work entails both getting paid (positive reinforcement) and suffering hassles (positive punishment), whereas calling in sick may forfeit some pay (negative punishment), avoid the hassles (negative reinforcement), allow a vacation (positive reinforcement), and incur some workplace disapproval (positive punishment). Which set of relations wins out depends on which relations are strong enough to dominate, and that depends on both the present circumstances and the person's history of reinforcement and punishment. (p. 68)

Vollmer (2002) suggested that the scientific study of punishment continue because unplanned and planned punishment occur frequently and that planned, sophisticated applications of punishment are within the scope of inquiry for applied behavior analysts. We believe that studying punishment is within the realm of a science of behavior. As Vollmer states, "Scientists and practitioners are obligated to understand the nature of punishment if for no other reason than because punishment happens." (p. 469)

Focused Research on Punishment Is Needed

Many inappropriate and ineffective applications of punishment may reflect our incomplete knowledge of this principle (Lerman & Vorndran, 2002). Our technical understanding about, and recommendations for, applying punishment are derived from

decades-old basic research. Although sound scientific data that describe still-relevant questions have an unlimited shelf life, additional basic research on the mechanisms and variables that produce effective punishment no doubt will uncover elements that remain tangled in complex variables and their interactions.

Basic laboratory research allows for the control of variables that is difficult or impossible to attain in applied settings. Once mechanisms are revealed in basic research, however, applications to real-world challenges may be devised or adapted with more confidence, but with the simultaneous recognition of limitations and ethics. Practitioners must acknowledge when, how, why, and under what conditions punishment produces behavioral suppression for the students, clients, or patients with whom they work. Further, we must come to the realization that while a laboratory finding, with all of its controls and high internal validity, might produce a resounding suppressive effect, an applied practitioner using an adaptation of that punishment application may only yield a fraction of that effect. Still, for the child who is self-mutilating, self-destructive, and seemingly only coming into contact with life-threatening situations, obtaining a fractional improvement in behavior suppression may be cause for celebrating progress.

There are at least two explanations for why it might be difficult to conduct experimental work on punishment. First, for a variety of reasons, Human Subjects Review Committees may be less than enthusiastic about supporting research on punishment. To the extent that fewer proposals to conduct basic research on punishment are approved, then fewer data will be available on its effects, side effects, and applicability in applied settings. Second, applied researchers, in response to complying with ethical considerations and the rights of individuals to least restrictive alternative treatments, have shifted their focus to positive reductive procedures or less intrusive negative punishment applications.

We support Horner's (2002) call for practical applications of punishment research in field settings. It is important to determine how punishment works in situations in which environmental variables may not be as well controlled and in which the practitioner delivering the punisher might not be a trained professional. Educational and clinical applications of punishment also demand that behavior analysts understand the individual, contextual, and environmental variables that produce effective application. Without a clear and refined knowledge base about these variables and conditions, applied behavior analysis as a science of behavior cannot make a legitimate claim to have achieved a comprehensive analysis of its own basic concepts (Lerman & Vorndran, 2002; Vollmer, 2002).

Interventions Featuring Unconditioned Punishers as Default Technologies

Iwata (1988) recommended that punishment-based interventions involving the contingent application of aversive stimulation be treated as default technologies. A default technology is one that a practitioner turns to when all other methods have failed. Iwata recommended that behavior analysts not advocate for the use of aversive technologies (because advocacy is not effective, not necessary, and not in the best interests of the field), but that they be involved in research and development of effective aversive technologies.

> We must do the work because, whether or not we like it, default technologies will evolve whenever there is failure and, in the case of aversive stimulation, we are in a unique position to make several contributions. First, we can modify the technology so that it is effective and safe. Second, we can improve it by incorporating contingencies of positive reinforcement. Third, we can regulate it so that application will proceed in a judicious and ethical manner. Last, and surely most important, by studying the conditions under which default technologies arise, as well as the technologies themselves, we might eventually do away with both. Can you think of a better fate for the field of applied behavior analysis? (p. 156)

SUMMARY

Definition and Characteristics of Punishment

1. Punishment has occurred when a response is followed immediately by a stimulus change that decreases the frequency of that type of behavior in the future.

2. Punishment is defined neither by the actions of the person delivering the consequences nor by the nature of those consequences. A decrease in the future occurrences of the behavior must be observed before a consequence-based intervention qualifies as punishment.

3. Positive punishment has occurred when the presentation of a stimulus (or an increase in the intensity of an already present stimulus) immediately following a behavior results in a decrease in the frequency of the behavior.

4. Negative punishment has occurred when the termination of an already present stimulus (or a decrease in the intensity of an already present stimulus) immediately following a behavior results in a decrease in future occurrences of the behavior.

5. Because aversive events are associated with positive punishment and with negative reinforcement, the term *aversive control* is often used to describe interventions involving either or both of these two principles.

6. A punisher is a stimulus change that immediately follows the occurrence of a behavior and reduces the future frequency of that type of behavior.

7. An unconditioned punisher is a stimulus whose presentation functions as punishment without having been paired with any other punishers.

8. A conditioned punisher is a stimulus that has acquired its punishing capabilities by being paired with unconditioned or conditioned punishers.

9. A generalized conditioned punisher will function as punishment under a wide range of motivating operations because of its previous pairing with numerous unconditioned and conditioned punishers.

10. A discriminative stimulus for punishment, or S^{Dp}, is a stimulus condition in the presence of which a response class occurs at a lower frequency than it does in the absence of the S^{Dp} as a result of a conditioning history in which responses in the presence of the S^{Dp} have been punished and similar responses in the absence of that stimulus have not been punished (or have resulted in a reduced frequency or magnitude of punishment).

11. Punishment's suppressive effects on behavior are usually not permanent. Recovery from punishment is especially likely when the behavior being punished also obtains reinforcement.

Factors That Influence the Effectiveness of Punishment

12. Results of basic and applied research show that punishment is more effective when
    - the onset of the punisher occurs as soon as possible after the occurrence of a target response,
    - the intensity of the punisher is high,
    - each occurrence of the behavior is followed by the punishing consequence,
    - reinforcement for the target behavior is reduced, and
    - reinforcement is available for alternative behaviors.

Possible Side Effects and Problems with Punishment

13. Punishment sometimes causes undesirable side effects and problems, such as the following:
    - Emotional and aggressive reactions
    - Escape and avoidance behaviors
    - Behavioral contrast: Reduced responding from punishment in one setting or situation may be accompanied by increased responding in another setting or situation in which responses go unpunished
    - Modeling of undesirable behavior
    - Overuse of punishment caused by the negative reinforcement of the punishing agent's behavior

Positive Punishment Interventions

14. Reprimands: Used sparingly, a firm reprimand such as "No!" can suppress future responding.

15. Response blocking: When the learner begins to emit the problem behavior, the therapist physically intervenes to prevent or "block" the completion of the response.

16. Response interruption and redirection (RIRD): This approach is a variation of response blocking that consists of interrupting stereotypic behavior at its onset and redirecting the individual to complete high-probability behaviors instead.

17. Contingent exercise: In this intervention, the client is required to perform a response that is not topographically related to the problem behavior.

18. Overcorrection: This is a punishment-based tactic in which, contingent on each occurrence of the problem behavior, the learner is required to engage in effortful behavior that is directly or logically related to the problem.

19. Restitutional overcorrection: In this intervention, the learner is required to repair the damage caused by the problem behavior and then to engage in additional behavior that brings the environment to a condition better than it was prior to the misbehavior.

20. Positive practice overcorrection: In this type of overcorrection, the learner repeatedly performs a correct form of the behavior, or a behavior incompatible with the problem behavior, for a specified time or number of responses.

21. Contingent exercise: In this intervention, the client is required to perform a response that is not topographically related to the problem behavior.

Guidelines for Using Punishment

22. To apply punishment with optimal effectiveness while minimizing undesirable side effects, a practitioner should:
    - Select effective and appropriate punishers: (a) conduct punisher assessments to identify the least intrusive punisher that can be applied consistently and safely; (b) use punishers of sufficient quality and intensity; (c) use a variety of punishers to combat habituation and increase the effectiveness of less intrusive punishers.
    - If problem behavior consists of a response chain, deliver the punisher as early in the response sequence as possible.
    - Punish each occurrence of the behavior.
    - If maintaining a continuous schedule is impractical, gradually shift to an intermittent schedule of punishment combined with extinction.
    - Mediate unavoidable response-to-punishment delays.
    - Supplement punishment with complementary interventions, in particular, differential reinforcement, extinction, and antecedent interventions.
    - Watch and be prepared for negative side effects.
    - Record, graph, and evaluate data daily.

Ethical Considerations Regarding the Use of Punishment

23. The first ethical responsibility for any human services professional or agency is to do no harm. Any intervention

must be physically safe for all involved and contain no elements that are degrading or disrespectful to the client.

24. The doctrine of the least restrictive alternative holds that less intrusive procedures (e.g., positive reductive approaches) must be tried first and found to be ineffective before more intrusive procedures are implemented (e.g., a punishment-based intervention).

25. A client's right to effective treatment raises an important ethical issue. Some maintain that the failure to use a punishment procedure that research has shown to suppress self-destructive behavior is unethical because it withholds a potentially effective treatment and may maintain a dangerous or uncomfortable state for the client.

26. Agencies and individuals providing applied behavior analysis services can help ensure that applications of punishment-based interventions are safe, humane, ethical, and effective by creating and following a set of policy standards, procedural safeguards, and evaluation requirements.

Concluding Perspectives

27. Applied behavior analysts should recognize and appreciate the natural role of punishment and the importance of punishment to learning.

28. Many misapplications of punishment reflect the field's incomplete knowledge of the principle. More basic and applied research on punishment is needed.

29. Applied behavior analysts should advocate for the judicious and ethical application punishment, incorporate a full range of differential reinforcement contingencies, antecedent interventions, and extinction to reduce behaviors, study the conditions under which default technologies are considered and used, so as to eventually make them unnecessary.

KEY TERMS

behavioral contrast
conditioned punisher
discriminative stimulus for punishment
generalized conditioned punisher
negative punishment
overcorrection
positive practice overcorrection
positive punishment
punisher
punishment
recovery from punishment
response blocking
response interruption and redirection (RIRD)
restitutional overcorrection
unconditioned punisher

MULTIPLE-CHOICE QUESTIONS

1. Which of the following statements describes the definition of positive punishment?
   a. The presentation of a stimulus that increases the rate of occurrence of the target behavior
   b. The presentation of a stimulus that decreases the rate of occurrence of the target behavior
   c. The removal of a stimulus that decreases the rate of occurrence of the target behavior
   d. The removal of a stimulus that increases the rate of occurrence of the target behavior

   Hint: (See "Positive Punishment and Negative Punishment")

2. Which of the following statements describes the definition of negative punishment?
   a. The presentation of a stimulus that increases the rate of occurrence of the target behavior
   b. The presentation of a stimulus that decreases the rate of occurrence of the target behavior
   c. The removal of a stimulus that decreases the rate of occurrence of the target behavior
   d. The removal of a stimulus that increases the rate of occurrence of the target behavior

   Hint: (See "Positive Punishment and Negative Punishment")

3. Which statement best describes recovery from punishment?
   a. After punishment is discontinued, sometimes the behavior that experienced the punishment contingency will recover.
   b. When the punishment contingency is implemented, the behavior of interest may initially increase in rate, followed by a rapid decline in frequency.
   c. After punishment is discontinued, the behavior of interest may gradually reappear, only to disappear on its own, regardless of existing environmental contingencies.
   d. The period of time the implementer of the punishment contingency requires to "recover" from the emotional side effects of using punishment.

   Hint: (See "Recovery from Punishment")

4. Which of the following is not a factor that influences the effectiveness of punishment listed in the chapter?
   a. Immediacy
   b. Intensity
   c. Variation
   d. Schedule

   Hint: (See "Factors That Influence the Effectiveness of Punishment")

5. The use of a punishment procedure may cause unwanted side effects to appear. The chapter presents several side effects associated with the use of punishment. Which of the following is not a side effect listed in the chapter?
   a. Undesirable emotional responses
   b. Avoidance and escape
   c. Increased rate of problem behavior
   d. Decreased self-esteem
   Hint: (See "Possible Side Effects and Problems with Punishment")
6. Little Peter was walking along the fence of his uncle's dairy farm. Peter reached up and grabbed the wire along the fence, not realizing it was electrified. After recovering from the pain caused by the shock, Peter never again touched the fence wires. Which statement best describes the shock stimulus felt by Peter?
   a. Negative Reinforcement
   b. Negative Punishment
   c. Bad Judgment
   d. Positive Punishment
   Hint: ("Positive Punishment Interventions")
7. Which statement best describes positive punishment?
   a. The delivery of a stimulus, following a behavior, which increases the likelihood that the behavior will occur again
   b. The delivery of a stimulus, following a behavior, which decreases the likelihood that the behavior will occur again
   c. A stimulus delivered with good intentions
   d. The removal of a stimulus, following a behavior, which decreases the likelihood that the behavior will occur again
   Hint: (See "Positive Punishment Interventions")
8. Which statement best describes the procedure of response blocking?
   a. Blocking the occurrence of the antecedent stimulus associated with the occurrence of the problem behavior
   b. Delivering a wood block to the student prior to the occurrence of a behavioral response
   c. Physically intervening as soon as the student begins to emit a problem behavior to prevent the completion of the response
   d. The interventionist closing his or her eyes to deny the student pleasure after engaging in the problem behavior
   Hint: (See "Response Blocking")
9. Punishment should be thought of as an "eye-for-an-eye" procedure.
   a. True
   b. False
   Hint: (See "Guidelines for Using Punishment")
10. Which statement is not recommended as a guideline for the use of punishment?
   a. Test punisher on your pet prior to implementing it with your student
   b. Conduct punisher assessment
   c. Punish each occurrence of the behavior
   d. Deliver the punisher immediately
   Hint: (See "Guidelines for Using Punishment")
11. Carr and Lovaas (1983) recommended that practitioners experience any punisher personally before the treatment begins for what reason?
   a. It reminds the practitioner that it is a sadistic procedure.
   b. It reminds the practitioner that the technique produces physical discomfort.
   c. It reminds the practitioner that the technique is designed to increase the appropriate behavior of the student.
   d. It allows the practitioner to determine a baseline of discomfort which he/she then increases rapidly as it is administered to the student.
   Hint: (See "Guidelines for Using Punishment")
12. Which of the following is not listed in the chapter as an ethical consideration regarding the use of punishment?
   a. Right to safe and humane treatment
   b. Least restrictive alternative
   c. Right to effective treatment
   d. Most restrictive alternative
   Hint: (See "Ethical Considerations Regarding the Use of Punishment")
13. Sean was responsible for designing an intervention for a fifth-grade student who engaged in severe problem behavior consisting of throwing chairs at the teacher when an assignment was given. Sean decided to utilize a contingent physical restraint every time the child threw a chair. Sean is violating the ethical consideration of:
   a. Right to safe and humane treatment
   b. Least restrictive alternative
   c. Right to effective treatment
   d. Sean is not violating any ethical considerations
   Hint: (See "Ethical Considerations Regarding the Use of Punishment")

14. Which statement regarding the strength of applied behavior analysis is not supported in the punishment chapter?

a. Recognize and appreciate punishment's natural role and contributions to survival and learning

b. Increase the use of punishment procedures over the use of reinforcement-based interventions

c. Increase basic and applied research on punishment

d. View treatments featuring positive punishment as default technologies

Hint: (See "Concluding Perspectives")

15. Many of the recommendations for punishment are derived from basic research conducted more than _____ years ago.

a. 5

b. 20

c. 10

d. 40

Hint: (See "Concluding Perspectives")

ESSAY-TYPE QUESTIONS

1. Explain the procedures of positive punishment and negative punishment. Be sure to include in your answer factors that may influence the effectiveness of the punisher.

   Hint: (See "Definition and Characteristics of Punishment")

2. Discuss the possible side effects of using punishment.

   Hint: (See "Possible Side Effects and Problems with Punishment")

3. Define and give examples of the five types of positive punishment given in the chapter: reprimands, response blocking, contingent exercise, overcorrection, and response interruption and redirection.

   Hint: (See "Positive Punishment Interventions")

4. With the decision to use punishment-based treatment, everything should be done to ensure that the punishment is as effective as possible. Identify and discuss the suggested guidelines for the use of punishment.

   Hint: (See "Guidelines for Using Punishment")

5. The use of punishment presents some major ethical concerns. Identify and discuss two of the ethical concerns associated with the use of punishment and give an example of a situation in which the concern is involved.

   Hint: (See "Ethical Considerations Regarding the Use of Punishment")

6. Most of the punishment research is derived from basic studies that occurred more than 40 years ago. Discuss and contribute to Horner's (2002) call for practical applications of punishment research in field settings.

   Hint: (See "Concluding Perspectives")

NOTES

1. Although the term *automatic punishment* is used infrequently in the behavior analysis literature, it is similar to *automatic reinforcement*. Automatic punishment occurs when a punishing consequence (e.g., burned finger) is a socially unmediated, unavoidable outcome of a response (e.g., touching a hot stove).
2. A stimulus that becomes a conditioned punisher does not have to be a neutral stimulus prior to its pairing with a punisher. The stimulus could already function as a reinforcer under other conditions. For example, the onset of a blue light that has been paired repeatedly with reinforcement in one setting and with punishment in another setting is a conditioned reinforcer or a conditioned punisher, depending on the setting.
3. Instructions or conditioned stimuli that have been paired with known aversives can mitigate the time-delay gap.
4. Multiple schedules of reinforcement are described in Chapter 13.
5. When an extinction procedure is first implemented, an increase in responding, called an *extinction burst*, is sometimes observed before the response rate begins to decline. The principle, procedure, and effects of extinction are detailed in Chapter 22.
6. Increasing the effort or force required to perform a behavior can also be an effective tactic for reducing responding (Friman & Poling, 1995). There is no consensus as to whether punishment accounts for the reduced responding. As with response blocking, one perspective from which increased response effort can be conceptualized as a punishment procedure is to consider the movement necessary to come into contact with the increased effort requirement as a member of the target behavior response class. In that case, the increased effort required to continue the response to completion is (a) a consequence for the response that brought the learner into contact with it and (b) aversive stimulation that functions as punishment as the frequency of future responding decreases.
7. Chapter 31 discusses ethical issues and practices for applied behavior analysts.

CHAPTER 15

Negative Punishment

LEARNING OBJECTIVES

- Define negative punishment.
- Define nonexclusion time-out.
- Define exclusion time-out.
- State the procedures for implementing planned ignoring.
- State the procedures for implementing contingent observation.
- State the procedures for implementing withdrawal of a specific positive reinforcer.
- State the procedures for using a time-out room.
- State the procedures for implementing a partition time-out.
- List the decisions a practitioner must make prior to, during, and after a time-out application.
- Define response cost.
- List the undesirable aspects of negative punishment.

Half a minute into watching the funniest Internet video ever, Ruth clicked a button. Instead of seeing the full-screen view that she expected, the video disappeared. She reopened the video, advanced the cursor to the previous time stamp, clicked the same button, and once again lost access to the video. Ruth never again clicked the button that makes videos disappear!

Kent selected the last two front-row tickets for an upcoming concert by his favorite band. After entering his credit card information and billing address, he was prompted to review the details before clicking the purchase button. Just then Kent's cell phone buzzed with a text message, which led to several minutes of exchanged messages. When Kent returned to the ticket seller's website, the two tickets were no longer available. Kent no longer accepts cell phone texts when completing online purchases.

Negative punishment contingencies changed the behavior of both actors. Ruth no longer clicks the button that causes videos to disappear; Kent does not reply to text messages when shopping online. In **negative punishment**, a response is followed immediately by the *removal* of a stimulus that decreases future occurrences of similar responses. By contrast, in positive punishment, a response is followed immediately by the *presentation* of a stimulus that decreases future occurrences of similar responses. Both negative and positive punishment contingencies decrease future occurrences of behaviors. The distinction is in the type of stimulus change—removal or presentation—that functions as the punishing consequence (see Figures 15.1 and 14.2).

Applied behavior analysts implement negative punishment with two principal tactics: time-out from positive reinforcement and response cost. This chapter defines and operationalizes time-out and response cost, describes how these negative punishment tactics are used in applied settings, outlines desirable and undesirable aspects of each procedure, and offers practical and ethical guidelines to help practitioners implement time-out and response cost effectively.

TIME-OUT FROM POSITIVE REINFORCEMENT DEFINED

Time-out from positive reinforcement (or simply **time-out**) is the immediate response-contingent withdrawal of the opportunity to earn positive reinforcers or the immediate loss of access to positive reinforcers for a specified time. To function as negative punishment, the time-out procedure must decrease future occurrences of similar behaviors. Implicit in the definition of time-out are three important factors: (a) The discrepancy between the "time-in" and the time-out environments must be discriminative, (b) the response-contingent loss of access to reinforcement must occur immediately, and (c) a resultant decrease in the future frequency of the time-out–producing behavior must occur.[1]

Time-out can be viewed from a procedural, conceptual, or functional perspective. Procedurally, time-out entails removing the person from a reinforcing environment, or prohibiting access to reinforcers within his current environment for a specified period of time contingent upon the occurrence of problem behavior.

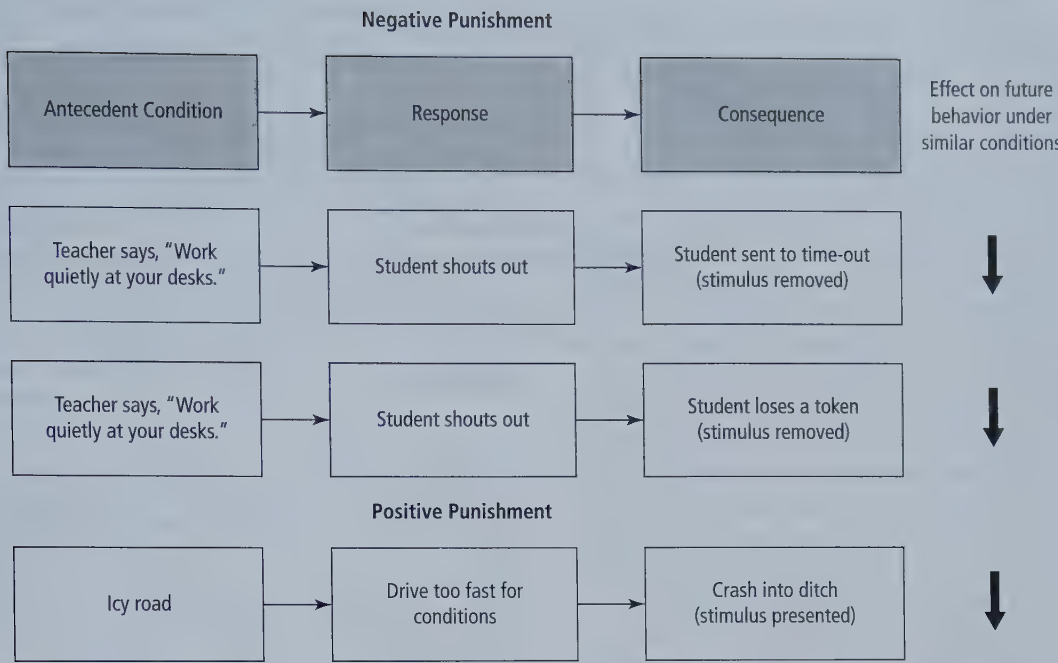

Figure 15.1 Negative punishment and positive punishment are distinguished by the type of stimulus change that functions as the punishing consequence.

Conceptually, the client must discriminate between the time-out and the time-in environment: that is, the more discriminatively reinforcing the time-in setting, the more effective time-out is as a negative punisher (Solnick, Rincover, & Peterson, 1977). In other words, the greater the difference between the reinforcing value of time-in and absence of that reinforcing value in the time-out setting, the more effective time-out will be.

From a functional perspective, time-out involves reduced future occurrences of similar behaviors. Without a reduction of future similar behavior, time-out is not in effect, even if the person has been removed from the setting, segregated briefly from the group but remains in the setting, or loses access to reinforcers. Assuming an exclusion time-out procedure was intended, if a teacher removes a student from the classroom—presumably the time-in setting—but upon the student's return, the problem behavior continues, effective time-out cannot be claimed.

So, contrary to popular thinking, time-out does not involve simply removing an individual to a sequestered setting. Although such removal may arguably describe an element of isolation, exclusion, or seclusion (Costenbader & Reading-Brown, 1995), the mere removal to another location falls far short of being accurately named time-out from positive reinforcement. Procedural, conceptual, and functional criteria need to be met to assert that claim.

TIME-OUT TACTICS FOR APPLIED SETTINGS

There are two basic categories of time-out available in applied settings: nonexclusion and exclusion. Within each type, several procedural variations provide options for the practitioner when deciding on a course of action to reduce similar behavior in the future (see Figure 15.2). As a rule, nonexclusion time-out should be the method of first choice because practitioners are ethically bound to employ the most powerful, but least restrictive, alternative when deciding on eligible variations. Regardless of which category is employed, we believe that, as a rule, time-out sessions should be brief, lasting not more than 2 to 5 minutes.

Nonexclusion Time-Out

Nonexclusion time-out means that contingent on the occurrence of the target behavior, the participant remains physically within the time-in setting, but elements of that setting are changed so that (a) the opportunity to earn reinforcers is removed; (b) a specific reinforcer is terminated; (c) repositioning occurs so that observations of ongoing activity continue, but without reinforcement; or (d) the individual is removed to a different space within the time-in setting.

Nonexclusion time-out is typically implemented using one of four tactics: planned ignoring, terminate specific reinforcer contact, contingent observation, and partition/select space time-out.

Planned Ignoring

Planned ignoring occurs when, contingent on the occurrence of an inappropriate behavior, the opportunity to earn social reinforcers—usually attention, physical contact, or verbal interaction—is removed. Operationally, planned ignoring involves systematically looking away from the individual, remaining quiet, or refraining from any interaction whatsoever for a specific time (Kee, Hill, & Weist, 1999). For example, if a behavior targeted for time-out occurred in a one-to-one instructional session, the therapist would simply turn her back to the learner for the duration of the time-out interval. The therapist's turning away essentially removes the time-in environment and denies the learner access to reinforcers.

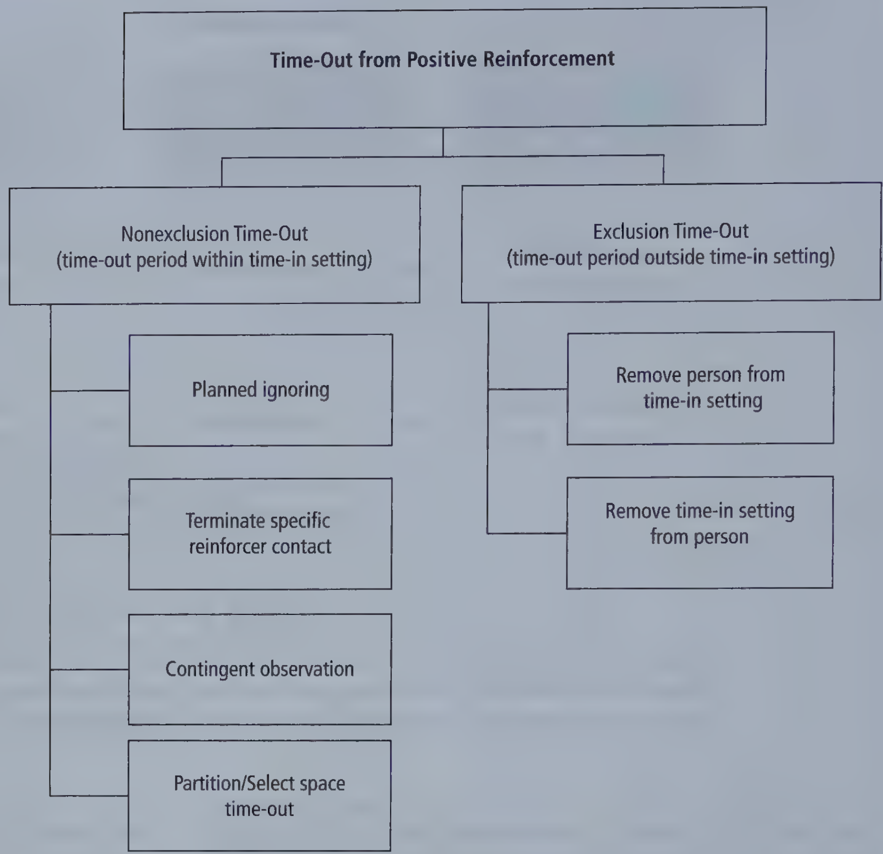

Figure 15.2 Tactics for implementing time-out from positive reinforcement.

Terminate Specific Reinforcer Contact

Terminate specific reinforcer contact is a variation of time-out whereby each occurrence of the target behavior immediately stops an activity or sensory reinforcer. West and Smith (2002) reported an application of this tactic to reduce noise level during school lunchtime. They mounted a facsimile traffic signal light to the cafeteria wall and fitted the light with a sensor to detect noise levels. When the sensor detected an acceptable conversation decibel level, a green light registered on the traffic signal and music played through cafeteria speakers (i.e., music was identified as a reinforcer and constituted the time-in condition). The music played as long as the students engaged in an appropriate level of conversation. If the conversational decibel level increased to a predetermined threshold, the traffic light changed from green to yellow, visibly warning the students that further increases in noise would lead to time-out from music. If the decibel level rose still higher, the traffic signal turned from yellow to red, and the music ceased for 10 sec. Under this group procedure, louder decibel conversations were reduced.

Bishop and Stumphauzer (1973) demonstrated that the contingent termination of television cartoons successfully reduced thumb sucking in three young children. Unknown to the children, a remote on/off switch was attached to the television. Baseline data indicated that each child emitted a high rate of thumb sucking while viewing the cartoons. During the terminate contact with a specific reinforcer variation of time-out, the television was immediately turned off when thumb sucking occurred, and it was turned back on when thumb sucking stopped. The procedure was effective in reducing thumb sucking not only in the treatment location (an office) but also during a story period at school.

Contingent Observation

In **contingent observation**, the person is repositioned within an existing setting such that he or she can observe ongoing activities, but access to available reinforcers is lost. A teacher uses contingent observation after an undesirable behavior when she redirects the offending student to move from the group, but remain visible, and reinforcers are withheld for a specified time. In short, the student is directed to "sit and watch" (Twyman, Johnson, Buie, & Nelson, 1994; White & Bailey, 1990). When the contingent observation period ends, the student rejoins the group, and is then able to earn reinforcers for appropriate behavior. An athletic analog to contingent observation occurs when an athlete commits an unnecessary foul during a game, and, in turn, the coach immediately "sidelines" the player. The player can still see the game; however, he cannot participate in it, or receive social reinforcers for contributing to the outcome (e.g., crowd cheers, praise from fellow players).

Figure 15.3 shows the effects of White and Bailey's (1990) use of contingent observation in reducing the number of disruptive behaviors in two inclusive physical education classes. When contingent observation was in effect (i.e., sit and watch), the number of disruptive behaviors across two classrooms decreased and remained near zero levels.

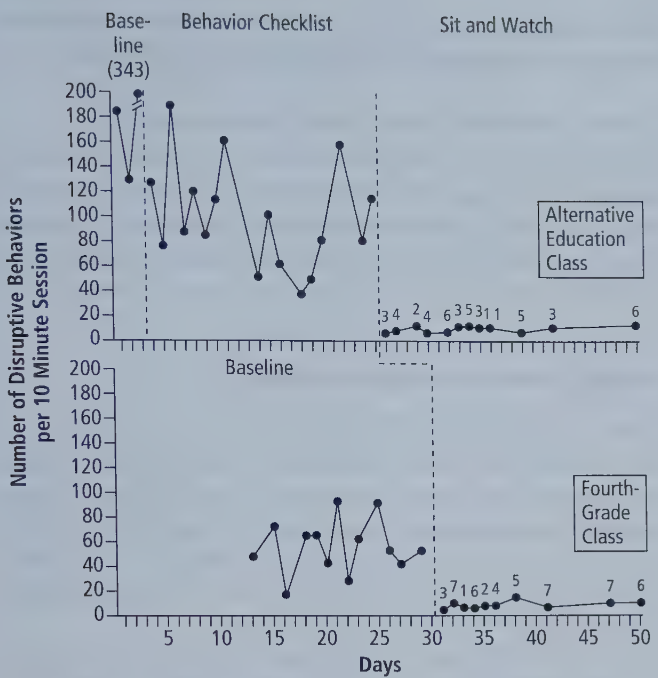

Figure 15.3 Number of disruptive behaviors per 10-min observation period. The numbers above the data points represent the number of times "sit and watch" was implemented during the class.

From "Reducing Disruptive Behaviors of Elementary Physical Education Students with Sit and Watch", A. G. White and J. S. Bailey, 1990, *Journal of Applied Behavior Analysis, 23*, p. 357. Reproduced with permission of John Wiley & Sons Inc.

Partition/Select Space Time-Out

In **partition or select space time-out**, the student remains within the time-in setting, but his view within the setting is restricted by a panel or cubicle, or a select space is arranged to serve as the time-out area (i.e., a carpet, a corner). A teacher would use partition time-out by directing a student, contingent on a misbehavior, to move from his assigned seat to that partitioned location for a specified time period. Although partition or select space time-out has the advantage of keeping the student within the time-in setting—presumably to hear academic content and the teacher praising other students for appropriate behavior—it also can be disadvantageous. That is, the individual may still be able to obtain reinforcement from other students, reducing effectiveness. Second, the student might become the object of disparaging comments from other students (e.g., "Brandon is a dummy; he's in trouble."). Third, since the individual's view—and the teacher's view—can be at least partially restricted, undesirable surreptitious behaviors may occur. Also, public perceptions must again be taken into account with this form of exclusion. Finally, even though the student remains in the room, the partition time-out area might be viewed as exclusionary.

Exclusion Time-Out

Exclusion time-out is the physical separation of the participant from the time-in environment when time-out goes into effect. There are two basic tactics for implementing exclusion time-out contingent on the occurrence of the target behavior: (a) The participant is removed immediately from the time-in environment, or (b) the time-in environment is removed immediately from the participant.

Participant Removed from Time-In Setting

A *time-out room* is any confined, safe, secure, supervised, and continuously monitored area within the participant's normal educational or treatment facility that is devoid of existing positive reinforcers, that does not have access to potential positive reinforcers, and in which the person can be securely placed. A time-out room should preferably be located in close proximity to the time-in setting, and it should have minimal furnishing (e.g., a chair and a table). It should have adequate light, heat, safety features, and ventilation, but should not contain potentially reinforcing items (e.g., pictures on the wall, telephones, breakable objects, windows with access to playgrounds, or busy streets). The room should not be locked, and it must be monitored continuously by staff.

A time-out room has several advantages that make it attractive to practitioners. First, the opportunity to acquire reinforcement during time-out is eliminated or reduced substantially because the time-out environment is physically constructed to minimize such stimuli. Second, after a few exposures to the time-out room, students learn to discriminate this room from other rooms in the building. The room assumes conditioned aversive properties, thus increasing the probability that the time-in setting will be more reinforcing. Third, the risk of a student hurting other students in the time-in setting is reduced when the offending student is removed to this space.

However, before using a time-out room, the practitioner must consider several strong and compelling disadvantages. Escorting a student to the time-out room is not without its potential challenges: Practitioners can encounter resistance and outbursts, and they should also anticipate and be fully prepared to deal with emotional escalations. Using a time-out room may serve as a negative reinforcer for the teacher, thus increasing its use (Skiba & Raison, 1990). Also, the time-out room may set the occasion for the person to engage in undetected self-destructive or self-stimulatory behaviors that should be stopped (Solnick et al., 1977). This situation compromises the effectiveness of time-out. Practitioners must be sensitive to the public's perception of the time-out room. Even a benign-appearing time-out room can be viewed with distrust by persons who perceive the intent of the room differently and are misinformed about its purpose.

In recent years, the use of the time-out room has increasingly fallen into disfavor with practitioners, members of professional associations, and client rights advocacy groups, all of whom embrace less intrusive, but still effective, interventions for problem behavior.[2]

Hallway time-out used to be common practice in schools, and some teachers continue to employ it, despite increasing administrative mandates to prohibit it. In *hallway time-out*, the student is directed to leave the classroom and sit (or stand) outside the classroom in the hallway or corridor until the time-out period expires. We do not recommend this procedure for several reasons: (a) Many school districts and child service agencies prohibit teachers and staff from placing children in

unsupervised settings; (b) the student can obtain "bootleg" reinforcement from a multitude of sources (e.g., students in other rooms, individuals walking in the hallway, school visitors); (c) there is increased likelihood of the student escaping (i.e., the student may run away from the school altogether); (d) the teacher is less likely to be able to monitor the student outside of her line of sight; and (e) unattended students, especially those in the midst of a behavioral episode, may represent a safety hazard to themselves or others. Therefore, for ethical, safety, and programmatic reasons, we strongly recommend that practitioners seek alternatives to hallway time-out when trying to decrease problematic behavior.

Time-In Setting Removed from Participant

This variation of exclusion time-out does not require changing the participant's physical location. Instead, contingent on the occurrence of the target behavior, the time-in environment is removed from the participant. This form of time-out is a feature of some computer-based learning programs whereby certain error responses are followed immediately by the screen going dark (or blank) for several seconds, denying the user access to the activity, and, hence, its reinforcers.

Desirable Aspects of Time-Out

Ease of Application

Time-out, especially in its nonexclusion variations, is relatively easy to apply. The teacher can accomplish even physically removing a student from the environment with comparative ease if the teacher acts in a businesslike fashion and does not attempt to embarrass the student. Issuing a direction privately (e.g., "Deion, you have disrupted Monique twice; time-out is now in effect.") can help the teacher handle a student who has misbehaved but who does not want to leave the room. If the behavior warrants exclusion time-out, the teacher must insist that the student leave; however, the teacher should communicate this insistence at close range so that the student is not placed in a position of challenging the teacher openly to save face with a peer group. Teachers should consult district policy on whether an administrator, or other staff member, should be called to assist with escorting the student to the time-out location.

Acceptability

Time-out, especially in its nonexclusion variations, meets an acceptability standard because practitioners regard it as appropriate, fair, and effective. Even so, practitioners should always check with the appropriate administering body to ensure compliance with school or agency policy before applying time-out for major or minor infractions.

Rapid Suppression of Behavior

When effectively implemented, time-out suppresses the target behavior in a moderate to rapid fashion. Sometimes only a few applications are needed to achieve acceptable reduction levels. Other reductive procedures (e.g., extinction, differential reinforcement of low rates) also produce decreases in behavior, but they can be time-consuming. Practitioners may not have the luxury of waiting several days or a week for a behavior to decrease. In such instances, time-out merits consideration.

Can Be Combined with Other Applications

Time-out can be combined with other procedures, extending its usability in applied settings (Dupuis, Lerman, Tsami, & Shireman, 2015). When combined with differential reinforcement, time-out can increase desirable behavior and decrease undesirable behavior (Byrd, Richards, Hove, & Friman, 2002).

USING TIME-OUT EFFECTIVELY

Although time-out has shown effectiveness in reducing behavior, it should not be the method of first choice. Practitioners faced with the task of reducing behavior should initially consider nonpunitive methods for reducing the target behavior (e.g., differential reinforcement of alternative behavior, extinction). Time-out should be considered only when the evidence shows that less intrusive procedures have failed.

Further, effective implementation of time-out requires the practitioner to make several decisions prior to, during, and after time-out implementation. Figure 15.4 shows Powell and Powell's (1982) time-out implementation checklist as an aid in the decision-making process. The following sections expand on several major points underlying many of these decisions.

Enrich the Time-In Environment

Selected behaviors in the time-in environment must be reinforced. In choosing the behaviors to reinforce during the time-in setting, practitioners should identify behaviors that are alternative to, or incompatible with, behaviors that will lead to time-out (e.g., using differential reinforcement of alternative behavior, differential reinforcement of incompatible behavior). Differential reinforcement will facilitate the development of appropriate behaviors. Further, the ratio of reinforcing statements to reprimanding comments should strongly fall in favor of reinforcing statements. Additionally, upon return from time-out, reinforcement for appropriate behavior should be delivered as quickly as possible.

Assuming that the effectiveness of any reinforcing or punishing stimulus is derived from the antecedent-behavior-consequence contingency, practitioners should examine all aspects of this relationship, including the time-in setting. Answering the following questions will help in that regard.

- Are the presumed reinforcers actually functioning as reinforcers?
- What function does the target behavior serve (i.e., attention, escape)?
- Is the time-out setting appropriate, and is the contingency being delivered immediately?

Within this context, practitioners are then charged with individualizing time-out to the specific circumstances at hand. Solnick et al. (1977) provide guidance: "This view of timeout suggests that there can be no 'standard' timeout procedure that will reliably reduce problem behavior. Alternatively, we are left

with the task of monitoring the relative reinforcing properties of the timein and timeout setting for each child" (p. 423).

Define the Behavior That Will Lead to Time-Out

Before time-out is implemented, all of the appropriate parties must be informed of the target behaviors that will lead to time-out. If a teacher decides to use time-out, she should describe in explicit, observable terms the behavior that will result in time-out. Merely informing students that disruptive behavior will result in time-out is not sufficient. Giving specific examples and nonexamples of what is meant by disruptive behavior is a better course to follow. Donaldson and Vollmer (2011) provided operational definitions using measurable criteria for screaming, disrupting, and aggressive behaviors. It is important to measure behaviors precisely because in post–time-out interviews, Readdick and Chapman (2000) discovered that children were not always aware of the reasons time-out was implemented. Providing explicit examples and nonexamples addresses this problem.

Determine the Form and Variation of Time-Out

School board policy or institutional constraints may be established that set the parameters for time-out variations that can be used in applied settings. In addition, physical factors within the building (e.g., a lack of available space) may prohibit exclusionary forms of time-out. As stated previously, the behavior analyst should first consider nonexclusion time-out tactics.

Obtain Permission

One of the more important tasks a practitioner must perform prior to using time-out, especially in its exclusionary variations, is to obtain permission from supervisors or administrators. Because of the potential to misuse time-out (e.g., leaving the person in time-out too long, continuing to use time-out when it is not effective), practitioners must obtain administrative approval before employing it. However, interactions can happen so fast in applied settings that obtaining permission on an instance-by-instance basis would be unduly cumbersome. A preferred method is for the practitioner, in cooperation with administrators, to decide beforehand the type of time-out that will be implemented for certain offenses (e.g., nonexclusion versus exclusion), the duration of time-out (e.g., 2 to 5 minutes), and the behaviors that will demonstrate reinstatement to the time-in environment. Communicating these procedures and/or policies to other practitioners and caretakers in the building, as well as to parents, is advisable.

Explain the Time-Out Procedure and Rules

In addition to posting the behaviors that will lead to time-out, the teacher should also post the rules. Posting helps make explicit the behaviors that produce the contingencies (Van Houten, 1979). Minimally, these rules should focus on the initial duration of time-out and the exit criteria (i.e., rules that determine when time-out is in effect, when it is over, and what happens if ongoing inappropriate behavior occurs when the scheduled time-out period ends).

Determine the Duration of the Time-Out Period

Time-out periods should be as brief as possible while maintaining effectiveness. Time-out durations of 2 to 5 minutes are often effective in reducing behavior, although a short duration may be ineffective initially if an individual has had a history of longer time-out periods. As a rule, time-out periods exceeding 15 minutes are not effective.

Longer time-out periods are counterproductive for several reasons. First, the person may develop a tolerance for the longer duration and find ways to obtain reinforcers during time-out. Observing the person unobtrusively in time-out may provide evidence of the reinforcers being obtained (Solnick et al., 1977). This situation occurs with people who have a history of self-stimulatory behavior. The longer the duration of time-out, the more opportunity there is to engage in self-stimulation, and the less effective time-out becomes. Second, longer time-out periods remove the person from the educational, therapeutic, or family time-in environment in which the opportunity to learn and earn reinforcers is available. Third, given the undesirable practical, legal, and ethical aspects of longer time-out periods, a prudent course of action is for the practitioner to use relatively short, but consistent, time-out periods. When these periods are short, student academic achievement is not affected adversely (Skiba & Raison, 1990).

Apply Time-Out Consistently

Each occurrence of the undesirable behavior should lead to time-out. If a teacher, parent, or therapist is not in a position to deliver the time-out consequence after each occurrence of the target behavior, it may be better to use an alternative reductive technique. Using time-out occasionally may lead to student or client confusion about which behaviors are acceptable and which are not.

Establish Exit Criteria

Practitioners can consider exit criteria options to include: (a) extending the time-out period for a predetermined amount of additional time, (b) continuing the time-out period until the disruptive behavior ceases, or (c) requiring the absence of misbehavior for a specified time prior to the end of the fixed time-out period (e.g., no misbehavior for the last 30 seconds of the 5-min period). This latter tactic is termed a *release contingency*. The rationale for implementing a release contingency is twofold: (1) to mitigate the risk of adventitiously reinforcing the behavior that leads to time-out by releasing the person while that behavior is being emitted (i.e., an escape contingency); and (2) to reduce the effects of the time-out behavior from carrying over, or spilling into, the time-in setting. A release contingency has been evaluated in several studies (e.g., Donaldson & Vollmer, 2011; Erford, 1999; Mace, Page, Ivancic, & O'Brien, 1986).

Donaldson and Vollmer (2011) compared fixed-duration versus a release contingency time-out procedures. Participants were four preschool children who exhibited high rates of problem behavior (e.g., screaming, crying, aggression, disruptions). The researchers collected data on (a) behaviors that led to time-out and (b) delay-producing responses (i.e., problem behavior that occurred during the time-out period). During baseline, teachers, parents, and experimenters conducted regularly scheduled playground or circle time activities as usual. Children were expected to participate in a variety of low-demand activities, and programmed consequences were not delivered should a disruptive episode occur. If children engaged in potentially dangerous behavior—jumping from playground equipment, for example—teachers or experimenters intervened by blocking and redirecting, but not by reprimanding.

During the fixed-duration time-out condition, the child was shown a yellow card prior to the start of each session and told, "If you are sent to time-out, you only have to stay for 4 minutes, no matter what" (p. 698). The yellow card was then placed in a visible location, and each occurrence of problem behavior resulted in a fixed-duration 4-min time-out.

During the release contingency time-out condition, the participant was shown a red card prior to the start of each session and told, "If you are sent to time-out, you will have to stay for 4 minutes, but you cannot leave time-out until you are calm" (p. 698). The red card was placed where the child could see it, and each occurrence of problem behavior resulted in a fixed-duration 4-min time-out. However, if disruptive behavior occurred during the last 30 seconds of that 4-min interval, time-out was extended until 30 seconds elapsed without problem or until 10 minutes passed.

Both time-out procedures reduced problem behavior by all four participants (see Figure 15.5). Donaldson and Vollmer (2011) reported that problem behavior that occurred during either the fixed-time or the release contingency time-out periods did not predict spillover effects in the classroom, home, or playground after time-out periods were terminated. They concluded the discussion of the study's results with this recommendation: "A fixed duration time-out should be considered first because there was no apparent benefit to including a release contingency, release contingencies resulted in longer time-outs, and the effort required to implement a release contingency time-out is greater than that required to implement a fixed-duration time-out" (p. 704).

The decision to exit time-out should consider not only the child's behavior during or shortly before time-out ends but also the effect of reintroducing an explosive, out-of-control client back into the time-in setting. Reintroducing a misbehaving student to the time-in setting may bring about two undesirable outcomes: (1) the offending student may learn that regardless of his behavior, he will be able to rejoin his classmates after a short period, and (2) classmates predisposed to act out may realize that they, too, can escape but later rejoin the group without having to change their behavior. Time-out should not be terminated until such behaviors are under control, or an alternative form of behavior suppression can be executed.

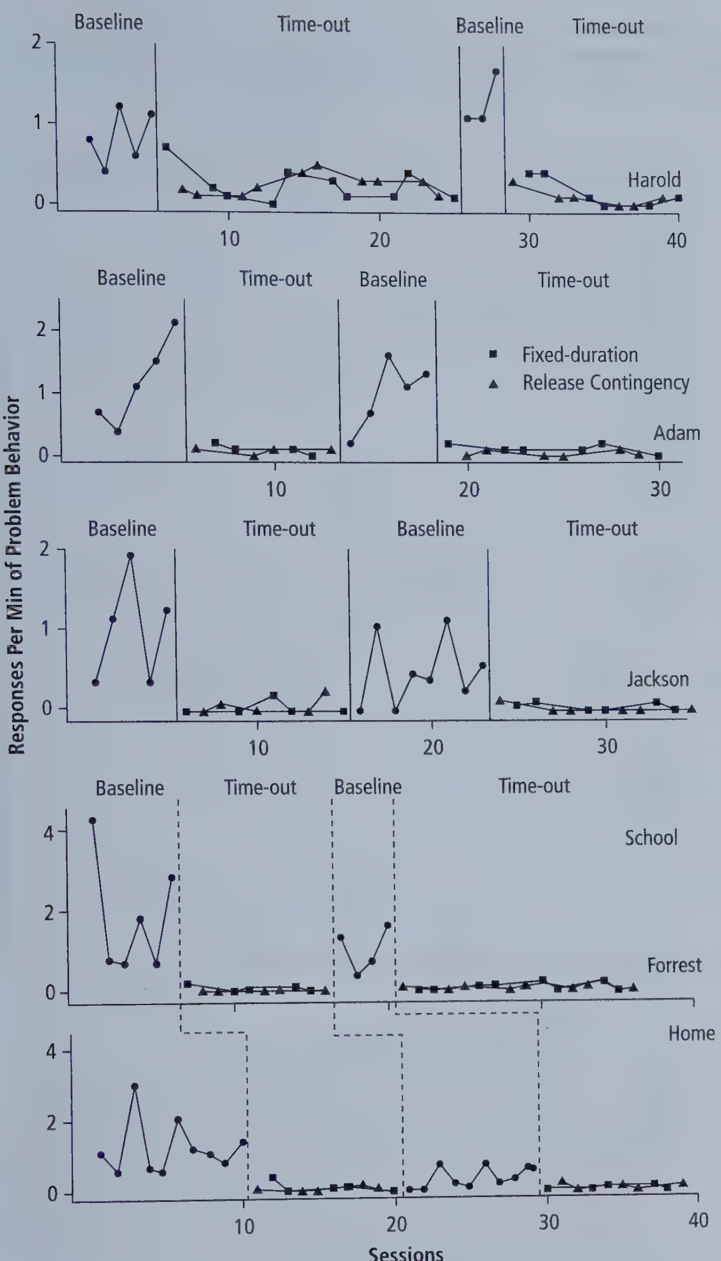

Figure 15.5 Rate of time-out–producing problem behavior across sessions for each participant.

"An Evaluation and Comparison of Time-Out Procedures with and without Release Contingencies", J. M. Donaldson and T. R. Vollmer, 2011, p, 699, *Journal of Applied Behavior Analysis, 44*. Reproduced with permission of John Wiley & Sons Inc.

If the practitioner anticipates that the inappropriate behavior that led to time-out may occur when time-out ends, then the individual should not be released from time-out. Exit criteria should establish this contingency, thereby increasing the potential that the problem behavior will not carry over to the time-in setting. Use of prompts, cues, or other discriminative stimuli toward the end of the time-out session may set the occasion for improved performance during the remaining minutes of time-out (e.g., "Rosario, when your time-out ends in 2 minutes, you may rejoin your classmates").

Ensure Compliance with Legal and Ethical Guidelines

The use of time-out in applied settings has been much discussed. Although litigation surrounding the use of this procedure has focused primarily on institutionalized populations (e.g., *Morales v. Turman*, 1973; *Wyatt v. Stickney*, 1974), the rulings in these cases have had a profound effect on the use of time-out in classroom, center, and clinical settings. The issues before the courts focus on the protection of client rights, whether time-out represents cruel and unusual punishment, and the degree of public acceptability of the time-out procedure.

The upshot of major court rulings has been that a person's right to treatment includes the right to be free from unnecessary and restrictive isolation. However, rulings also include language that permits the use of time-out in a behavior change program as long as the program is closely monitored and supervised and is designed to protect the individual or others from bodily harm.

In response to changing conditions in practice, court cases, increased knowledge about effective instruction, best practice, and input from practitioners, parents, and caretakers, the *Behavior Analyst Certification Board* (BACB) (2014) codified its view

	Definition	*Requirements*	*Compatible with Behavior Intervention Program (BIP)?*
Time-Out from Positive Reinforcement (Time-Out)	Immediate response-contingent withdrawal of the opportunity to earn positive reinforcers or the immediate loss of access to positive reinforcers for a specified time.	• A behavioral intervention plan (BIP) if exclusion time-out is used • Informed consent	• Yes, to the extent time-out is protective and therapeutic.
Seclusion	Involuntary isolation of the individual to a private, escape-proof setting, physically displacing the person from *time-in* to interrupt problem or harmful behavior.	• A BIP prohibiting use of a locked room & involuntary sedation • Informed consent • Alternative, evidence-based practices to be reviewed • Continuous monitoring	• Yes, to the extent seclusion is protective and therapeutic.
Restraint	Restricting the free movement of a person physically (e.g., basket hold) or mechanically (by a device) to prevent severe episodic, or self-injurious, behavior.	• Training on positive behavioral methods • De-escalation training • Regular safety, fire, and programmatic inspections • Continuous monitoring • Training to ensure health and welfare of the individual during restraint	• Yes, to the extent restraint is protective and therapeutic. • Yes, when used in an emergency situation to prevent immediate harm.

Based on The Council for Exceptional Children's (CEC, 2009) Policy on Physical Restraint and Seclusion Procedures in School Settings is an important source of guidance for school-based practitioners.

on ethical issues of punishment in its *Professional and Ethical Compliance Code for Behavior Analysts*. In this document, the BACB reaffirmed three guiding principles: (1) The welfare of the individual served is the highest priority, (2) individuals (and parents/guardians) have a right to choose, and (3) the principle of least restrictiveness should be followed. The BACB also provides its view on the use of punishment in applied settings in this document.

The Association for Behavior Analysis International's (ABAI) *Position Statement on Restraint and Seclusion* differentiates time-out, restraint, and seclusion in the context of serving clients with severe problem behavior. Figure 16.5 defines and summarizes key distinctions between these interventions.

Behavior analysts who serve clients with severe problem behavior should familiarize themselves with the entire ABAI position statement, which includes sections on client rights, clinical oversight, procedural safeguards, and ongoing evaluation based on objective data.

Applied behavior analysts who serve students with challenging behavior must also abide by policies and regulations governing the application of crisis interventions in schools. The Council for Exceptional Children's (CEC; (2009) *Policy on Physical Restraint and Seclusion Procedures in School Settings* is an important source of guidance for school-based practitioners (see https://www.cec.sped.org/~/media/Files/Policy/CEC%20Professional%20Policies%20and%20Positions/restraint%20and%20seclusion.pdf). Chapter 31 provides additional details on the ethical use of negative and positive punishment.

Evaluate Effectiveness

At the very least, data need to be obtained on the inappropriate behavior that initially led to time-out. If time-out is effective, the level of that behavior should be reduced substantially, and that reduction should be noticed by other persons in the environment. For legal and ethical reasons, additional records should be kept, documenting the use of time-out; the duration of each time-out episode; and the individual's behavior before, during, and after time-out (Yell, 1994).

Resources permitting, in addition to collecting data on the target behavior, it is sometimes beneficial to collect data on collateral behaviors, unexpected side effects, and the target behavior in other settings. For instance, time-out may produce emotional behavior (e.g., crying, aggressiveness, withdrawal) that might overshadow positive gains. Keeping a record of these episodes is helpful. Also, Reitman and Drabman (1999) suggested that for home-based applications of time-out, parents keep a record of the date, time, and duration of time-out, as well as a brief anecdotal description of the effects of time-out. When reviewed with skilled professionals, these anecdotal logs provide a session-by-session profile of performance, making adjustments to the time-out procedure more informed. In the view of Reitman and Drabman:

> The time-out record and discussions centered around it yielded a wealth of information including the type, frequency, context, and rate of misbehavior. . . . Graphing these

data provided visual feedback to both the therapists and the clients regarding the extent to which behavior change had occurred and facilitated the setting of new goals. (p. 143)

Terminate the Time-Out Program

Time-out has the potential to be employed well beyond its effective date. "Given the clinical and administrative effort required to initiate punishment programs, agencies may be inclined to keep them in place longer than needed rather than to expend more effort in evaluating their continued necessity" (Iwata, Rolider, & Dozier, 2009, p. 204).

Notwithstanding the general recommendation that the overall length of any behavior change program should be determined by data, the plan to eliminate time-out should begin shortly after the procedure is initiated. That is, once time-out has been introduced, and data show reduced levels of the target behavior, efforts should be made to switch to positive behavior reductive approaches (e.g., differential reinforcement of alternative behaviors, differential reinforcement of incompatible behaviors) or to reduce implementation over time. Conceptualizing time-out as existing on a continuum may give practitioners context for deciding for whom and under what conditions time-out is warranted. Stated in the form of questions, analysts might ask: Is time-out still necessary for this individual? Are there other less intrusive behavior reduction procedures that could be employed? If time-out is still considered the best method to reduce behavior, how can it be implemented less intrusively (nonexclusion versus exclusion)? Continuing time-out—or any punishment approach—beyond the point of its demonstrated effectiveness risks ethical violations and is counterproductive.

RESPONSE COST DEFINED

Response cost is the response-contingent loss of a specific number of positive reinforcers that has the effect of decreasing the future occurrence of similar responses. Essentially, response cost constitutes a fine for misbehavior.

Response cost typically involves the loss of one or more generalized conditioned reinforcers (e.g., money, tokens), tangibles (e.g., stickers, marbles), or minutes of already-earned time with a preferred activity (e.g., listening to music, playing a computer game) (Lee, Penrod, & Price, 2017; Musser, Bray, Kehle, & Jenson, 2001; Tanol, Johnson, McComas, & Cote, 2010; Wahl, Hawkins, Haydon, Marsicano, & Morrison, 2016). A teacher implements response cost by removing a specific number of positive reinforcers already held by a student contingent on the occurrence of a targeted inappropriate behavior.

The punitive value of the lost reinforcers depends on the individual reinforcement preferences of the participant. Hall and colleagues (1970), for example, found that the response-contingent removal of slips of paper bearing the student's name had a reductive effect on the number of complaints by a boy during 30-minute reading and math periods. Prior to each period during the response cost condition, the teacher placed five slips of paper bearing the boy's name on his desk. Each time the boy cried, whined, or complained during the period, the teacher removed a slip. A multiple baseline across academic periods with a reversal to baseline analysis revealed a functional relation between response cost and a marked decrease in disruptive behaviors (see Figure 15.7).

Desirable Aspects of Response Cost

Effectiveness

Response cost reduces the future occurrence of similar behaviors. According to Lerman and Toole (2011), ". . . the contingent removal of a specific amount of reinforcement (e.g., tokens) can function as an effective punisher" (p. 352). Boerke and Reitman (2011) underscore this point, citing the wide range of successful reductive response cost applications in home-, academic-, and hospital-based settings. Practitioners who face important challenges with disruptive,

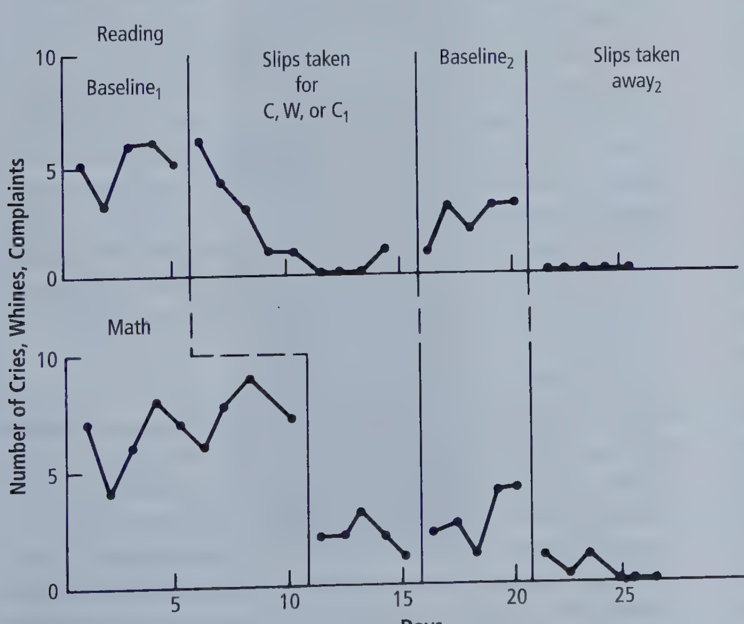

Figure 15.7 The number of cries, whines, and complaints by Billy during the 30-minute reading and arithmetic periods.

From "Modification of Disrupting and Talking-Out Behavior with the Teacher as Observer and Experimenter," by R. V. Hall, R. Fox, D. Williard, L. Goldsmith, M. Emerson, M. Owen, E. Porcia, and R. Davis, 1970, paper presented at the American Educational Research Association Convention, Minneapolis. Reprinted with permission.

off-task, non-compliant, and even life-threatening behaviors need a procedure that produces reliable reductive results. Response cost addresses this criterion.

Even though the data from numerous studies show the shorter term effectiveness of response cost, the longer term benefits for the individual, and the significant others with whom the individual interacts, are still largely unknown (Lerman & Toole, 2011). In their summary on developing function-based punishment procedures, of which response cost is a prime example, Lerman and Toole provide a number of recommendations for improving the long-term effectiveness of response cost:

> . . . punishment can be improved by (1) selecting punishers via pretreatment avoidance, choice, or activity assessments; (2) delivering the consequences immediately following each instance of the behavior; (3) ensuring that alternative sources of reinforcement are readily available; (4) establishing discriminative control . . . ; and (5) . . . using conditioned punishers. (pp. 363–364)

Practitioners would do well to follow Lerman and Toole's guidelines. Furthermore, applied behavior analysts charged with training field-based practitioners would also be wise to incorporate these five suggestions into their initial and recurrent response cost training programs. Chapter 31 contains additional strategies for trainers placed in supervisory positions.

Least Restrictive Alternative

We state repeatedly throughout this text, and especially in Chapter 31, that behavior analysts must comply with an ethical code of conduct. One important application of this code is that practitioners use interventions that are consistent with the principle of the least restrictive alternative as detailed in the Professional and Ethical Compliance Code for Behavior Analysts (2014). Briefly, this principle states that the most powerful, yet least intrusive, method be employed first and found to be ineffective, before more restrictive options are exercised. Hence, when analysts face challenging behaviors, especially those that have been resistant to other reductive treatment (e.g., extinction, differential reinforcement of lower rates of behavior), it is incumbent on the analyst to continue exploring least restrictive measures. Lerman and Toole (2011) add the following guidance.

> Ethical guidelines mandate that priority should be given to the least restrictive alternative procedure that is clinically effective. . . . Inherent in this approach to treatment selection is the need to arrange punishment procedures hierarchically based on the degree of restrictiveness (i.e., how much the procedure limits an individual's freedom or intrudes into an individual life in some manner) or aversiveness (i.e., how much the procedure produces discomfort, pain, or distress). Nonexclusionary time-out and response cost typically are considered the least restrictive of the procedures, followed by exclusionary time-out, overcorrection, and other physical punishers. (p. 353)

Moderate to Rapid Decrease in Behavior

Like other forms of punishment, response cost usually produces a moderate to rapid decrease in behavior. Unlike other behavior-reductive procedures that may require more time to show a significant effect (e.g., extinction, differential reinforcement of alternative behaviors), response cost tends to produce changes quickly. Suppressive effects are noted rapidly, within two to three sessions, as evidenced by Hall and colleagues' data (see Figure 15.7) and replicated by Donaldson, DeLeon, Fisher, and Kahng (2014) (see Figure 15.8).

For instance, when the response cost contingency was introduced during "Tokens" (denoted by the square data points in Figure 15.8), students lost one token per disruption, and the number of disruptive responses per minute fell to near zero. In a contrasting Token Earn condition, students could earn one token for emitting any appropriate behavior at the time a signal was emitted to record occurrences or nonoccurrences. This rapid loss was again noted after "Tokens: Choice" was reintroduced following Baseline 2. Overall, the data show an immediate and significant reduction in disruptive behavior. Interestingly, when students were given a choice (i.e., token earn or token loss), all four students shown in Figure 15.8, and two thirds of the other students in the entire study, preferred token loss over token gain.

Convenience

Response cost is convenient to implement and can be used in a variety of school-, home-, hospital-, and center-based settings (Ashbaugh & Peck, 1998; Musser et al., 2001). For example, if students are expected to follow explicitly stated classroom procedures, rules, or contracts, then any rule infraction will produce a loss of a specified reinforcer (e.g., a token), and it signals to the student that future occurrences of the misbehavior will result in the same consequence. Under these conditions, decision rules about implementation can be made expediently.

At home, response cost is convenient to the extent that it can be incorporated into an existing routine. For instance, if a child earns an allowance of $7 per week ($1 per day) for cleaning her room and placing her dishes in the sink after eating, noncompliance with one or both of these behaviors would lead to a monetary loss (e.g., 50¢ per infraction). In this setting, a response cost chart, posted in a visible location, would provide a convenient feedback mechanism to show the child and her parents accumulated losses (Bender & Mathes, 1995).

Figure 15.9 shows a sample response cost chart as it might be used in a classroom or tutorial setting. To implement the response cost procedure, the teacher writes a column of decreasing numbers on the board or chart. Immediately following the occurrence of a disruptive behavior, the teacher crosses off the highest remaining number. If the teacher places the numbers 15 through 0 on the board and three disruptive behaviors happened, the students would receive 12 minutes of preferred activity time that day.

Can Be Combined with Other Approaches

Response cost can be combined with other behavior change procedures (Athens, Vollmer, Sloman, St. Peter Pipkin, 2008; DeLeon et al., 2008; Long, Miltenberger, Ellingson, Ott, 1999; Watkins & Rapp, 2014). For instance, practitioners might add response cost to an existing treatment to further reduce levels of a target behavior. Researchers might add response cost to an existing procedure, withdraw it, and then reinstitute response

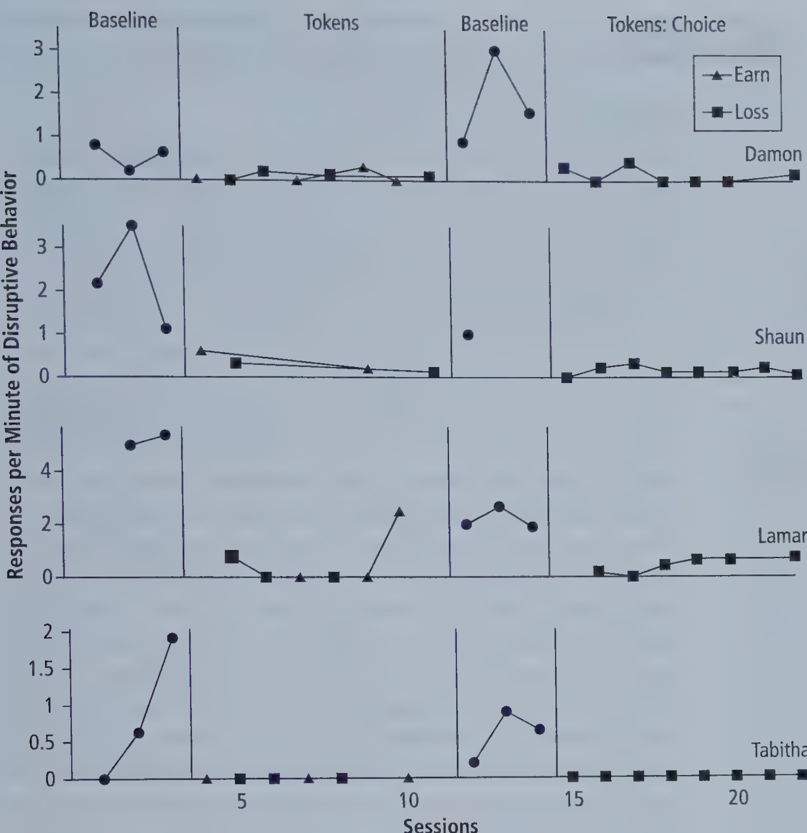

Figure 15.8 Responses per minute of disruptive behavior across sessions for Damon, Shaun, Lamar, and Tabitha.

"Effects of and preference for conditions of token earn versus token loss" by J. M. Donaldson, I. G. DeLeon, A. B. Fisher, and S. W. Kahng, 2014, *Journal of Applied Behavior Analysis*, p. 544. Reproduced with permission of John Wiley & Sons Inc.

cost, as part of a component analysis to calibrate the occurrence, rate, or percentage reduction. Such analysis might address important questions as to whether response cost alone is sufficient to produce desirable reductive levels, or whether it must be applied with another procedure to gain this effect. The following sections describe a few of these alternatives.

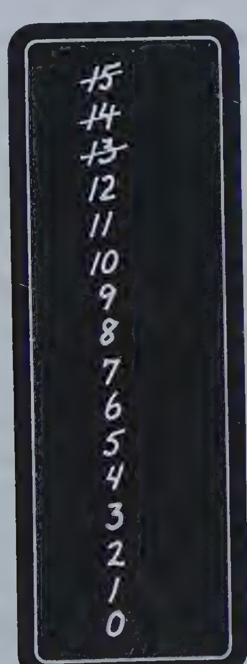

Figure 15.9 A response cost chart showing number of minutes of free time remaining after three rule infractions.

Response Cost with Positive Reinforcement. Response cost can be combined with positive reinforcement. For example, a student might receive a point, a star, or a sticker for each academic assignment completed during the morning seatwork period, but lose a point, a star, or a sticker for calling out without permission. Donaldson et al. (2014) used this dichotomous gain-loss procedure in their study.

Musser and colleagues (2001) combined response cost and positive reinforcement to improve the compliant behavior of three students with emotional disturbance and oppositional defiant behavior. Briefly, the procedures involved the teacher making a normal request for compliance (e.g., "Take out your book, please"). If the student complied within 5 seconds, the teacher delivered praise. If a 30-min period expired and no episodes of noncompliance were recorded, a sticker was delivered to the student. If the student failed to comply with a request within 5 seconds, the teacher waited 5 seconds and issued another directive (e.g., "Take out your book"). The teacher then waited an additional 5 seconds for compliance. If the student complied, the teacher issued praise. If not, one sticker was deducted for noncompliance. Stickers were later exchanged for a "mystery motivator" (e.g., a backup reinforcer from a grab bag). Results for all three students showed marked decreases in noncompliant behavior. Thus, a dual system, which was user friendly and convenient, proved to be effective insofar as the students earned stickers for intervals of compliant behavior, but lost stickers—the response cost contingency—for noncompliant behavior.

This method of combining response cost with positive reinforcement has at least two advantages: (1) If all of the tokens or points are not lost through response cost, the remaining ones can

be traded for backup conditioned or unconditioned reinforcers; and (2) the practitioner's behavior is not entirely focused on delivering a negative punishment contingency. Presumably, the practitioner will also focus on the occurrence of positive, constructive behaviors to reinforce. In doing so, the practitioner teaches new behaviors to the individual and reduces legal and ethical concerns.

Response Cost with Group Consequences. Response cost can be combined with group consequences. That is, contingent on the inappropriate behavior of any member of a group, the whole group loses a specific number of reinforcers. The Good Behavior Game, discussed in Chapter 28, serves as an excellent illustration of how response cost can be applied with groups.

Response Cost with Differential Reinforcement of Alternative Behavior (DRA). Response cost has been combined with differential reinforcement of alternative behavior (DRA) to treat the food refusal behavior of a 5-year-old child with developmental delay. Kahng, Tarbox, and Wilke (2001) replicated the Keeney, Fisher, Adelinis, and Wilder (2000) study, except that response cost was combined with DRA. During a baseline condition, various food group trials were presented every 30 seconds. If food was accepted, praise was delivered. If food was refused, the behavior was ignored. Based on reinforcer assessments, during DRA and response cost, books and audiotapes were made available at the meal. If food was accepted, praise was delivered. If food was refused, the books and audiotapes were removed for 30 seconds. The books and audiotapes were replaced during the next trial contingent on accepting food (i.e., DRA). Parents and grandparents were also trained in the DRA plus response cost procedures. Results showed a substantial increase in the percentage of intervals of food acceptance and a dramatic decrease in the percentage of intervals of food refusal and disruption.

Other Combinations. Watkins and Rapp (2014) combined response cost with environment enrichment to reduce the stereotypy behavior of five preadolescent and adolescent individuals with autism. In their study, participants were exposed to three conditions: no interaction; environment enrichment, during which reinforcers identified through a stimulus preference assessment were available; and environment enrichment, during which those preferred reinforcers were removed for 15 seconds contingent upon each occurrence of stereotypy behavior. Results showed that when environment enrichment and response cost were combined, the stereotypy behavior of all five individuals decreased immediately and markedly. Further, after these two procedures were withdrawn, the stereotypy behavior of three of the five participants did not increase.

In sum, the findings of studies directly combining response cost with other procedures have been positive. Whether response cost is used alone, or in combination with other procedures, it works. Still, practitioners should remember that (1) punishment procedures do not teach "new" behaviors; instead, they are designed to reduce the frequency of problem behavior; and (2) the environment where the target behavior occurs also needs to provide an ample number of reinforcers for appropriate behaviors. Stated differently, response cost should not be used as a sole behavior change approach without also considering the beneficial effects that accrue when positive reinforcement is provided. Combining response cost procedures with behavior-building approaches (e.g., DRA) is a good plan.

Established Social Validity

As discussed in Chapter 10, a procedure is considered socially valid if it meets three criteria: (1) The target behavior is significant for the individual, (2) the methodological procedures are acceptable and meet the standard of best care, and (3) the results produce meaningful positive change.

On the basis of these criteria, a legitimate claim can be made that response cost is socially valid. Typically, the behaviors selected for a response cost procedure call attention to themselves and have not improved in any meaningful way given prior interventions. Also, teachers and the students themselves report that response cost procedures are acceptable (Donaldson et al., 2014; Hirst, Dozier, & Payne, 2016). The dramatic reductive effect that response cost produces reaches the level of significance for those involved. That is, their lives are improved. Ultimately, they come into contact with more reinforcers and fewer punishers in the future.

Embry and Biglan (2008) included response cost in their list of 52 fundamental units of behavioral influence. In their view, response cost meets this designation because it is socially valid, is easy to implement, and produces clear and discrete outcomes that have been verified repeatedly by experimental and applied analyses.

RESPONSE COST METHODS

Response cost is implemented using two principal methods. The practitioner can (a) levy a fine against an individual's existing cache of previously earned reinforcers; or (b) levy a fine against an individual's surplus of extra, noncontingently provided reinforcers.

Existing Cache Response Cost

When a fine is levied against a person's existing cache of positive reinforcers, the individual loses a specific number of positive reinforcers from a supply of currently available reinforcers. For example, each occurrence of noncompliant behavior would produce a loss of 1 minute of free time from a current allocation of 15 minutes. In this case, response cost is applied to stimuli known to be reinforcing and accessible to the person.[3]

Bonus Response Cost

Bonus response cost operates when practitioners make additional reinforcers available noncontingently to the participant, specifically for removal when a target behavior occurs. Box 15.1 presents a vignette of how a father might implement a bonus response cost procedure with his two sons to reduce their fighting and squabbling at the dinner table.

USING RESPONSE COST EFFECTIVELY

To use response cost effectively, the behavior targeted for response cost, the timing of the fine, and the amount of the fine need to be explicitly stated. For instance, the behavior analyst

BOX 15.1

Father and Sons Vignette

Father: Boys, I'd like to talk to you.

Tom and Pete: OK.

Father: We have to find a way to stop the fighting and squabbling at the dinner table. The way you two go at each other upsets everyone in the family, and I can't eat my dinner in peace.

Tom: Well, Pete usually starts it.

Pete: I do not!

Tom: You do, too . . .

Father: (Interrupting) That's enough! This is just what I mean, nit-picking at each other. It's ridiculous and it needs to stop. I've given it some thought, and here's what we're going to do. Since each of you earns an allowance of $5 per week for doing household chores, I was tempted to take it away from you the next time either of you started squabbling. But I've decided against doing that. Instead, I'm going to make an additional $5 available to each of you, but for each sarcastic comment or squabble you get into at the dinner table, you'll lose $1 of that extra money. So, if you act properly, you'll get an additional $5 per week. If you have two squabbles, you'll lose $2 and earn only an additional $3. Do you understand?

Pete: How about if Tom starts something and I don't?

Father: Whoever does any fighting or squabbling loses $1. If Tom starts something and you ignore him, only he loses. Tom, the same thing holds true for you. If Pete starts something and you ignore him, only Pete loses. One more thing. Dinnertime starts when you are called to the table; it ends when you are excused from the table. Any other questions?

Tom: When do we begin?

Father: We'll begin tonight.

It is important to note that the father described the contingencies completely to his sons. He told them what would happen if no squabbles occurred—they would earn an additional $5 per week—and he told them what would happen if one sibling or the other started to bicker but the other ignored him. In addition, he clearly defined when dinnertime would begin and end. Each of these explanations was necessary for a complete description of the contingencies. Note that the money the boys normally earned as an allowance for doing household chores was not affected by this bonus response cost contingency. Ideally, the father praised his sons for their appropriate table manners and decorum when it occurred so that these behaviors could be reinforced and strengthened.

might say, "Any occurrence of an off-task behavior during reading will be subject to an immediate loss of one token." Further, any rules that would apply for refusal to comply with the response cost procedure need to be explained. However, in situations in which multiple behaviors are subject to the response cost contingency, or in which the degree of severity of the behavior determines the response cost, correspondingly greater fines should be associated with more severe behaviors. In effect, the magnitude of the punishment (response cost) should reflect the magnitude of the targeted behavior.

According to Weiner (1962)—the originator of the term *response cost*—the magnitude of the response cost fine is important. As the magnitude of the fine increases, larger reductions in the rate of the undesirable behavior may occur. However, if the loss of reinforcers is too great and too rapid, the person will soon be exhausted of his or her supply of reinforcers, and a deficit situation will exist. As a general rule, the fine should be large enough to suppress the future occurrence of the behavior, but not so large as to bankrupt the person or cause the system to lose its effectiveness. In short, if a client loses tokens or other reinforcers at too high a rate, he or she may give up and become passive or aggressive, and the procedure will become ineffective. Furthermore, fines should not be changed arbitrarily. If a teacher imposes a 1-unit token loss for each noncompliant response in the morning, the teacher should not impose a 3-unit token loss for the same behavior in the afternoon.

Deliver Fines Immediately

Ideally, the fine should be imposed immediately after the occurrence of each undesirable behavior. The more quickly response cost is applied subsequent to the occurrence of the behavior, the more effective the procedure becomes.

Response Cost or Bonus Response Cost?

Three considerations may help practitioners decide whether to initiate a response cost or a bonus response cost procedure. First, the least aversive procedure should be attempted initially. Consistent with the principle of the least restrictive alternative, an effort should be made to ensure that the minimum loss of reinforcers occurs for each infraction. Bonus response cost may be the less aversive of the two variations because the reinforcers are not deducted directly from the individual cache of reinforcers; instead, they are lost from a pool of noncontingently available (i.e., bonus) reinforcers.

The second consideration is similar to the first and can be stated in the form of a question: What is the potential for aggressive, emotional outbursts? From a social validity perspective, students (and their parents) would probably find it more agreeable to lose reinforcers from an available reserve than from their earnings. Consequently, a bonus response cost procedure may spark fewer aggressive or emotional outbursts, or be less offensive to students or their parents.

A third consideration is the need to reduce the behavior quickly. Combative or noncompliant behavior may be more

appropriately suppressed with response cost because the contingency directly reduces the student's available reinforcers. The response-contingent withdrawal of reinforcers serves to reduce the behavior swiftly and markedly.

Ensure Reinforcer Reserve

Positive reinforcers cannot be removed from a person who does not have any. Prior to using response cost, the practitioner must ensure a sufficient reinforcer reserve. Without such a reserve, the procedure is unlikely to be successful. For example, if a teacher used response-contingent withdrawal of free time for each occurrence of inappropriate behavior in a highly disruptive class, the students could exhaust all of their available free time before the end of the first hour, leaving the teacher wondering what to do for the remainder of the day. Deducting free time from time earmarked for succeeding days would hardly be beneficial.

Two suggestions apply to reduce the likelihood of having no reinforcers available. First, the ratio of points earned to points lost can be managed. If baseline data indicate that the inappropriate behavior occurs at a high rate, more reinforcers can be programmed for removal. Also, determining the magnitude of the fine, and stating it explicitly beforehand, is helpful. Minor infractions may warrant relatively smaller fines, whereas major infractions may warrant substantially higher fines. Second, if all reinforcers are lost and another inappropriate behavior occurs, the analyst might consider implementing time-out from positive reinforcement as a supplemental procedure.

To establish the initial number of available reinforcers, practitioners collect baseline data on the occurrence of inappropriate behavior during the day or session. The mean baseline figure can be increased for the number of reinforcers to ensure that all reinforcers are not lost when response cost is in effect. Although no empirically verifiable guidelines are available, a prudent approach is to increase the number of reinforcers 25% above the mean number of occurrences during baseline. For example, if baseline data indicate that the mean number of disruptions per day is 20, the practitioner might establish 25 minutes of free time (the positive reinforcer) as the initial level (i.e., 20×1.25). If the practitioner calculates points instead of percentages, she could add an additional 10 to 20 points to ensure an adequate buffer.

Recognize the Potential for Unplanned or Unexpected Outcomes

Two situations may require the implementation of a contingency plan. One occurs when the repeated imposition of response cost serves to reinforce, and not punish, the undesirable behavior. When this situation arises, the practitioner should stop using response cost and switch to another reductive procedure (e.g., time-out or DRA). The second situation occurs when the person refuses to hand over positive reinforcers. To reduce the likelihood of this event, the practitioner should clarify the consequences of such refusal beforehand and (a) make sure that an adequate supply of backup reinforcers is available, (b) impose an additional penalty for not giving up the reinforcer (e.g., the sticker) (Musser et al., 2001), (c) refund some fractional portion of the fine for complying with immediate payment, or (d) sidestep the whole possibility of refusal by maintaining control of the tokens on a ledger, electronically, or in a jar placed out of the participant's reach.

Avoid Overusing Response Cost

Response cost should be saved for those major undesirable behaviors that call attention to themselves and need to be suppressed quickly. A teacher's or parent's primary attention should always focus on positive behavior to reinforce; response cost should be implemented as a last resort and should be combined with other procedures that ultimately are designed to build adaptive behavior.

Keep Records

Each occurrence of response cost and the behavior that occasioned it should be recorded. Minimally, the analyst should record the number of times fines are imposed, the persons to whom fines are issued, and the effects of the fines. Daily data collection helps to determine the efficacy of the response cost procedure that might otherwise remain undetected (Boerke & Reitman, 2011). By graphing the effects of the response cost intervention, a chart is created that the behavior analyst can use to (1) determine the immediacy, the extent, and the duration of the suppressive effect of the procedure, and (2) document the effectiveness to a skeptical practitioner predisposed to using response cost based on biased personal beliefs, or inadequate preservice training (Cooke, 1984).

RESPONSE COST CONSIDERATIONS

Increased Aggression

Response-contingent withdrawal of positive reinforcers may increase student verbal and physical aggressiveness. The student who loses several tokens, especially within a short time, may verbally or physically assault the teacher. Emotional behaviors should be ignored whenever possible if they accompany the implementation of response cost (Walker, 1983). Still, teachers should anticipate this possibility and (a) preempt a decision to use response cost if they suspect that a worse condition will result in the aftermath of an emotional episode, or (b) be prepared to "ride out the storm."

Avoidance

The setting in which response cost occurs or the person who administers it can become a conditioned aversive stimulus. If this situation occurs in school, the student may avoid the school, the classroom, or the teacher by being absent or tardy. A teacher can reduce the likelihood of becoming a conditioned aversive stimulus by contingently delivering positive reinforcement for appropriate behavior.

Collateral Reductions of Desired Behavior

The response-contingent withdrawal of positive reinforcers for one behavior can affect the occurrence of other behaviors as

well (St. Peter, Byrd, Pence, & Foreman, 2016). If the teacher fines Angelina 1 minute of recess each time she calls out during math class, the response cost procedure may reduce not only her call-outs but also her math productivity. Angelina may say to the teacher, "Since I lost my recess time for calling out, I am not going to do my math." She could also become passive-aggressive by sitting in her seat with arms folded and not work. Teachers and other practitioners should anticipate such collateral behaviors and clearly explain the response cost rules, reinforce other classmates as models of appropriate behavior, and avoid face-to-face confrontations.

Calling Attention to the Punished Behavior

Response cost calls attention to the undesirable behavior. That is, upon the occurrence of an inappropriate behavior, the student is informed of reinforcer loss. The teacher's attention—even in the form of notification of reinforcer loss—could serve as an attention-getting reinforcing event. In effect, the teacher's attention may increase the occurrence of future misbehavior. For instance, the teacher may have difficulty because every mark that she places on the chalkboard indicates that a positive reinforcer has been lost (e.g., minutes of free time). To counteract the possibility of calling attention to inappropriate behavior, the teacher should ensure that the delivery ratio of reinforcers to the removal ratio of reinforcers favors positive reinforcement.

Unpredictability

As with other forms of punishment, the side effects of response cost can be unpredictable and are related to a number of variables that are not fully understood or well investigated across participants, settings, or behaviors. These variables include the magnitude of the fine, the previous punishment and reinforcement history of the individual, the number of times behaviors are fined, and the availability of alternative responses that are eligible for reinforcement.

Treatment Integrity

Treatment integrity is the accuracy and procedural consistency with which a planned intervention is executed. If the plan is not implemented with high fidelity, then it becomes extremely difficult to determine if the lack of demonstrated improvement is due to the intervention not being implemented as designed, or if the treatment itself was not robust enough to affect the change.

Response cost, like other behavior-building or -suppressing procedures, suffers from two possible threats to treatment integrity: omission errors and commission errors. Omission errors occur when the analyst fails to apply the response cost contingency and levy the appropriate fine after target behavior occurrence. In this situation, a target behavior occurs, and the practitioner either does not register the behavior as an occurrence or observes the behavior but still fails to apply the fine. In either case, an omission error occurs. Commission errors occur when practitioners levy fines for behavior that should not have been subjected to response cost. In other words, a conditioned generalized reinforcer is removed from the individual when it should not have been.

Three points are worth noting about omission and commission errors. First, providing supervisory training, practice, feedback, and recurrent maintenance instruction reduces the chances of these types of errors. Second, the higher the fidelity of treatment integrity—that is, approaching 100%—the more suppressed the behavior becomes. Finally, at least some data in nonclinical applications suggest that even if a response cost procedure is implemented partially incorrectly (e.g., a mix of omission and/or commission errors), acceptable suppression may still result (St. Peter et al., 2016). On the continuum of errors scale, obviously, practitioners should aim for zero, or few, errors, but be comforted by the fact that some errors can exist without the entire response cost program being severely compromised.

SUMMARY

Time-Out from Positive Reinforcement Defined

1. Time-out from positive reinforcement (or simply time-out) is the immediate response-contingent withdrawal of the opportunity to earn positive reinforcers or the immediate loss of access to positive reinforcers for a specified time.

2. To function as negative punishment, the time-out procedure must decrease future occurrences of similar behaviors. Implicit in the definition of time-out are three important factors: (a) The discrepancy between the "time-in" and the time-out environments must be discriminative, (b) the response-contingent loss of access to reinforcement must occur immediately, and (c) a resultant decrease in the future frequency of the time-out–producing behavior must occur.

Time-Out Tactics for Applied Settings

3. There are two basic types of time-out: nonexclusion and exclusion.

4. Nonexclusion time-out means that contingent on the occurrence of the target behavior, the participant remains physically within the time-in setting, but elements of that setting are changed so that (a) the opportunity to earn reinforcers is removed; (b) a specific reinforcer is terminated; (c) repositioning occurs so that observations of ongoing activity continue, but without reinforcement; or (d) the individual is removed to a different space within the time-in setting.

5. Nonexclusion time-out is typically implemented using one of four tactics: planned ignoring, terminate specific reinforcer contact, contingent observation, and partition/select space time-out.

6. Exclusion time-out is the physical separation of the participant from the time-in environment when time-out goes into effect.
7. There are two basic tactics for implementing exclusion time-out contingent on the occurrence of the target behavior: (a) The participant is removed immediately from the time-in environment, or (b) the time-in environment is removed immediately from the participant.
8. Time-out is a desirable alternative for reducing behavior because of its ease of application, acceptability, rapid suppression of behavior effects, and ability to be combined with other approaches.

Using Time-Out Effectively

9. The time-in environment must be reinforcing if time-out is to be effective.
10. Effective use of time-out requires that the behaviors leading to, the duration of, and exit criteria for time-out be explicitly stated. Further, practitioners must decide whether to use nonexclusion or exclusion time-out.
11. The exit criteria for time-out can be conceptualized in three dimensions: (a) the duration of any individual time-out session, (b) the behavioral criteria for leaving time-out and returning to the time-in setting, and (c) the overall length of the time-out program.
12. The duration of any individual time-out session, the behavioral criteria that prompt termination of time-out, and the duration of the time-out program need to be made explicit before launching time-out, and appropriate ethical and legal guidelines should be followed.
13. In the majority of applications, permission is required before time-out can be implemented.
14. Practitioners should be aware of legal and ethical considerations before implementing time-out. As a punishment procedure, it should be used only after positive reductive procedures have failed, and with planned monitoring, supervision, and evaluation considerations in place.

Response Cost Defined

15. Response cost is the response-contingent loss of a specific number of positive reinforcers that has the effect of decreasing the future occurrence of similar responses.
16. Response cost constitutes a fine for misbehavior.
17. Response cost typically involves the loss of one or more generalized conditioned reinforcers, tangibles, or minutes of already-earned time with a preferred activity.
18. The punitive value of the lost reinforcers depends entirely on the individual reinforcement preferences of the participant.
19. Response cost affords practitioners a number of desirable features. It is effective, meets the standard for least restrictive alternative, produces rapid suppression of behavior, is convenient, can be combined with other procedures, and is socially valid.

Response Cost Methods

20. Response cost is implemented using two principal methods. The practitioner can (a) levy a fine against an individual's existing cache of previously earned reinforcers; or (b) levy a fine against an individual's surplus of extra, noncontingently provided reinforcers.
21. When a fine is levied against a person's existing cache of positive reinforcers, the individual loses a specific number of positive reinforcers from a supply of currently available reinforcers.
22. Bonus response cost operates when practitioners make additional reinforcers available noncontingently to the participant, specifically for removal when a target behavior occurs.

Using Response Cost Effectively

23. To use response cost effectively, practitioners should deliver fines immediately, decide whether bonus response cost is a preferred option, ensure reinforcer reserve, recognize the potential for unplanned or unexpected outcomes, avoid overusing response cost, and keep records on its effects.

Response Cost Considerations

24. Implementing response cost may increase aggression, produce avoidance responses, affect collateral reductions of desired behaviors, call attention to the punished behavior, be unpredictable, and suffer treatment integrity challenges.

KEY TERMS

bonus response cost
contingent observation
exclusion time-out
negative punishment
nonexclusion time-out
partition or select space time-out
planned ignoring
response cost
terminate specific reinforcer contact
time-out from positive reinforcement (time-out)

MULTIPLE-CHOICE QUESTIONS

1. A punishment procedure has been put in place for Carlos. Whenever he swears in class his teacher says, "Carlos, swearing is not allowed in this classroom," and he is escorted to the time-out room where he has to stay for at least five minutes. His teacher has used the procedure for three weeks and his swearing has not decreased at all. What is the problem in this example?
   - **a.** The time-out room is not functioning as punishment.
   - **b.** Carlos should be placed in the time-out room for a longer period of time.
   - **c.** His teacher needs to explain to him why he is being placed in time-out.
   - **d.** His teacher has not done enough to reinforce the time-in setting.

   Hint: (See "Exclusion Time-Out")

2. Before implementing a contingent observation program for cutting in line at the drinking fountain, Mrs. Salkey made sure to send a note home to guardians telling them about the program and asking the guardians to contact her if there were any objections. In addition she checked with her principal to make sure she was following the schoolwide behavior management program. Which part of using time-out effectively does this example best exemplify?
   - **a.** Reinforce and enrich the time-in environment.
   - **b.** Define the behaviors leading to time-out.
   - **c.** Define the procedures for the duration of time-out.
   - **d.** Explain the time-out rules.
   - **e.** Evaluate effectiveness.
   - **f.** Obtain permission.

   Hint: (See "Using Time-Out Effectively")

3. When implementing a contingent observation program for cutting in line at the drinking fountain, Mrs. Salkey made sure to provide lots of tokens for students who waited their turn. Which part of using time-out effectively does this example best exemplify?
   - **a.** Reinforce and enrich the time-in environment.
   - **b.** Define the behaviors leading to time-out.
   - **c.** Define the procedures for the duration of time-out.
   - **d.** Explain the time-out rules.
   - **e.** Evaluate effectiveness.
   - **f.** Obtain permission.

   Hint: (See "Using Time-Out Effectively")

4. When implementing the contingent observation program, Mrs. Salkey kept a record of each student who cut in line every day for one week. By Friday, there were no students who cut in line. Which part of using time-out effectively does this example best exemplify?
   - **a.** Reinforce and enrich the time-in environment.
   - **b.** Define the behaviors leading to time-out.
   - **c.** Define the procedures for the duration of time-out.
   - **d.** Explain the time-out rules.
   - **e.** Evaluate effectiveness.
   - **f.** Obtain permission.

   Hint: (See "Using Time-Out Effectively")

5. Mrs. Salkey used tokens for waiting along with a contingent observation program. This approach best exemplifies:
   - **a.** Rapid suppression of behavior
   - **b.** Combined approaches
   - **c.** Ease of application
   - **d.** Acceptability

   Hint: (See "Desirable Aspects of Time-Out")

6. Mr. Marley docks the class one minute of extra recess time every time he has to say, "people quiet down please." This best exemplifies which response cost method?
   - **a.** Direct fines
   - **b.** Bonus response cost
   - **c.** Using a response cost with a group
   - **d.** Combining with positive reinforcement

   Hint: (See "Response Cost Methods")

7. In addition to using a response cost with an entire group, Mr. Marley is also using which procedure?
   - **a.** Direct fines
   - **b.** Bonus response cost
   - **c.** Using a response cost with a group
   - **d.** Combining with positive reinforcement

   Hint: (See "Response Cost Methods")

8. Mrs. Webb uses a response-cost procedure in which a student loses all points toward participation in a monthly pizza party any time he or she says "shut up" to another student. As a result, whenever students lose their points, they say "shut up" more often. What is the problem?
   - **a.** The magnitude of the fine is too great.
   - **b.** The points weren't functioning as reinforcers.
   - **c.** The students became more aggressive.
   - **d.** The fine should have been larger.

   Hint: (See "Using Response Cost Effectively")

ESSAY-TYPE QUESTIONS

1. As Type II punishment, response cost can be classified and is defined by function. Specifically, if the future frequency of the punished behavior is reduced by the response-contingent withdrawal of a positive reinforcer then a response cost has occurred. However, if the removal of the reinforcer increases the level of the behavior or has no effect on it, response cost has not occurred. This distinction between application and effect is the key aspect in the definition of response cost. Why is it important to make a distinction between application and effect?

   Hint: (See "Response Cost Defined")

2. Why is it important to reinforce functional alternatives to a problem behavior when using Type II punishment?

   Hint: (See "Using Time-Out Effectively" and "Response Cost Methods")

3. Suppose you are a third-grade teacher of a classroom with 25 students. Three of the students in the classroom are causing problems. The problems include failure to complete assignments and talking during independent seat-work. Pick a Type II punishment and pair it with a reinforcement program that you will use for the entire class. Please refer to Powell and Powell's (1982) time-out implementation checklist.

   Hint: (See "Using Time-out Effectively" and "Using Response Cost Effectively")

4. List the undesirable aspects of negative punishment and describe how one might minimize those aspects.

   Hint: (See "Response Cost Considerations")

NOTES

1. The term *time-out from positive reinforcement* first appeared in the behavioral literature in a monograph authored by Charles Ferster (1958). He described five experiments with chimpanzees and pigeons. "The basic paradigm used . . . 'time out' from positive reinforcement as the aversive event. To study the effect of the time out, a simple response, such as a pigeon's peck at a circular disk, or a chimpanzee's press of a toggle switch, was maintained when occasional pecks or presses were followed with food. To generate the aversive event, reinforcement was withheld in the presence of one stimulus but alternately continued in the presence of a second stimulus. When the rate of responding fell to zero in the presence of the stimulus where reinforcement was discontinued, that stimulus, called the time-out stimulus, could then be used as an aversive event and its effect on the base-line performance measured" (p. 1).
2. See the Association for Applied Behavior Analysis International's *Statement on Restraint and Seclusion, 2010.*
3. In some situations, removing unconditioned and conditioned reinforcers (e.g., food, free time) from a person is legally and ethically inappropriate. For instance, it would be inadvisable to remove minutes from mandated, structured leisure or free time using response cost. To avoid any potential problems, practitioners should consider another method, or they must obtain permission from the local human rights review committee by justifying the rationale for removing this reinforcer using response cost.

PART 6

Antecedent Variables

Parts 4 and 5 detailed the effects of various types of stimulus changes immediately following behavior. The two chapters in Part 6 address the effects of stimulus conditions and changes that take place prior to a behavior occurring. Behavior does not occur in an environmental vacuum. Every response is emitted in the context of a particular set of antecedent conditions, and these antecedent events play a critical role in motivation and learning.

What people do at any particular moment is partly a function of what they want at that moment. In Chapter 16, Jack Michael and Caio Miguel describe motivating operations, environmental variables that (a) alter the momentary effectiveness of some stimulus, object, or event as a reinforcer (or punisher); and (b) alter the current frequency of all behaviors that have been followed by that form of reinforcement.

Although the defining feature of reinforcement is an increase in the future frequency of behavior, reinforcement produces a second important effect. Chapter 17 details how stimuli immediately preceding a response, or present during reinforcement, acquire an evocative function over future occurrences of the behavior. The chapter describes how behavior analysts use differential reinforcement under changing antecedent stimulus conditions to achieve the desired degrees of stimulus discrimination and generalization.

CHAPTER 16

Motivating Operations

Jack Michael and Caio Miguel

LEARNING OBJECTIVES

- Define an establishing operation and provide characteristics of an establishing operation.
- Discuss the recent movement to the term motivating operation.
- Describe the difference between motivating operations and discriminative relations.
- Define unconditioned motivating operations.
- State various examples of UMOs as related to the human organism.
- Define conditioned motivating operations.
- State the different classifications of CMOs and how they operate.
- State various examples of CMOs as related to the human organism.
- Name some general implications for the use of motivating operations in the study of behavior analysis.

We (Jack and Caio) just love Mexican food, especially tacos. Of course, we do not think about Mexican food all the time, only around lunch- or dinnertime—in other words, when we have not had food for a while, or when we are hungry. However, sometimes, even if we have already eaten, just the sight of our favorite Mexican restaurant, or maybe even a TV ad about Mexican food, makes us want some. At those times, we look for a good Mexican restaurant and feel quite satisfied when we find one. When we get to the restaurant, the sight of tortilla chips makes us want salsa. We can eat salsa at any time, but it doesn't sound good unless we are eating some tortilla chips. After eating the chips and salsa, all we can think about is taking a sip of that ice-cold margarita. And when the chips are gone, finding the waiter to get some more, and to order our tacos, becomes the most important thing in the world.

The scenario above suggests that the value of certain stimuli may vary conditionally with other environmental factors. Mexican food is not wanted all the time, and behaviors that produce it (e.g., driving to the restaurant) vary depending on someone's motivation. From a behavior analytic perspective, if a certain behavior is not occurring, there is a chance that reinforcing consequences are not being produced. However, even if consequences are available, their value or effectiveness can vary over time. Thus, the concept of reinforcement alone cannot properly explain a person's motivation to act (Michael, 1993). Going to a restaurant and ordering food invariably produces food. However, the likelihood of going to a restaurant may vary depending on one's motivation to eat. When we say someone is motivated or wants to do something, we are assuming that (a) what is wanted would function as a reinforcer at that moment, and (b) the current frequency of any behavior that has previously been so reinforced will increase. This chapter discusses motivation from a behavior analytic perspective.

DEFINITION AND CHARACTERISTICS OF MOTIVATING OPERATIONS

Early in his career, Skinner (1938) used the term *drive* to describe changes in behavior that were a function of motivational variables.[1] Although the term appeared in Keller and Schoenfeld's (1950) didactic treatment of Skinner's work, these authors placed an emphasis on the specific environmental operations (i.e., deprivation, satiation, and aversive stimulation) that are necessary to establish the drive (Miguel, 2013). Although not conforming to the same usage set forth by Keller and Schoenfeld, the term **establishing operation (EO)** was reintroduced by Michael (1982, 1993) to describe any environmental variable that momentarily alters (a) the effectiveness of some stimulus, object, or event as a reinforcer; and (b) the current frequency of all behavior that has been reinforced by that stimulus, object, or event. Subsequently, Laraway, Snycerski, Michael, and Poling (2003) proposed the inclusive term **motivating operation (MO)** to encompass the fact that these variables serve not only to strengthen, but also to weaken, the value of a consequence as a reinforcer.[2] The term *setting event* has also been used to describe some of the variables that may fit under the MO definition (see Box 16.1: "What's a Setting Event?").

BOX 16.1

What's a Setting Event?

The term *setting event* appeared in the behavior analytic literature (e.g., Bijou & Baer, 1961; Kantor, 1959) to describe a set of variables that may affect stimulus-response relationships (e.g., McLaughlin & Carr, 2005). More specifically, this description pertains to variables that are not discrete, such as the presence/absence of immediate events or objects, deprivation/satiation, or recent social interactions, all of which may differentially affect specific functions of stimuli (Leigland, 1984; Wahler & Fox, 1981). An example would be sleep deprivation affecting rates of crying (Bijou & Baer, 1961).

The term *setting event* seems to describe the same set of environmental variables that we have classified as motivating operations (MOs). However, no clear definition or functional description of the term has appeared in the literature, and most descriptions of setting events are topographical rather than functional (Leigland, 1984; Nosik & Carr, 2015; Smith & Iwata, 1997).

The MO concept, on the other hand, describes any variable that has two specific effects, namely, value-altering and behavior-altering effects. Thus, "a greater evidential requirement exists to classify an event as an MO than to classify it as a setting event." (Nosik & Carr, 2015, p. 221). We agree with Nosik and Carr that the MO concept, with its functional definition and increasing evidence of its utility, is a better taxonomic option for describing the variables subsumed under the term *setting event*.

Thus, an MO can be defined as an environmental variable that has two effects: value-altering and behavior-altering effects. The **value-altering effect** is either (a) an increase in the reinforcing effectiveness of some stimulus, object, or event, in which case the MO is an establishing operation (EO); or (b) a decrease in reinforcing effectiveness, in which case the MO is an **abolishing operation (AO)**. The **behavior-altering effect** is either (a) an increase in the current frequency of behavior that has been reinforced by some stimulus, object, or event, called an **evocative effect**; or (b) a decrease in the current frequency of behavior that has been reinforced by some stimulus, object, or event, called an **abative effect**. In addition to frequency, other aspects of behavior such as response magnitude, latency, and relative frequency (occurrence per opportunity) can be altered by an MO. These relations are shown in Figure 16.1.

Food deprivation is an EO that *increases* the effectiveness of food as a reinforcer (value-altering effect) and *evokes* all behavior that has been reinforced by food (behavior-altering effect). In other words, after not having food for a while, food becomes a reinforcer, and behaviors such as looking for food are increased. Food ingestion (consuming food) is an AO that *decreases* the effectiveness of food as a reinforcer (value-altering effect) and *abates* all behavior that has been followed by food reinforcement (behavior-altering effect). In other words, after eating, the reinforcing effectiveness of food is decreased, and so is looking for food (along with other previously learned behaviors that have produced food). These changes of behavior are said to be momentary. For instance, food deprivation (MO) increases the value of food, as well as all behaviors that have led to food, for as long as the organism is deprived. As food is obtained, the effectiveness of food deprivation as an MO is decreased (the animal becomes less hungry), as evidenced by a reduction in (a) the value of food as a reinforcer and (b) food-seeking behaviors.

Although the term *hunger* has been used to describe the effects of food deprivation, the term is simply a description (i.e., tact) of physiological changes that may accompany food deprivation (e.g., hunger pangs). Although these physiological sensations may prompt someone to get food, deprivation operations have direct value-altering and behavior-altering effects (Miguel, 2013). Thus, terms such as *hunger* and *thirst* are unnecessary (intervening) variables that may obscure a behavior analysis of motivation. The effects of the MO related to food are shown in Figure 16.2.

Painful stimulation is an EO that *increases* the effectiveness of pain reduction as a reinforcer and *evokes* all behavior that has been reinforced by pain reduction. So, a headache would make its reduction (or elimination) an effective reinforcer, and would also evoke behaviors, such as taking an aspirin, that have produced headache removal in the past. Of course, these two effects would only be observed while the organism is experiencing a headache, and for this reason we refer to the effects of the MO as being momentary. Conversely, a decrease in painful stimulation is an AO that *decreases* the effectiveness of pain reduction as a reinforcer and *abates* all behavior that has been followed by pain reduction. In other words, once the headache is gone, its elimination no longer functions as a reinforcer, and the likelihood of taking an aspirin is greatly reduced. The effects of the MO related to painful stimulation are shown in Figure 16.3.

Most of the statements in this chapter about value-altering and behavior-altering effects refer to relations involving reinforcement rather than punishment. It is reasonable to assume that MOs also alter the effectiveness of stimuli, objects, and events as *punishers*, with either establishing or abolishing effects; and also alter the current frequency of all behavior that has been *punished* by those stimuli, objects, or events, either abating or evoking such behavior. Later in the chapter we will consider MOs for punishment.

Isolating Value- and Behavior-altering Effects

The value-altering effect of an MO influences the potency of a reinforcer to increase the future frequency of behavior (Laraway, Snycerski, Olson, Becker, & Poling, 2014). An MO's

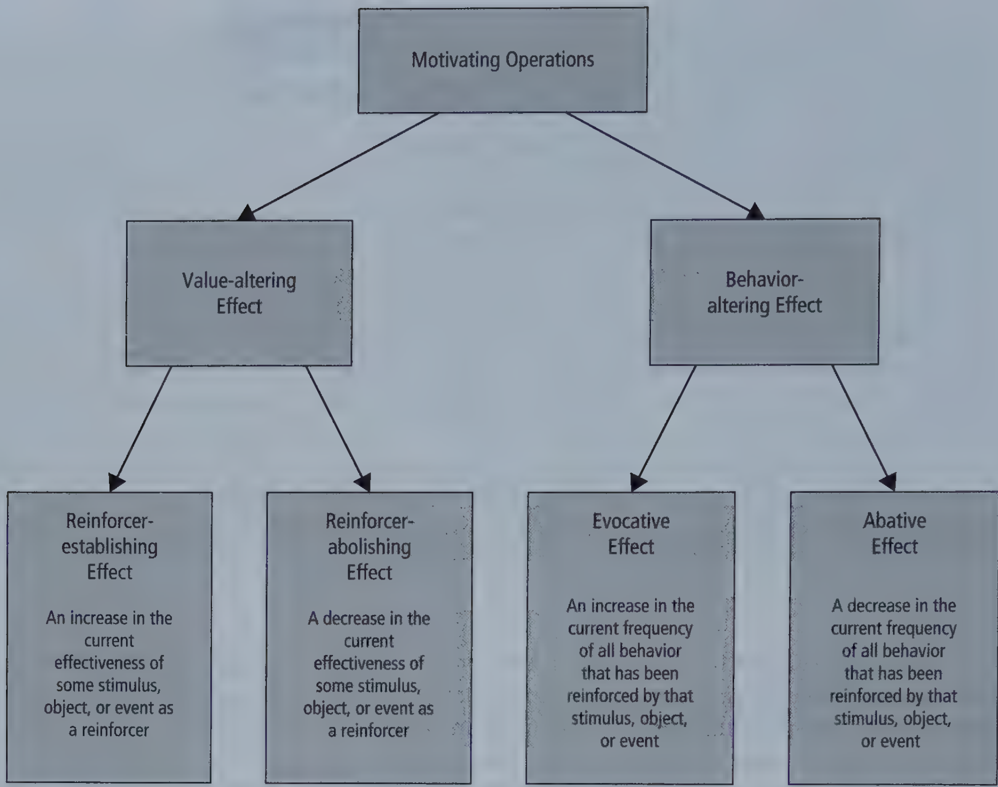

Figure 16.1 Motivating operations and their two defining effects.

value-altering effect is observed when the manipulation of certain environmental variables (e.g., 4, 8, and 12 hours of food deprivation) affects the speed with which an organism acquires new behaviors that produce the relevant consequence (e.g., food). In this way, an MO directly changes the potency of reinforcers (or punishers) to increase and maintain (or decrease and eliminate) behavior (Laraway et al., 2014).

The value of a reinforcer may also vary depending upon specific response requirements (DeLeon, Frank, Gregory, & Allman, 2009). One way to assess the potency of a specific reinforcer is to use a progressive ratio (PR) schedule in which response requirements increase after the delivery of each reinforcer (Roane, 2008; see Chapter 13). Under this arrangement, an organism may respond under high schedule requirements to obtain one consequence, but not another, even when both consequences have been observed to increase behavior under low response requirements (Roane, Lerman, & Vorndran, 2001). This procedure may serve to measure the momentary value of a reinforcer whose effectiveness varies depending on the MO. Other potential measures of reinforcer potency may include choice preparations, and latency to respond during a discrete trial (Poling, Lotfizadeh, & Edwards, 2017).

The behavior-altering effect is interpreted as a change in frequency due to the organism's behavior contacting reinforcement, implying that this change occurs only *after* the reinforcer has been obtained. However, a strong relation exists between the level of the MO and responding *under extinction*—when no reinforcers are being received (Keller & Schoenfeld, 1950). Early research (Skinner, 1938) showed that rats that had learned to press a lever to obtain food, when exposed to an extinction condition at different levels of deprivation, pressed the lever at different rates according to their levels of deprivation. Thus, different deprivation levels differentially evoked responses that had been previously learned. Similarly, if a child's tantrum has been followed by a parent's attention, the duration and intensity of the tantrum may be correlated with the amount of attention that the child has received before the tantrum.

The value-altering and behavior-altering effects of an MO occur simultaneously but are considered independent in the sense that one does not derive from the other. Food deprivation, for instance, increases behaviors that have been previously reinforced by food *prior to obtaining any food* (evocative effect). Food deprivation would also increase the reinforcing potency of food (the establishing effect). Thus, food-seeking behaviors would increase further after contacting food (Michael, 2000). Unfortunately, once behavior contacts reinforcement, these two effects may become difficult to discern (Poling et al., 2017).

Direct and Indirect Effects of Motivating Operations

The behavior-altering effect of an MO can increase (or decrease) the frequency of behavior because of a direct evocative (or abative) effect. The strength of the MO seems to be correlated with its capacity to directly evoke previously learned behavior. For example, when food deprivation is high, food-seeking behaviors may occur in situations that differ from the situations in which those behaviors were reinforced in the past (Lotfizadeh, Edwards, Redner, & Poling, 2012). An individual who has not eaten for a few hours is likely to request a snack from an acquaintance who usually carries some in her backpack (S^D). However, under extreme food deprivation, the individual might

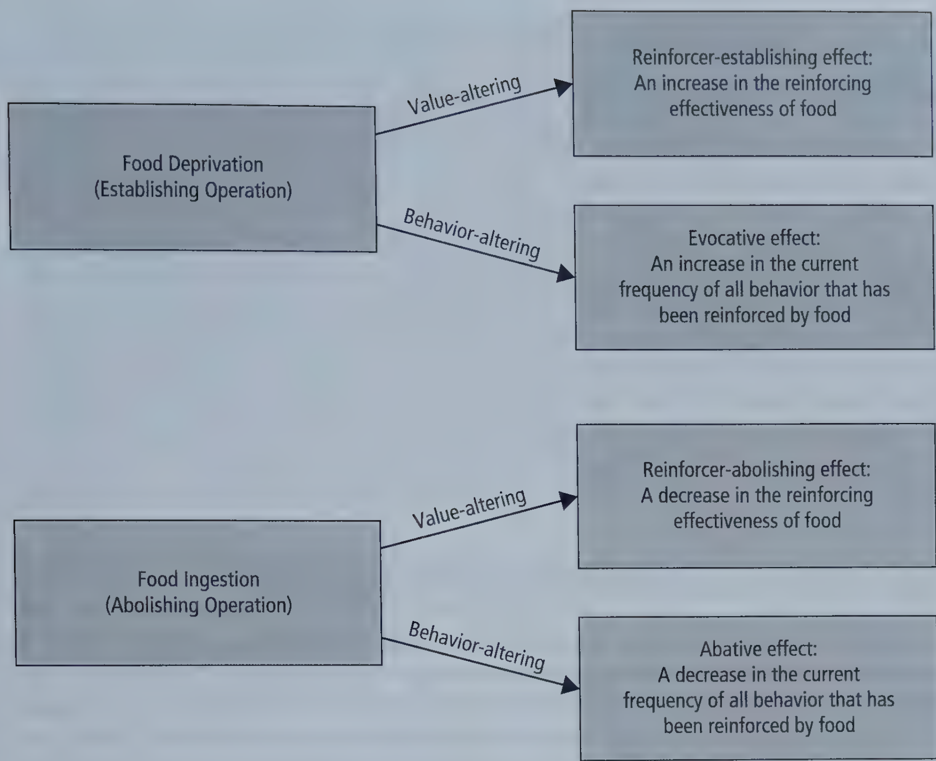

Figure 16.2 Motivating operations related to food.

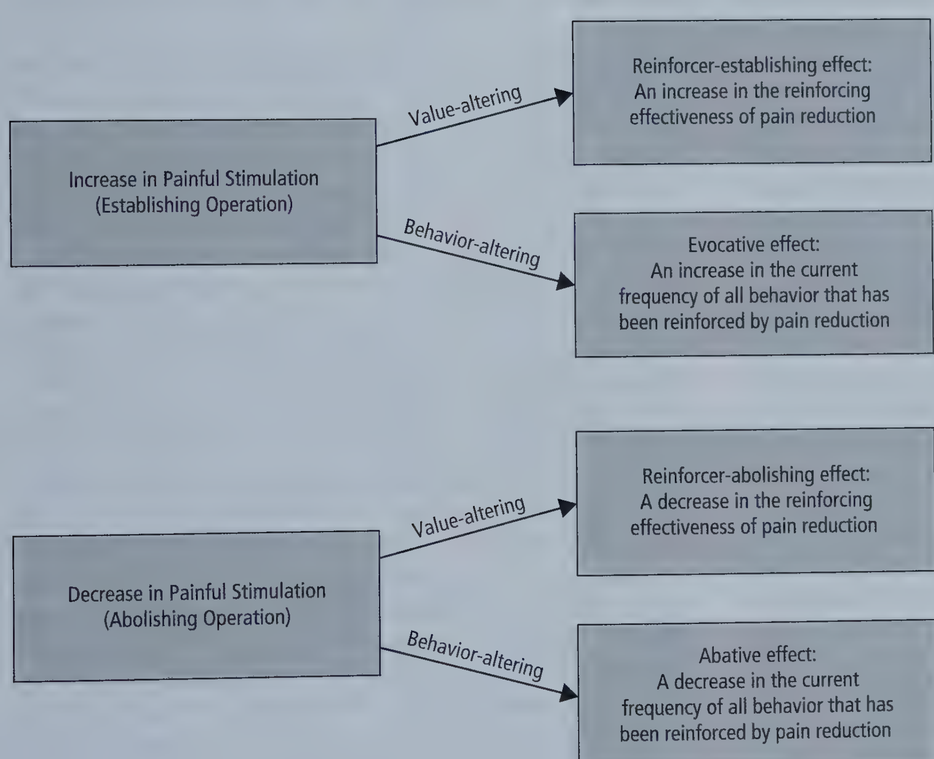

Figure 16.3 Motivating operations related to painful stimulation.

ask strangers for a snack, even though there has been no previous history of obtaining food from them. It seems that "the range of stimuli that evokes responding is wider when deprivation is high than when it is lower" (Lotfizadeh et al., 2012, p. 98). In other words, strong MOs can directly evoke behavior in the absence of relevant discriminative stimuli or, at least, in the presence of untrained stimuli. Thus, the direct evocative effect of the MO may be described as its capacity to evoke behavior irrespective of relevant discriminative stimuli.[3] It is important to remember that individuals do not need to be "aware" of the effects of reinforcement for it to affect behavior. Likewise, the effectiveness of MOs does not depend on individuals being able to describe the effects of MOs upon their behavior (see Box 16.2, "Do You Need to Know You Are Motivated?").

BOX 16.2

Do You Need to Know You Are Motivated?

The variables responsible for behavior-altering effects are often misconstrued by assuming that individuals must understand (verbally describe) the situation, and then behave appropriately as a result of this understanding. It is safe to assume that when pressing a lever to obtain water, a rat does not understand that lever presses have been reinforced by water in the past, nor that it should press the lever when water deprived. Similarly, humans do not need to verbally describe the situation for the MO to affect behavior. The fact that the effects of reinforcement upon behavior are automatic suggests that the behavior that has led to reinforcement will be momentarily increased when the relevant MO is in effect. Thus, just as the effects of reinforcing consequences do not depend on the organism's understanding of the contingency, neither do the effects of the MO upon behavior require that the organism be able to describe the relationship between behavior and consequence. Someone who spends a lot of time studying may not be able to identify the contingencies that have led to the establishment of this behavior or serve to momentarily evoke it. The frequency (or duration) of studying is still a function of environmental variables, whether the individual can describe them or not.

The MO indirectly affects the evocative or abative strength of relevant discriminative stimuli (S^Ds). Food deprivation, for instance, would increase the discriminative control of any stimulus that has been correlated with the availability of food. Therefore, the friend who carries snacks in her backpack would serve as a stronger S^D that would evoke a request when food deprivation is high. Also, the stronger the headache (MO), the more likely it is that the sight of the aspirin (as an S^D) would evoke the behavior of taking it. Note that the value of reinforcers present during discrimination training also depends upon a current MO (Laraway et al., 2003). In other words, the establishment of stimulus control over behavior not only depends on but also varies as a function of MOs. For instance, a child would never learn to discriminate between blue and red if no *effective reinforcer* were available for correct responses. To summarize, in the absence of an MO that establishes the value of the consequence as a reinforcer, discrimination learning is unlikely to occur, and a previously effective S^D would also not evoke behavior.

The value-altering effect also indirectly influences the reinforcing effectiveness of relevant conditioned stimuli. For example, food deprivation not only increases the capacity of food as a consequence to strengthen behavior (direct establishing effect), but also enhances the reinforcing effectiveness of all other stimuli that have been correlated with food, such as the smell of food, the sight of a restaurant, and so on. In the same way, a headache would not only establish its removal as an effective reinforcer, but also all stimuli that have been paired with pain reduction, such as an aspirin, a nap, a dark environment, and so forth. The latter effect, a conditioned one, will be discussed in the section on conditioned MOs, below. Figure 16.4 displays the different direct and indirect effects of the MO.

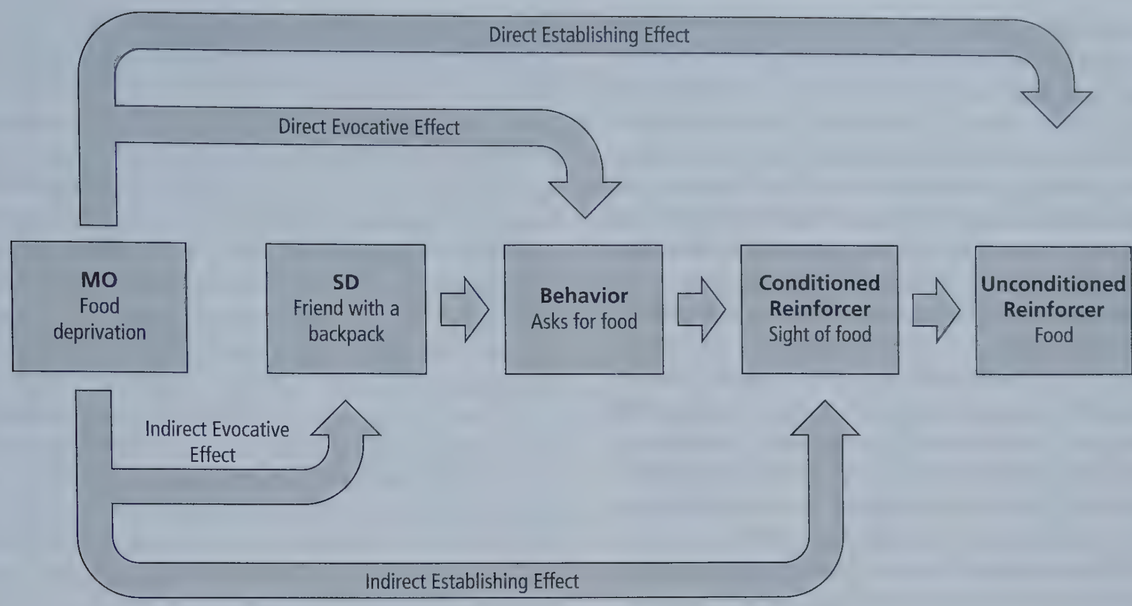
Behavior-altering versus Function-altering Effects[4]

Both MOs and S^Ds are antecedent variables that have behavior-altering effects. Antecedents can evoke or abate responses, but their occurrence does not alter the organism's functional behavioral repertoire. Thus, as antecedent variables, MOs alter the *current* frequency of all behaviors relevant to that MO. For example, a difficult task may serve as an establishing operation that momentarily increases all behaviors that in the past have produced removal of the task. Presenting a difficult task to a child who has learned that tantrums often result in task postponement or removal is likely to produce a tantrum (i.e., evocative effect). Conversely, if the task is not presented, or made easier (an abolishing operation), then the likelihood of tantrums is diminished (i.e., abative effect). However, as an intervention strategy, the removal of the task does not alter the child's repertoire; it only momentarily abates behavior that would otherwise occur if the motivating variable (difficult task) were in place. In other words, the child will not behave differently in the presence of difficult tasks solely as a result of antecedent manipulations.[5] Thus, reducing or eliminating the MO for a specific problem behavior is a temporary rather than permanent solution. When the MO is again in place, the problem behavior may re-occur (Michael, 2000). Nonetheless, eliminating environmental conditions (e.g., MOs) that contribute to the occurrence of problem behavior may be necessary,[6] especially when these conditions are impoverished or aversive (McGill, 1999).

Consequences can change the organism's repertoire, enabling the organism to behave differently in the future. Thus, consequences have **function-altering effects**. These variables include reinforcers, punishers, and the occurrence of a response without its reinforcer (extinction procedure), or without its punisher (recovery from punishment procedure). Consequences alter the *future* frequency of whatever behavior immediately preceded those consequences. In the previous example, if task removal or reduction of task difficulty is made contingent upon the child asking for a break or help, the frequency of these behaviors would increase under similar conditions in the future. In other words, the child's functional repertoire is changed as he or she can engage in two new responses: asking for a break or asking for help.

DISTINGUISHING BETWEEN MOs AND S^Ds

As described above, MOs and S^Ds are both antecedent variables that alter the current frequency of some particular behavior (i.e., evoke). Each operant variable influences response frequency because of its relation to reinforcing or punishing



Food deprivation directly establishes food as a reinforcer (value-altering effect) and evokes food-seeking behaviors (behavior-altering effect). Food deprivation indirectly establishes the effectiveness of all conditioned reinforcers correlated with food (value-altering effect) and indirectly affects the salience of the discriminative stimulus correlated with food (behavior-altering effect).

Figure 16.4 Direct and indirect effects of a motivating operation (MO).

consequences. An S^D affects behavior because its presence has been correlated with the *differential availability* of an effective reinforcer in the past. Differential availability means the relevant consequence has been available in the presence of the S^D (i.e., reinforcement) and unavailable in its absence (i.e., extinction; see Chapter 24).

For instance, if a food-deprived rat receives food for lever presses in the presence, but not absence, of a light, the light will eventually evoke lever presses. In this case, the light would be functioning as an S^D, since food delivery was more available in its presence than in its absence. Note that although food was never delivered when the light was off (the S^Δ condition), food would have served as an effective reinforcer had it been delivered when the light was off. In other words, food was valued (i.e., reinforcing) in both conditions, but available only when the light was on. The reduced frequency of lever presses during the S^Δ condition is due to extinction.

An MO, in contrast, controls behavior because of its relation to the *differential effectiveness* of a reinforcer for that behavior. Differential effectiveness means that the relevant consequence has been effective in the presence of, and ineffective in the absence of, the MO. In the example above, the rat would press the lever only in the presence of the light (S^D) when the MO is present (i.e., food deprived) and not when the MO is absent (i.e., food satiated). When the MO is absent, behavior decreases not because the reinforcer is unavailable (extinction), but because it is no longer valuable or effective.

Now imagine that the rat learns to press the lever to eliminate shock. In this case, pressing the lever produces pain reduction (or elimination) as a form of reinforcement. If painful stimulation as an antecedent were to be considered an S^D, pain reduction (the reinforcer) must have been available as a consequence in the presence of painful stimulation, but not in its absence. More importantly, like food in the previous example, pain reduction would have been effective as a reinforcer in both conditions, regardless of its availability. It is with respect to this requirement that some motivating variables fail to qualify as discriminative stimuli. Pain reduction could not serve as a reinforcer in the absence of pain as an antecedent.[7] In other words, in the absence of painful stimulation, behavior has not decreased due to extinction, but because there is no possible valuable reinforcer. The organism is not motivated to engage in behavior to reduce pain, if no pain is being felt.

In the previous example of light-on/light-off discrimination training, the reinforcer is available in the light-on condition and unavailable, yet still effective, in the light-off condition. In other words, the rat still "wants food" when the light is off but food is not available. The behavior occurs less frequently in the light-off (S^Δ) condition because it no longer produces an effective reinforcer. In contrast, in the absence of food deprivation or painful stimulation, food or pain removal, respectively, is not an effective reinforcer. Hence, food deprivation and painful stimulation qualify as MOs because they momentarily alter (a) the effectiveness of some stimuli, objects, or events as reinforcers (value-altering effect); and (b) the frequency of the behavior that has been reinforced by those stimuli, objects, or events (behavior-altering effect).

Similarly, an itch does not serve as a discriminative stimulus that evokes scratching it. Although the reinforcer (removing the itch) is available in the presence of the itch and unavailable in the absence of the itch, this is not an effective reinforcer in the absence of the itch. In this sense, the itch is best interpreted as functioning as an MO that establishes its removal as an effective reinforcer, and momentarily evokes scratching. In other words, having an itch is what motivates you to scratch.

Many antecedent stimuli that have been considered to evoke behavior as S^Ds would be better classified as MOs. This is particularly the case with aversive stimuli. For example, a headache is an MO that directly establishes headache removal as an unconditioned reinforcer and indirectly establishes aspirin as a conditioned reinforcer (see Figure 16.5). A headache also evokes behaviors that have produced pain reduction (finding and taking aspirin) in the past. If aspirin is found in the bathroom but not in the kitchen, then the bathroom will function as an S^D for the behavior of looking for aspirin because it has been correlated with *availability* of an *effective* reinforcer, while the kitchen will function as an S^Δ for looking for aspirin because it has been correlated with the *unavailability* of an *effective* reinforcer. In other words, for discrimination to take place, an individual needs to find aspirin in the bathroom, and not find aspirin in the kitchen, respectively, when needed (MO; see first two rows of Figure 16.5). In the absence of the headache (AO), one can still find aspirin in the bathroom, but there is no reason to look for it (available, but not a reinforcer), since there is no headache to be removed (unavailable non-reinforcer). Thus, in the absence of the headache, looking for an aspirin will not occur in either location (see bottom row of Figure 16.5).

In applied settings, when a child is given an instruction to complete a difficult task, the reinforcer may be task completion or termination. Additionally, the instruction would also acquire conditioned aversive properties due to its correlation with difficult tasks. Thus, the instruction could serve as an MO that establishes its removal as a reinforcer and evokes avoidance behavior (Carbone, Morgenstern, Zecchin-Tirri, & Kolberg, 2010). In contrast, if task completion has produced praise as a reinforcer in the presence, but not the absence, of the instruction, then the instruction may be functioning as an S^D. Other events best classified as MOs rather than S^Ds will be discussed later in this chapter, most specifically in the section on conditioned motivating operations.

Although behavior analysts use the three-term contingency (antecedent-behavior-consequence) to understand operant behavior, any given response may be evoked by a multitude of variables functioning as antecedents (i.e., multiple control). A child who enters the kitchen and asks for a cookie does so because in the past such behavior has produced reinforcement under similar circumstances. These circumstances involve variables that establish cookies as reinforcers, as well as increase the likelihood of asking for them (food deprivation as an MO). However, the behavior is more likely to occur in environments where cookies are available (kitchen as an S^D) and in the presence of an adult (also an S^D) who can give the child a cookie (Skinner, 1957). In this case, food deprivation is correlated with increasing the effectiveness of cookies as reinforcers, while the kitchen and the adult are both correlated with the availability of cookies.

To summarize, S^Ds alter the differential availability of a currently effective form of reinforcement for a particular type of behavior; MOs alter the differential reinforcing effectiveness of a particular type of environmental event. In nontechnical terms, an S^D tells you that something you want is available; an MO makes you want something.

UNCONDITIONED MOTIVATING OPERATIONS (UMOs)

For all organisms there are events, operations, and stimulus conditions with unconditioned *value-altering* effects. In other words, these MOs establish or abolish the value of stimuli

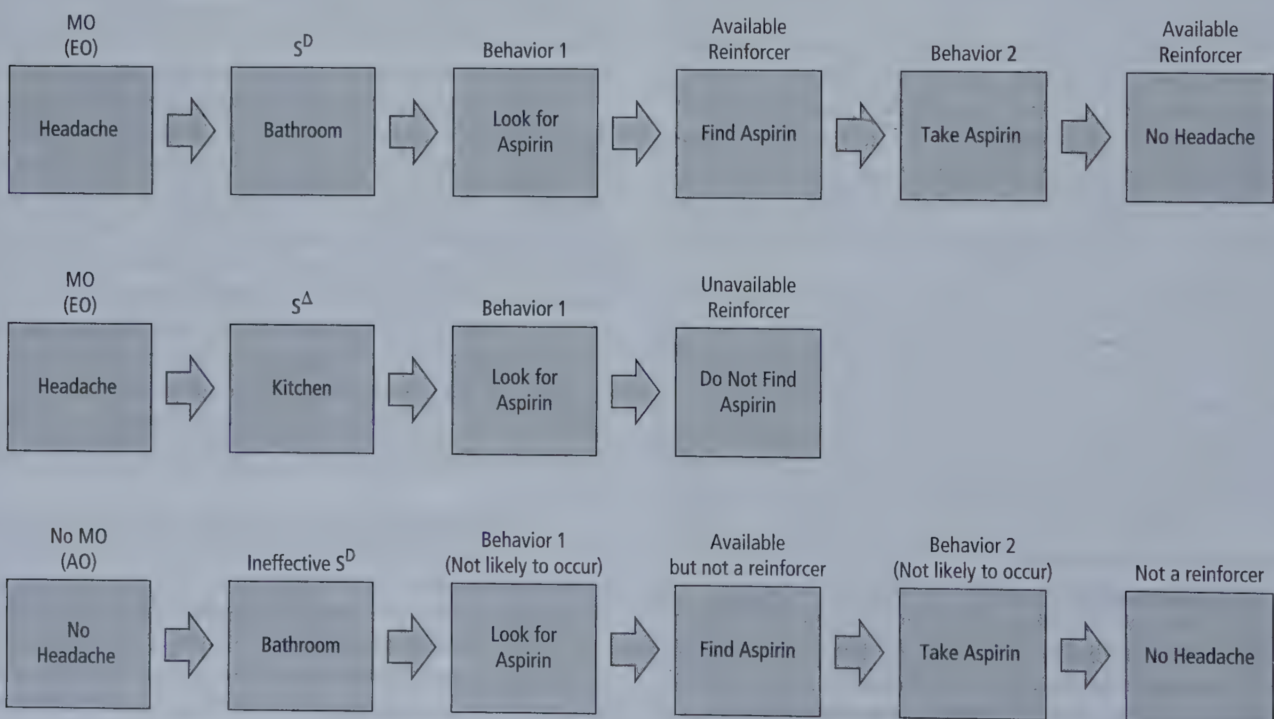


Figure 16.5 Distinguishing between S^D and MO.

as reinforcers in the absence of prior learning. For example, humans are born with the capacity to be affected by food reinforcement as a result of food deprivation and by pain reduction reinforcement as a result of pain onset or increase. Thus, food deprivation and painful stimulation are **unconditioned motivating operations (UMOs)**.[8]

MOs are classified as unconditioned based upon the unlearned aspect of their value-altering effects, since the behavior-altering effects of MOs are usually learned. Said another way, we are born with the capacity to be affected by food reinforcement as a result of food deprivation, but we learn the behaviors evoked by food deprivation—asking for food, going to where food is kept, cooking, and so forth.

Deprivation of food, water, oxygen, activity, and sleep all have **reinforcer-establishing** and **evocative effects** (see Table 16.1). For instance, water deprivation momentarily establishes the effectiveness of water as a reinforcer and evokes all behaviors that have produced water. By contrast, food and water ingestion, oxygen intake, being active, and sleeping have **reinforcer-abolishing** and **abative effects** (see Table 16.2). For instance, water ingestion abolishes the effectiveness of water as a reinforcer and abates all behaviors that have produced water.

The passage of time since last sexual activity functions as a UMO relevant to sexual stimulation. This form of deprivation establishes the effectiveness of sexual stimulation as a reinforcer and evokes behavior that has produced such stimulation. In contrast, sexual orgasm is a UMO that abolishes (weakens) the effectiveness of sexual stimulation as a reinforcer and abates (decreases the frequency of) behavior that has achieved that kind of reinforcement. In addition, tactile stimulation of erogenous regions of the body seems to function as a UMO in making further similar stimulation even more effective as a reinforcer, and in evoking all behavior that in the past has achieved such stimulation.

UMOs related to temperature changes include becoming uncomfortably cold and uncomfortably warm. Getting cold is a UMO that establishes getting warmer as a reinforcer and evokes behavior that has produced warmth, such as putting on a jacket or moving closer to a heat source. A return to a comfortable (i.e., nonaversive) temperature is a UMO that abolishes increased warmth as a reinforcer and abates behavior that has produced warmth. In this case, behaviors such as putting on a jacket are less likely to occur. Getting uncomfortably warm is a UMO that establishes a cooler temperature as an effective reinforcer and evokes behaviors that have resulted in a body-cooling effect. For example, getting warm may evoke the behavior of turning on the air conditioning. A return to a normal temperature abolishes being cooler as a reinforcer and abates body-cooling behavior. In this case, turning on the air conditioning is less likely to occur.

An increase in painful stimulation establishes pain reduction as a reinforcer and evokes the (escape) behavior that has achieved such reduction. As described previously, a headache establishes its own removal as a reinforcer and evokes any behavior that has eliminated headaches, such as taking aspirin. A decrease in painful stimulation abolishes the effectiveness of pain reduction as a reinforcer and abates the behavior that has been reinforced by pain reduction. Thus, when a headache is gone, headache removal is no longer a reinforcer and taking an aspirin is less likely to occur.

TABLE 16.1 Unconditioned Motivating Operations (UMOs) That Increase Reinforcer Effectiveness and Evoke Relevant Behavior

UMO	Reinforcer-Establishing Effect	Evocative Effect
Food deprivation	Increases effectiveness of food as a reinforcer	Increases current frequency of all behavior previously reinforced with food
Water deprivation	Increases effectiveness of water as a reinforcer	Increases current frequency of all behavior previously reinforced with water
Sleep deprivation	Increases effectiveness of sleep as a reinforcer	Increases current frequency of all behavior previously reinforced with being able to sleep
Activity deprivation	Increases effectiveness of activity as a reinforcer	Increases current frequency of all behavior previously reinforced with activity
Oxygen deprivation[a]	Increases effectiveness of breathing (oxygen) as a reinforcer	Increases current frequency of all behavior previously reinforced with being able to breathe
Sex deprivation	Increases effectiveness of sex stimulation as a reinforcer	Increases current frequency of all behavior previously reinforced with sexual stimulation
Becoming too warm	Increases effectiveness of temperature decrease as a reinforcer	Increases current frequency of all behavior previously reinforced with becoming cooler
Becoming too cold	Increases effectiveness of temperature increase as a reinforcer	Increases current frequency of all behavior previously reinforced with becoming warmer
Increase in painful stimulus	Increases effectiveness of pain decrease as a reinforcer	Increases current frequency of all behavior previously reinforced with a decrease in painful stimulation

[a]It is not actually oxygen deprivation that functions as a UMO, but rather the buildup of carbon dioxide in the blood as a result of not being able to excrete carbon dioxide because of not being able to breathe or because of breathing in air that is as rich in carbon dioxide as the exhaled air.

TABLE 16.2 Unconditioned Motivating Operations (UMOs) That Decrease Reinforcer Effectiveness and Abate Relevant Behavior

UMO	Reinforcer-Abolishing Effect	Abative Effect
Food ingestion (after food deprivation)	Decreases effectiveness of food as a reinforcer	Decreases current frequency of all behavior previously reinforced with food
Water ingestion (after water deprivation)	Decreases effectiveness of water as a reinforcer	Decreases current frequency of all behavior previously reinforced with water
Sleeping (after sleep deprivation)	Decreases effectiveness of sleep as a reinforcer	Decreases current frequency of all behavior previously reinforced with sleep
Being active (after activity deprivation)	Decreases effectiveness of activity as a reinforcer	Decreases current frequency of all behavior previously reinforced with activity
Breathing (after not being able to breathe)	Decreases effectiveness of breathing (oxygen) as a reinforcer	Decreases current frequency of all behavior previously reinforced with being able to breathe
Orgasm or sexual stimulation (after sex deprivation)	Decreases effectiveness of sexual stimulation as a reinforcer	Decreases current frequency of all behavior previously reinforced with sexual stimulation
Becoming cooler (after being too warm)	Decreases effectiveness of temperature decrease as a reinforcer	Decreases current frequency of all behavior previously reinforced with becoming cooler
Becoming warmer (after being too cold)	Decreases effectiveness of temperature increase as a reinforcer	Decreases current frequency of all behavior previously reinforced with becoming warmer
Painful stimulation decrease (while in pain)	Decreases effectiveness of pain decrease as a reinforcer	Decreases current frequency of all behavior previously reinforced with a decrease in pain

In addition to establishing pain reduction as a reinforcer and evoking the behavior that has produced pain reduction, painful stimulation may evoke aggressive behavior toward another organism.[9] Painful stimulation may function as a UMO that establishes events such as signs of damage as effective reinforcers and evokes behaviors that have been reinforced by such signs. Skinner (1953) made this case in his analysis of anger and extended it to the emotions of love and fear.[10]

Although it is indisputable that both food deprivation/satiation and painful stimulation/reduction have unlearned value-altering effects, restriction of and access to certain conditioned reinforcers also seem to affect their value. This is the case with social reinforcers, such as praise (Vollmer & Iwata, 1991). It could be argued that for infants, attention (e.g., touch, parent's voices) is a form of unconditioned reinforcer whose value may be affected by deprivation and satiation. However, for most adults, attention functions as a conditioned reinforcer due to its relation to other forms of effective reinforcers (Michael, 2000). In this case, access and restriction to attention (or any other conditioned reinforcer) would function as a type of conditioned MO, as discussed below.

MOs FOR PUNISHMENT

MOs may also alter (increase or decrease) the punishing effectiveness of a stimulus, as well as the frequency (evoke or abate) of behaviors that have been punished by that stimulus. Thus, an EO related to punishment would have a punisher-establishing effect and an abative effect. For example, a migraine would establish the effectiveness of bright light as a punisher and decrease the frequency of all behaviors that in the past have produced the bright light (e.g., opening the curtains, turning a light on). Some biological states, such as pregnancy, may establish certain tastes or smells as punishers and decrease the occurrence of behaviors that have produced them. An AO related to punishment would have a punisher-abolishing effect and an evocative effect, in that behaviors that have been punished would occur again (assuming that a reinforcer contingency for the previously punished behavior is intact). Ingesting alcohol may decrease the effectiveness of social disapproval as a punisher and increase behaviors that have produced some social embarrassment (assuming those behaviors also produced some reinforcement in the past).

Most punishers that affect humans are effective because of a learning history; that is, they are *conditioned* rather than *unconditioned* punishers. In the case of conditioned punishers that were established by having been paired with the removal (or reduced availability) of reinforcers (i.e., negative punishment), their effectiveness as conditioned punishers will depend on the same MOs that establish the value of the reinforcers that were removed. For instance, a parent's disapproving look may function as a conditioned punisher as a result of having been paired with restricted access to video games. The disapproving look will be most effective as a conditioned punisher when an MO for playing video games is in effect. If the child has already played enough video games for the day (i.e., is "satiated"), then the disapproving look will be less effective in reducing behavior. Thus, *social disapproval* (e.g., a frown, a head shake, or vocal response such as "No" or "Bad") that typically precedes withholding of a reinforcer will only function as an effective conditioned punisher when the MOs for the withheld reinforcers are in effect. However, it is possible for a stimulus to be associated with several different punishers. In this case, this stimulus may function as a generalized conditioned punisher, whose effectiveness will be almost free from the influence of MOs. If the disapproving look has been associated with the loss of a wide range of reinforcers, including generalized reinforcers such as money, then the look

may almost always function as a punisher, since at least one of the reinforcers will be valuable at any given moment.

The same applies for the negative punishment procedures *time-out* and *response cost* (see Chapter 15). Time-out will only be effective when "time-in" serves as a reinforcer when the behavior is being punished. Solnick, Rincover, and Peterson (1977) compared the effectiveness of time-out when the time-in environment was either impoverished or enriched when trying to decrease self-injury and stereotypy in a child diagnosed with intellectual disabilities. The impoverished time-in condition looked no different from the child's typical treatment session, in which correct responses (sorting blocks) were reinforced with praise, food, and toys. During the enriched time-in condition, the experimenters played music, introduced new toys, and increased social interaction by continuously prompting the participant to play with the toys. Time-out consisted of 90 sec of no access to reinforcers contingent upon problem behavior. Their results showed that time-out was effective when the time-in was enriched and generally ineffective when time-in was impoverished. This suggests that the effectiveness of a negative punishment procedure depends upon the MO for the reinforcer being eliminated. The same can be said about *response cost*; unless the events removed contingent upon behavior are effective as reinforcers at the time the procedure is implemented, response cost will not serve as an effective punishment procedure.

In general, when observing a punishment effect, one must also consider the status of the reinforcer responsible for the occurrence of the punished behavior. A behavior is targeted for reduction only if it has been occurring and its occurrence is a function of reinforcement. For instance, disruptive behavior maintained by attention may increase in frequency when it has not received much attention (MO for reinforcement). Any punishment procedure targeting this disruptive behavior will have to be delivered when the MO for attention is in effect.

Suppose a time-out procedure had been used to punish disruptive behavior. As mentioned earlier, only when the MO relevant to the reinforcer available (attention during time-in) was in effect should we expect time-out to function as punishment. And then only if those MOs were in effect should we expect to see the abative effect of the punishment procedure on disruptive behavior (i.e., immediate reduction in behavior). In the absence of the MO for disruptive behavior (lack of attention), there would be no behavior to be abated.

Although these complex behavioral relations have not received much attention in the conceptual, experimental, or applied behavior analytic literatures, they seem to follow naturally from existing knowledge of reinforcement, punishment, and motivating operations. Behavior analysts should be aware of the possible participation of these behavioral relations in any situation involving punishment.[11]

MULTIPLE EFFECTS OF MOs

Most environmental events have more than one effect upon behavior. It is important to recognize these various effects and to not confuse one effect with another (Skinner, 1953, pp. 204–224). Multiple effects are readily apparent in an animal laboratory demonstration of an operant chain. A food-deprived rat pulls a cord hanging from the ceiling of the chamber. Pulling the cord produces an auditory stimulus such as a buzzer. In the presence of the buzzer, the rat presses a lever and receives a food pellet. The onset of the buzzer has two obvious effects: (1) It evokes the lever press, and (2) it increases the future frequency of cord pulling. The buzzer functions as an S^D for the evocative effect and as a conditioned reinforcer for the reinforcement effect. Both effects influence behavior in the same direction: an increase in the current frequency and an increase in future frequency of the lever press.[12] Similarly, a hungry person may open the fridge to find her roommate's leftover Mexican food. The sight of the Mexican food evokes behaviors associated with eating it (e.g., getting it out of the fridge, heating it up), as well as possibly increasing the future frequency of opening the fridge.

Similarly, if pressing the lever in the presence of the buzzer produces an electric shock, then the sound of the buzzer would function as a *discriminative stimulus for punishment* (S^{Dp}). The buzzer would then have abative effects on the current frequency of lever pressing and function as a conditioned punisher that decreases the future frequency of cord pulling. Likewise, if the leftover food is spoiled, then it abates the behavior of eating it as well as decreases the behavior of opening the fridge to look for food.

Like S^Ds, events that function as UMOs will typically have behavior-altering effects on the current frequency of a type of behavior and, when presented as consequences, will have function-altering effects on the future frequency of behavior that immediately preceded their onset. An increase in painful stimulation will, as an antecedent, have MO establishing effects that would *increase* the *current* frequency of all behavior that has alleviated pain and, as a consequence, would *decrease* the *future* frequency of whatever behavior immediately preceded the increased pain.

As in the example above, events that have a UMO evocative effect, such as painful stimulation, will also function as punishment for the response immediately preceding the onset of the event. However, this statement must be qualified for events that have such gradual onsets (like food or water deprivation) that they cannot easily function as consequences. In other words, even though food deprivation can evoke all behaviors that have produced food in the past, it would likely not be effective as a punishing consequence to decrease the future frequency of behavior.

Events that have MO abolishing effects as antecedents may have reinforcing effects when presented as consequences for behavior. For example, food consumption momentarily decreases the reinforcing value of food as an effective reinforcer (abolishing effect), as well as momentarily decreases behaviors that have produced food in the past (abative effect). As a consequence, food consumption increases the future frequency of behaviors that have produced it (reinforcing effect). Thus, it is important to note that when edibles are used as consequences for increasing behavior (reinforcement effect), the repeated consumption of edibles decreases their value as an effective reinforcer (abative effect). Similarly, if an item is removed in an attempt to increase its value as a reinforcer (establishing effect), its removal may reduce the future frequency of whatever behavior immediately

preceded the removal (punishing effect). Tables 16.3 and 16.4 illustrate the multiple effects of environmental events.

CONDITIONED MOTIVATING OPERATIONS (CMOs)

Motivating variables that alter the reinforcing effectiveness of other stimuli, objects, or events as a result of the organism's learning history are called **conditioned motivating operations (CMOs)**. As with UMOs, CMOs alter the momentary frequency of all behavior that has been reinforced by those other events. In commonsense terms, some environmental variables, as a product of our experiences, make us want something different from what we wanted prior to encountering those variables, and encourage us to try to obtain what we now want. For example, needing to enter a room with a locked door establishes the key to the lock as an effective reinforcer. A locked door is a CMO because its value-altering effect is a function of a learning history involving doors, locks, and keys.

There seem to be at least three kinds of CMOs, all of which are motivationally neutral events prior to their relation to another MO or to a form of reinforcement or punishment.

TABLE 16.3 Contrasting the Behavior-altering (MO Evocative) and Function-altering (Punishing) Effects of Environmental Events

Environmental Event	Evocative Effect on Current Behavior as a UMO	Function-altering Effect on Future Behavior as Punishment
Deprivation of food, water, sleep, activity, or sex	Increases the current frequency of all behavior that has been reinforced with food, water, sleep, activity, or sex	Should be punishment, but onset is too gradual to function as a behavioral consequence
Oxygen deprivation	Increases the current frequency of all behavior that has been reinforced with being able to breathe	The sudden inability to breathe decreases the future frequency of the type of behavior that preceded that instance of being unable to breathe
Becoming too cold	Increases the current frequency of all behavior that has been reinforced by becoming warmer	Decreases the future frequency of the type of behavior that preceded that instance of becoming too cold
Becoming too warm	Increases the current frequency of all behavior that has been reinforced by becoming cooler	Decreases the future frequency of the type of behavior that preceded that instance of becoming too warm
Increase in painful stimulation	Increases the current frequency of all behavior that has been reinforced with pain reduction	Decreases the future frequency of the type of behavior that preceded that instance of painful stimulation

TABLE 16.4 Contrasting the Behavior-altering (MO Abative) and Function-altering (Reinforcing) Effects of Environmental Events

Environmental Event	Abative Effect on Current Behavior as a UMO	Function-altering Effect on Future Behavior as Reinforcement
Ingestion of food and water, sleeping, being active, or having sex	Decreases the current frequency of all behavior that has been reinforced with food, water, sleep, activity, or sex	Increases the future frequency of the type of behavior that immediately preceded the food or water ingestion, being able to sleep, being able to be active, or sexual activity
Breathing (after not being able to breathe)	Decreases the current frequency of all behavior that has been reinforced with (oxygen) being able to breathe	The sudden ability to breathe increases the future frequency of the type of behavior that preceded that instance of ability to breathe
Becoming cooler (after being too warm)	Decreases the current frequency of all behavior that has been reinforced by becoming cooler	Increases the future frequency of the type of behavior that preceded that instance of becoming cooler
Becoming warmer (after being too cold)	Decreases the current frequency of all behavior that has been reinforced by becoming warmer	Increases the future frequency of the type of behavior that preceded that instance of becoming warmer
Decrease in painful stimulation	Decreases the current frequency of all behavior that has been reinforced with pain reduction	Increases the future frequency of the type of behavior that preceded that instance of pain decrease

The distinction among these conditioned motivating operations is based upon how they were developed and how they affect behavior. A **surrogate conditioned motivating operation (CMO)** produces the same effects as another MO because of some type of pairing (i.e., a surrogate is a substitute or stand-in), a **reflexive CMO** alters a relation to itself (makes its own removal effective as reinforcement), and a **transitive CMO** makes something else effective as reinforcement (rather than altering itself).

Surrogate CMO (CMO-S)

A CMO-S is a previously neutral stimulus that acquired its MO effects by being paired with a UMO. This process is similar to how respondent conditioned stimuli, operant conditioned reinforcers, and operant conditioned punishers acquire their functions by being paired with another behaviorally effective stimulus.

For example, a restaurant may exert discriminative control over several behaviors, including ordering food, since restaurants have been differentially correlated with the availability of food. However, because we typically go to restaurants after a period in which we have not had any food (i.e., food deprivation as a UMO), it is possible that after multiple pairings with food deprivation, the restaurant would function as a CMO-S, (a) establishing food as a reinforcer and (b) evoking behaviors that have produced food (e.g., ordering some). Figure 16.6 exemplifies the establishment of the restaurant as a CMO-S.

However, the existence of this type of CMO seems to be opposed to the organism's best interest for survival (Mineka, 1975). For example, ordering food when satiated, as in the example above, would not seem healthy. However, a number of animal studies have shown that a stimulus paired with a reinforcer (e.g., food) under a high (e.g., 24 h) deprivation condition is preferred over a stimulus that was paired with the same reinforcer amount under a low (e.g., 12 h) deprivation condition (e.g., Lewon & Hayes, 2014; Vasconcelos & Urcuioli, 2008). In other words, when two stimuli are paired with the same reinforcer, but under different MO conditions, subjects that are mildly deprived chose the stimulus correlated with high-deprivation levels. It is possible that in addition to the food deprivation (mild deprivation), the presence of the stimulus

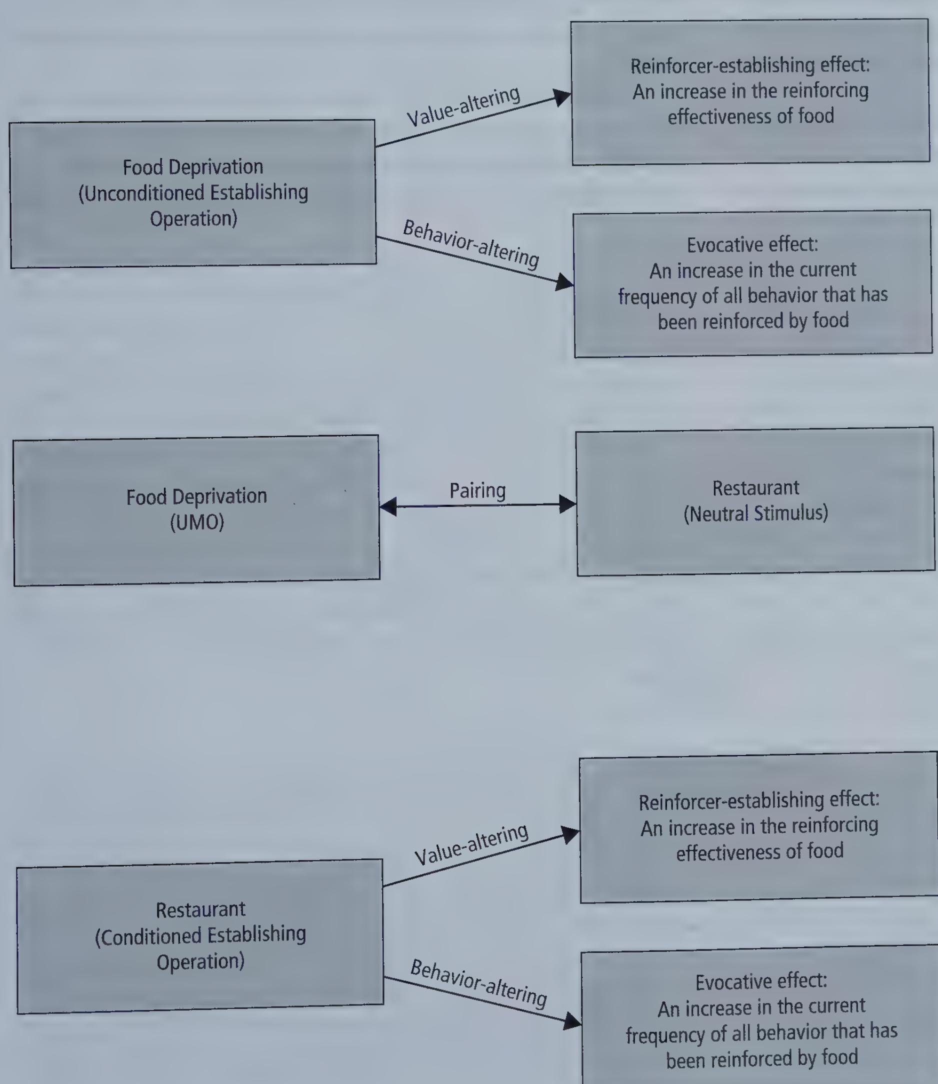

Figure 16.6 Example of a surrogate CMO (CMO-S).

correlated with high deprivation acts as a CMO-S, which makes the subjects behave as if they are "hungrier" than they would be otherwise, and this might be why they tend to respond more frequently to the high-deprivation alternative. Durlach, Elliman, and Rogers (2002) have found that adults under the same MO condition chose a flavored and colored drink that had been correlated with a high-value UMO for liquids (high-salt meal) over a drink that had been paired with a low-value UMO (low-salt meal), suggesting that the flavor and color acquired CMO-S properties.

O'Reilly, Lancioli, King, Lally, and Dhomhnaill (2000) found that aberrant behavior (pushing, pinching, property destruction, and self-injury) displayed by two individuals with developmental disabilities was maintained by attention when their parents were interacting with a third person (diverted attention). Given that parents provided low levels of attention when they were talking to a third person, diverted attention was paired with low attention (MO). This may have led to diverted attention functioning as a CMO-S. Figure 16.7 shows that for both participants, problem behavior that never occurred during the brief functional analysis did so when the diverted attention condition (CMO-S) was introduced. Providing attention noncontingently (abolishing operation) produced significant reductions in problem behavior. Follow-up observations showed reduced levels of problem behavior. These results seem to suggest that previously neutral stimuli may acquire MO functions due to being paired with another effective MO.

In a translational evaluation of the CMO-S, Lanovaz, Rapp, Long, Richling, and Carroll (2014) repeatedly paired a poster board with the presence of a condition (last 2 minutes of each session) known to function as an EO for stereotypy. After this pairing procedure, three out of four participants diagnosed with autism displayed higher rates of stereotypy in the presence of the poster board. These results have important applied implications, as there may be many environmental features in a therapeutic setting that could acquire CMO-S control over problem behavior simply by being paired with another MO. If a toy known for evoking stereotypy is delivered after compliance for a specific instruction, this repeated pairing may establish the instruction as a CMO-S that would increase the value of a specific form of automatic reinforcement and evoke stereotypy (Lanovaz et al., 2014).

The relationship between the CMO-S and an effective MO can generally be weakened by two kinds of **MO unpairing**: presenting the previously neutral stimulus (now CMO-S) without the effective MO or presenting the MO as often in the absence of the CMO-S as in its presence. In the examples above, if the instruction is no longer followed by the toy that usually evokes stereotypy, or a parent talking to a third person is no longer followed by low levels of attention, the value-altering and behavior-altering effects of the toy or diverted parental attention would be weakened. Similarly, if the toy known to evoke stereotypy is presented as often in the presence of the instruction as in its absence, or if differing levels of attention are associated with talking to a third person, their motivating effectiveness would be reduced.

The CMO-S appears to play a role in the development of behaviors that do not seem to make much sense, such as seeing a restaurant after dinner and wanting to eat again or feeling the urge to urinate after seeing the sign for the restroom. Both the

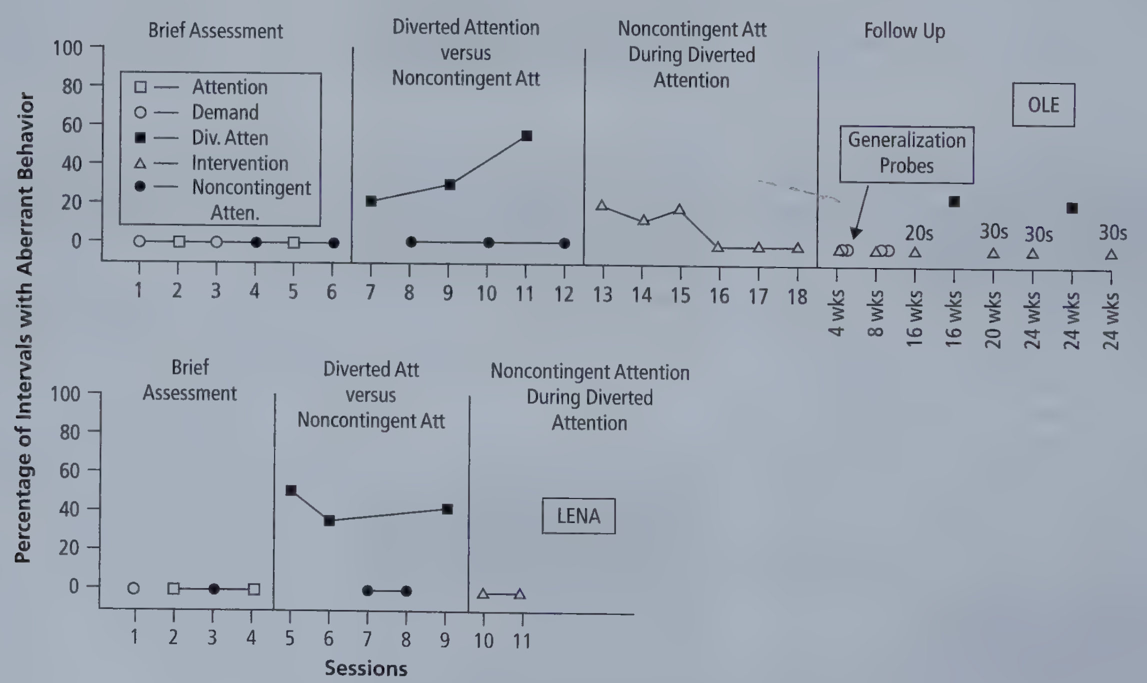

Figure 1. Percentage of intervals with aberrant behavior for Ole and Lena during assessment, treatment evaluation, and follow-up sessions.

Figure 16.7 Example of control by a motivating operation "a surrogate CMO (CMO-S)".

From "Using Brief Assessment to Evaluate Aberrant Behavior Maintained by Attention", M. F. O'Reilly, G. E. Lancioni, L. King, G. Lally, and O. N. Dhomhnaill, 2000, Reproduced with permission of John Wiley & Sons Inc.

restaurant and the restroom may evoke behavior as a CMO-S, given previous pairings with food deprivation and a full bladder, respectively (Miguel, 2013).

Reflexive CMO (CMO-R)

Any stimulus that systematically precedes the onset of painful stimulation becomes a CMO-R, in that its own offset functions as a reinforcer, and its occurrence evokes any behavior that has produced such reinforcement in the past. For example, in a traditional discriminated avoidance procedure,[13] after some interval of time, the onset of an initially neutral stimulus is followed by the onset of painful stimulation—usually electric shock (see Box 16.3, "What's an Aversive Stimulus?"). Some arbitrary response (one that is not part of the organism's phylogenic repertoire), such as lever pressing, terminates the painful stimulation (the animal *escapes* the pain) and restarts the interval. If the same response occurs during the warning stimulus, it terminates that stimulus and the shock does not occur on that trial. The response at this phase of the procedure is said to have avoided the pain and is called an *avoidance response*. Many organisms learn to respond during the onset of a warning stimulus, and thus receive very few shocks.

In this case, the warning stimulus functions similarly to the shock as an MO for the escape response, the reinforcer for which is shock termination. However, the capacity for the warning stimulus to establish its own termination as an effective reinforcer is a result of the organism's learning history, involving the pairing of the warning stimulus and shock. In other words, the warning stimulus evokes the avoidance response as a CMO, just as the painful stimulation evokes the escape response as a UMO.

The warning stimulus is not an S^D correlated with the *availability* of the consequence, but rather an MO related to the *reinforcing effectiveness* of the consequence. Recall that a discriminative stimulus is related to the current availability of a type of consequence for a given type of behavior. Availability is defined by two components: (a) An effective consequence (i.e., one whose MO is currently in effect) must have followed the response in the presence of the stimulus; and (b) the response must have occurred without the consequence (which would have been effective as a reinforcer if it had been obtained) in the absence of the stimulus. The relation between the warning stimulus and consequence availability does not meet the second requirement. In the absence of the warning stimulus, there is no effective consequence that could have failed to follow the response as an analog to the extinction responding that occurs in the absence of an S^D. The fact that the avoidance response does not turn off the absent warning stimulus is like the unavailability of food reinforcement for a food-satiated organism.

By contrast, a stimulus that has preceded some form of improvement may function as a CMO-R by (a) establishing its own offset as an effective punisher and (b) abating any behavior that has been so punished. For example, a positive evaluation from an employer may have been followed by a promotion or some sort of monetary bonus. This history would establish the offset of positive evaluations as a form of punishment and likely reduce the frequency of all behaviors that may have resulted in a bad evaluation (e.g., being late). Although this relation is quite plausible, little research has seemed to focus on this type of CMO-R.

The CMO-R plays an important role in identifying the negative aspects of many everyday interactions. Imagine that a stranger asks you where a particular building is located or asks for the time. The appropriate response is to give the information quickly or to say you don't know. Typically, the person who asked will smile and say, "thank you". Also, your question may be reinforced by the knowledge that a fellow human being has been helped (Skinner, 1957). In a sense, the question is an opportunity to obtain reinforcers that were not previously available. However, the question also begins a brief period that can be considered a warning stimulus, and if a response is not made soon, a form of social worsening (awkwardness) will occur. The stranger may repeat the question, stating it more clearly or more loudly, and will certainly think you are socially inept if you do not respond quickly. You would also consider it inappropriate to provide no answer. Even when no clear threat for nonresponding is implied by the person who asked, our social history under such conditions implies a form of worsening for continued inappropriate behavior. Many such situations probably involve a mixture of positive and negative components, but in those cases in which answering the question is an inconvenience (e.g., the listener is in a hurry), the stranger's thanks is not a strong reinforcer, nor is helping one's fellow human being, and the CMO-R is probably the main controlling variable.

Another example is when a person thanks another for doing a kindness of some sort. Saying "thanks" is evoked by the person's performing the favor or the kindness. Performing the favor may be considered an S^D in the presence of which one has learned to say "Thank you" and received reinforcement

BOX 16.3

What's an Aversive Stimulus?

A stimulus may be called aversive because its contingent removal functions as reinforcement, because its contingent presentation functions as punishment, because it evokes behavior that in the past has terminated it as an MO, or because it has evocative effects with respect to certain smooth muscle and glandular responses (e.g., heart rate increase, adrenal secretion) (Michael, 1993). Thus, *aversive stimulus* does not imply a specific functional relation; it is simply a behavioral translation of common sense expressions for "unpleasant feeling," "unpleasant states of mind," and so on—a form of usage possibly fostered by the term's lack of specificity.

consisting of the other person saying, "You're welcome." However, in many cases, ordinary courteous remarks may involve a CMO-R component. Consider the following scenario. Bill has his arms full, carrying something out of the building to his car. As he approaches the outer door, Danielle opens the door and holds it for Bill. Ordinarily, Bill would then smile and say, "Thanks." The CMO-R component can be illustrated by supposing that Bill just walks out without acknowledging the favor. In such circumstances, it would not be unusual for Danielle to call out sarcastically, "You're welcome!" Someone's favor may function as a warning stimulus (a CMO-R) that has systematically preceded some form of disapproval in the absence of some form of acknowledgement (saying "Thanks").

In the typical laboratory avoidance procedure, the response terminates the warning stimulus. In extending this analysis to the human situation, it must be recognized that the warning stimulus is not simply the event that initiated the interaction. In the previous example, the CMO-R is not the vocal request itself, which is too brief to be terminated. It is, instead, the more complex social stimulus situation consisting of having been asked and not having made a response during the time when such a response would be appropriate. The termination of that situation is the reinforcement for the response. Some social interactions with a stimulus—a facial expression, an aggressive posture—are more like the warning stimulus seen in the laboratory that can be terminated by the avoidance response, but most involve the more complex stimulus condition consisting of the request and the subsequent period described earlier.

In applied behavior analysis, the CMO-R is a component of training procedures for teaching individuals with defective social and verbal repertoires. During early intensive behavioral intervention, for example, learners are typically asked questions or given verbal instructions, followed by verbal or physical prompts so they can respond correctly. This arrangement may function as CMO-Rs, which will be followed by further intense social interaction if they do not respond appropriately (e.g., error correction). Such questions and instructions may be functioning primarily as CMO-Rs, rather than S^Ds related to the possibility of receiving praise or other positive reinforcers (Carbone et al., 2010). In other words, in these situations, it is likely that correct responses are partially maintained by negative rather than positive reinforcement. In addition to establishing their own removal as a reinforcer and evoking escape-maintained behaviors, these instructions may establish the value of activities or items unrelated to the task at hand as conditioned reinforcers. In this case, the instructions would function as transitive CMOs, as described in the following section (Michael, 2000). Figure 16.8 illustrates how, after preceding an aversive event, an instruction may become a CMO-R that would (a) establish its own removal as a conditioned reinforcer and (b) evoke any behavior that has produced such a reinforcer, such as compliance with the instruction.

Behaviors maintained by negative reinforcement are under the influence of a variety of antecedent stimuli, including task difficulty as a CMO-R. Changing these tasks may abolish the reinforcing effects of negative reinforcement and abate undesirable escape behaviors (Smith & Iwata, 1997). As an attempt to assess the function of problem behavior, as well as identify the specific features of the environment that served as EOs, McComas, Hoch, Paone, and El-Roy (2000) exposed three children diagnosed with developmental disabilities to a typical experimental functional analysis, a descriptive assessment to generate hypotheses about possible antecedents for destructive behavior, and an analysis in which they tested the evocative effects of the hypothesized EOs. Although all participants engaged in problem behavior in the presence of task demands, the specific task features that evoked problem behavior (CMO-Rs) varied across participants. However, problem behavior by all participants was reduced simply by making specific modifications to the instructional methods, without modifying the demands. For one participant (Eli), problem behavior was evoked by a novel or difficult task (CMO-R). During the EO analysis, the authors compared the level of problem behavior when an instructional strategy was used (i.e., manipulables available during a math task) versus when the strategy was not used. Problem behavior rarely occurred when the strategy was used, suggesting that the establishing and evocative effects of task demands on escape-maintained problem behavior were eliminated by the addition of the instructional strategy. This effect may have been achieved by making the tasks less difficult and, thus, unpairing task demands with aversive properties.

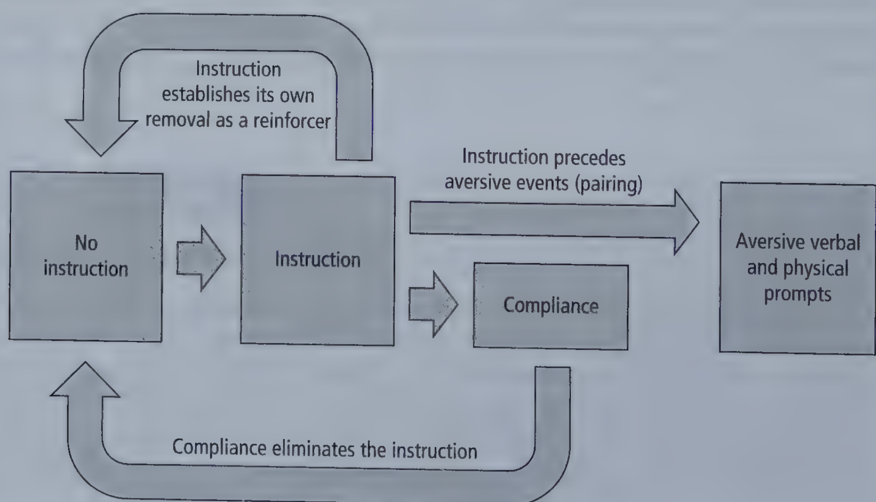

Figure 16.8 Illustration of how an instruction may become a reflexive conditioned motivating operation (CMO-R).

Results from a sample participant are shown in Figure 16.9. Functional analysis (top panel) suggested that problem behavior consisted of escape from academic tasks. During the EO analysis and follow-up (middle panel), problem behavior did not occur when the instructional strategy was employed, compared to when it was not. Additionally, the participant was more compliant when the instructional strategy was available (bottom panel).

Numerous treatments to weaken or abolish CMO-Rs that evoke problem behavior in the presence of task demands have been evaluated (see Carbone et al., 2010, for a review). These include programming competing reinforcers for compliance (e.g., Piazza et al., 1997), pairing stimuli that evoke problem behavior with reinforcement by embedding preferred activities during task presentation (e.g., Kemp & Carr, 1995), reducing the aversiveness of the task by using errorless procedures (Heckaman, Alber, Hooper, & Heward, 1998), systematically fading instructional demands (Pace, Iwata, Cowdery, Andree, & McIntyre, 1993), varying the tasks being presented (McComas et al. 2000; Winterling, Dunlap, & O'Neill, 1987), increasing the pace of instruction to produce higher rates of reinforcement for appropriate behavior (Roxburgh & Carbone, 2013), presenting highly preferred activities and low demands to neutralize CMO-Rs occurring prior to the session (e.g., Horner, Day, & Day, 1997), reducing the aversiveness of tasks by providing choices of activities and reinforcers during sessions (Dyer, Dunlap, & Winterling, 1990), interspersing easy tasks with difficult ones (Mace & Belfiore, 1990), gradually introducing novel tasks (Smith, Iwata, Goh, & Shore, 1995), and modifying task duration based on whether participants engage in problem behavior early or late in the session (Smith et al., 1995). It may also be possible to weaken the CMO-R by unpairing it with the aversive stimulus it precedes (Kettering, Neef, Kelley, & Heward, 2018).

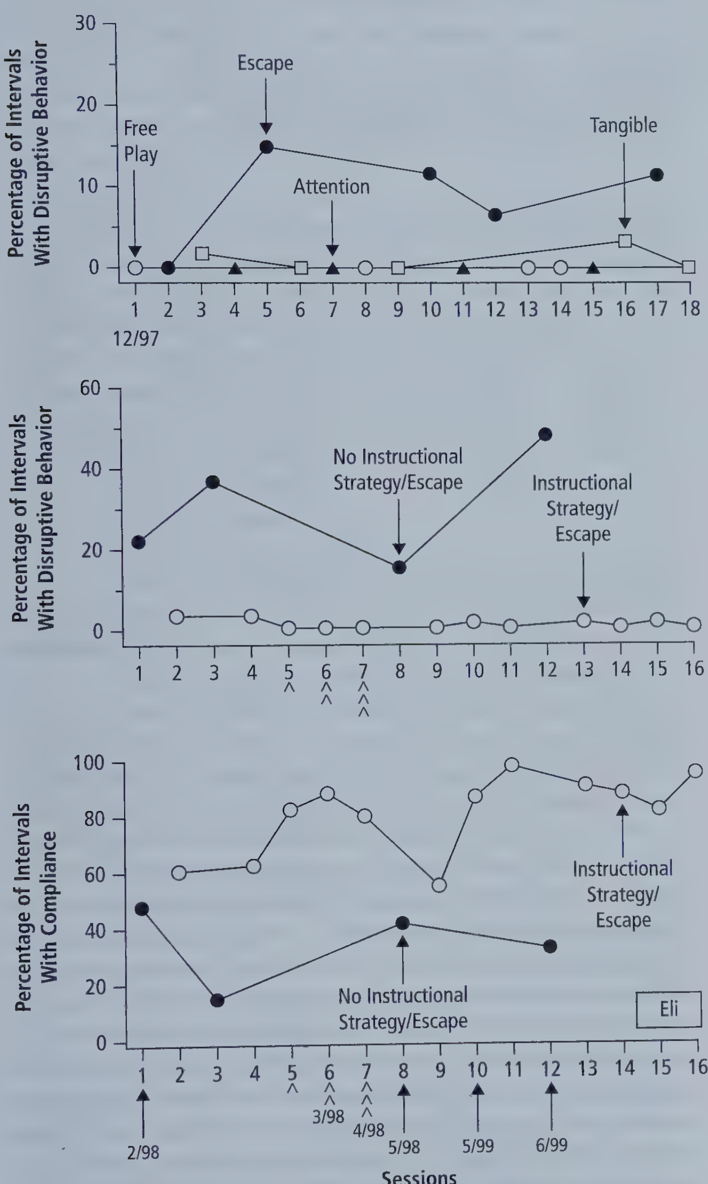

Figure 1. Percentage of intervals with shirt biting for Eli in the functional analysis (top panel) and EO analysis and follow-up (middle panel). Percentage of intervals with compliance is depicted in the bottom panel. Follow-up sessions begin in Session 5. The single carat indicates probe in novel setting, the double carat indicates probe with novel instructor, and the triple carat indicates probe with novel materials.

Figure 16.9 Example of control by a motivating operation a reflexive CMO (CMO-R).

From "Escape Behavior During Academic Tasks: A Preliminary Analysis of Idiosyncratic Establishing Operations" by J. J. McComas, H. Hoch, H., D. Paone, and D. El-Roy 2000, Reproduced with permission of John Wiley & Sons Inc.

It is important to note that negatively reinforced problem behaviors improve environmental conditions that are otherwise poor. Thus, it is the behavior analyst's ethical duty to identify and modify these aversive variables (including CMO-Rs), rather than simply reduce problem behavior through some form of consequence manipulation such as escape extinction (Carbone et al., 2010; McGill, 1999).

Transitive CMO (CMO-T)

When an environmental variable establishes the effectiveness of another event as a reinforcer or punisher, it is referred to as a CMO-T. This type of MO was previously described in the behavior analytic literature as an *establishing stimulus* (S^E; Michael, 1982) or *blocked-response CEO* (Michael, 1988; also see Miguel, 2013). Conditioned reinforcers are dependent upon a variable functioning as a CMO-T. Thus, all variables that function as UMOs also function as CMO-Ts for the stimuli that are conditioned reinforcers because of their relation to the relevant unconditioned reinforcer. For example, not only is food deprivation a UMO that momentarily (a) establishes the value of food as an unconditioned reinforcer and (b) evokes all behaviors that have produced food in the past; food deprivation is also a CMO-T that momentarily (a) establishes the value of all conditioned reinforcers paired with food (e.g., an attentive server in a restaurant, a menu, utensils) and (b) evokes all behaviors that have produced these conditioned reinforcers in the past.[14]

Consider the simple operant chain described earlier: A food-deprived rat pulls a cord that turns on a buzzer. In the presence of the buzzer sound, the rat then presses a lever and receives a food pellet. Food deprivation as a UMO makes food effective as an unconditioned reinforcer, a relation that requires no learning history. Food deprivation as a CMO-T also makes the buzzer sound effective as a conditioned reinforcer, which

clearly requires a learning history. Thus, food deprivation is a UMO with respect to the reinforcing effectiveness of food, and a CMO-T with respect to the reinforcing effectiveness of the buzzer sound. Conversely, food ingestion is a UMO that abolishes the reinforcing effectiveness of food and the buzzer sound.

In the Mexican restaurant, we may need to call the waiter to get his attention prior to ordering our tacos. In this scenario, food deprivation functions as a UMO that establishes food as an unconditioned reinforcer, and as a CMO-T that establishes the sight of the waiter as a conditioned reinforcer. As in the rat example above, food ingestion would decrease the reinforcing values of both food and the waiter.

Other UMOs, such as painful stimulation, also establish the reinforcing value of conditioned reinforcers. As mentioned above, as a UMO, a headache would establish its own removal as an unconditioned reinforcer. However, as a CMO-T, a headache also establishes the reinforcing value of other stimuli (e.g., aspirin) that have served to reduce headaches.

The relationship between UMOs and conditioned reinforcers cannot be overlooked by clinicians or educators who may make extensive use of conditioned reinforcers, including generalized ones, to strengthen academic or other socially significant behaviors. Studies have shown that the value of generalized conditioned reinforcers in the form of tokens decreases when participants have access to the primary and conditioned reinforcers paired with the tokens (Ivy, Neef, Meindl, & Miller, 2016; Moher, Gould, Hegg, & Mahoney, 2008). Conversely, when participants have restricted access to back-up reinforcers, tokens are more effective reinforcers, as evidenced by an increased rate of responding. In practice, these data suggest that the value of conditioned and generalized conditioned reinforcers (e.g., tokens) depends upon the MO relevant to their back-up reinforcers. Thus, it seems reasonable to assume that the effectiveness of generalized reinforcers would be increased when paired with a greater number of back-up reinforcers (Skinner, 1957, p. 54). More specifically, satiation may be prevented by pairing the putative generalized reinforcer with a variety of back-up reinforcers, such as food and drink that are under control of dissimilar MOs (Moher et al., 2008). Money, for instance, seems almost completely free from MO control, given that it has been paired with a multitude of effective reinforcers related to several different MOs. Thus, it is likely that one or more of these MOs will be in effect when money is delivered contingent on behavior, making its effectiveness almost impossible to abolish.

The reinforcing effectiveness of many (probably most) conditioned reinforcers is not only altered by relevant UMOs, as described above, but also dependent on other stimulus conditions. This is why the effectiveness of conditioned reinforcers is often said to be "context" dependent. When the context is not appropriate, the stimuli may be available but are not accessed because they are not effective as reinforcers. A change to an appropriate context will evoke behavior that has been followed by those stimuli, which are now effective as conditioned reinforcers. The occurrence of the behavior is not related to the availability, but rather to the value, of its consequence. For example, flashlights are usually available in home settings but are not accessed until a power failure makes them valuable. In this sense, the power failure (the sudden darkness) *evokes* the behavior that has obtained the flashlight in the past (rummaging around in a particular drawer). However, when the light is back on, the value of the flashlight as a reinforcer is abolished, and any behaviors that led to the flashlight are momentarily abated. The motivating nature of this CMO-T relation is not widely recognized, and the evocative variable (the sudden darkness) in this example is usually interpreted as an S^D.

Consider a workman disassembling a piece of equipment, with his assistant handing him tools as he requests them.[15] The workman encounters a slotted screw that must be removed and requests a screwdriver. The sight of the screw evoked the request, the reinforcement for which is receiving the tool. Prior to an analysis in terms of the CMO-T, the sight of the screw would have been considered an S^D for the request, but such screws have *not* been differentially related to the availability of reinforcement for requests for tools. In the typical workman's history, assistants have provided requested tools irrespective of the stimulus conditions in which the request occurred. The sight of the screw is more accurately interpreted as a CMO-T for the request, not as an S^D.

The fact that several S^Ds are involved in this complex situation makes the analysis somewhat difficult. The screw *is* an S^D for unscrewing movements (with a screwdriver in hand) or for selecting a screwdriver rather than another tool. The workman's verbal request for a screwdriver, although evoked by the sight of the slotted screw as a CMO-T, is dependent on the assistant's presence as an S^D. The offered screwdriver is also an S^D for the workman reaching to grasp it. The critical issue here, however, is the screw's role in evoking the request, and this is a motivating rather than a discriminative relation (Michael, 1982).

Another common example involves a stimulus related to some form of danger that evokes some relevant protective behavior. Imagine a night security guard is patrolling an area and hears a suspicious sound. He pushes a button on his phone that signals another security guard, who then activates his phone and asks if help is needed (which reinforces the first guard's call). The suspicious sound is not an S^D in the presence of which the second security guard's response is more available (the second guard would respond to the first guard's call whether or not the first guard heard the sound), but rather a CMO-T in the presence of which second guard's response is more valuable. S^Ds are involved, however. A ringing phone *is* an S^D in the presence of which one has activated the phone, said something into the receiver, and been reinforced by hearing a response from another person. Answering phones that are not ringing has typically not been so reinforced.[16] (Note, incidentally, that the effect of the danger signal is not to evoke behavior that produces its own termination, as with the CMO-R, but rather behavior that produces some other event, in this case, the sound of the security guard's colleague offering to help.)

Figure 16.10 shows an example of sudden darkness functioning as a CMO-T that establishes a flashlight as a conditioned reinforcer, as well as evoking the behavior of looking for a flashlight. Note that sudden darkness may also function as a CMO-R that establishes its own removal as a reinforcer.[17]

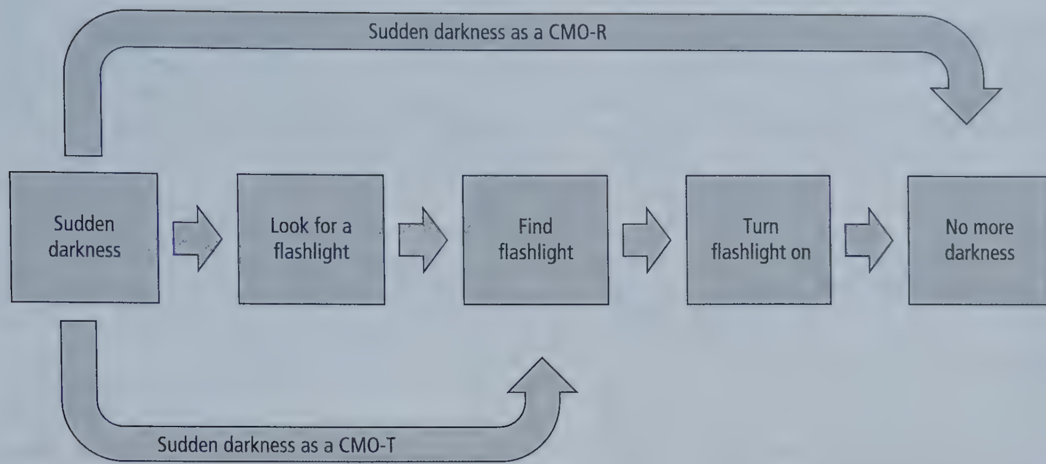

Figure 16.10 Illustration of a transitive conditioned motivating operation (CMO-T).

The distinction between an S^D and a CMO-T hinges on the relation between reinforcer availability and the presence or absence of the stimulus. If the reinforcer is more available in the presence than in the absence of the stimulus, the stimulus is an S^D; if the reinforcer is equally available in the absence and presence of the stimulus, the stimulus is a CMO-T. Screwdrivers have typically been available to the workman in the absence as well as in the presence of screws. The response by the security guard's colleague has been just as available in the absence as in the presence of a suspicious noise.

A CMO-T evokes behavior because of its relation to the *value* of a consequence rather than to the *availability* of a consequence. The two forms of behavioral control, the S^D and the CMO-T, which are so different in origin, would be expected to differ in other important ways. This is an example of terminological refinement in behavior analysis, not a discovery of new empirical relations. The value of this refinement will be found in the improved theoretical and practical effectiveness of behavior analysts whose verbal behavior has been affected by it.

Teaching Mands with CMO-Ts. Mand training is an essential aspect of language programs for individuals with severely deficient verbal repertoires (see Chapter 18). For such individuals, manding does not spontaneously arise from tact and receptive discrimination training (i.e., listener behavior). The learner has to want something, make an appropriate verbal response, and be reinforced by receiving what was wanted. This procedure places the response under control of the relevant MO. The manipulation of CMO-Ts allows the teacher to contrive a situation to get the learner to want something that can be a means to another end (e.g., obtaining information by asking a question). Any stimulus, object, or event can be a basis for a mand simply by arranging an environment in which that stimulus can function as a conditioned reinforcer. Thus, if a pencil mark on a piece of paper is required for an opportunity to play with a favorite toy, a mand for a pencil and for a piece of paper can be taught.

The manipulation of CMO-Ts is common practice when teaching mands to individuals with disabilities (e.g., Alwell, Hunt, Goetz, & Sailor, 1989; Betz, Higbee, & Pollard, 2010; Goetz, Gee, & Sailor, 1985; Lechago, Carr, Grow, Love, & Almason, 2010; Shillingsburg, Valentino, Bowen, Bradley, & Zavatkay, 2011). The typical procedure, termed *interrupted-chain* (Hall & Sundberg, 1987) involves withholding an item the learner needs to complete a previously learned task. This manipulation functions as a CMO-T, increasing the value of the item as a reinforcer, which creates the ideal condition for teaching the learner to mand for it. In a mand training study, Shillingsburg, Bowen, Valentino, and Pierce (2014) exposed three children with disabilities to two scenarios. One scenario involved varying the placement of a preferred item in one of nine different colored (or animal) cups. A stimulus that signaled the preferred item (e.g., an empty Skittles bag) was then placed next to the participant. When the participant asked for the item (e.g., "May I have a Skittle?"), the experimenter responded by saying that the item was under one of the cups, increasing the value of the information for the location of the item (which cup) as a conditioned reinforcer. The second scenario involved giving a highly preferred item to one of three adults when the participant was not looking. The stimulus that signaled the presence of the preferred item was presented again, and when the child asked for it, the therapist said that one of the other adults had it, without saying whom. This statement served as a CMO-T that increased the value of the information about who had the item as a conditioned reinforcer. The authors used a vocal prompt delay to teach participants to ask, "which cup?" and "who has it?" in scenarios 1 and 2, respectively. These CMO-T trials were alternated with trials in which the information was not valued as a reinforcer (abolishing operation; AO) to guarantee that behavior came under control of the EO, versus some other aspect of the environment. During AO trials, the therapist provided either the information about the location of the item or the name of the person who had it. In addition to the emission of mands, the authors also collected data on whether participants selected the correct cup or approached the correct adult to obtain the preferred item. All participants manded using "which" and "who" more often during EO rather than AO conditions, and approached the preferred items during both conditions, suggesting that the interrupted chain procedure was successful in placing mands under functional control of CMO-Ts. Figure 16.11 shows the results for the "which" questions. None of the participants manded for information during

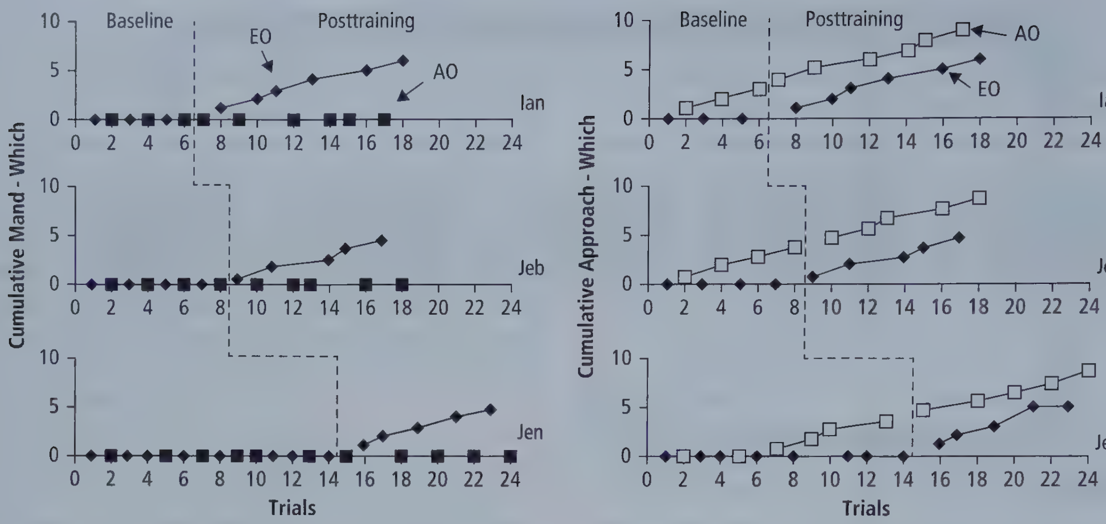

Figure 1. Cumulative record of independent responses for manding "which?" (left) and cumulative record for approach behavior (right) during baseline and posttraining probes for Ian, Jeb, and Jen.

Figure 16.11 Example of control by a motivating operation a transitive CMO (CMO-T).

From "Mands for Information Using "Who?" and "Which?" in the Presence of Establishing and Abolishing Operations" by M, A. Shillingsburg, C. N. Bowen, A. L. Valentino, and L. W. Pierce, 2014, Reproduced with permission of John Wiley & Sons Inc.

baseline (left panel), although each selected the correct container during the AO condition during which the information on the location of the item was provided (right panel). After training, participants manded only during the EO condition (left panel). Additionally, after receiving the information during the EO condition, participants started to select the correct containers to access the preferred item (right panel). Similar results were obtained for the "who" questions. Chapter 18 provides additional details about using CMO-Ts during mand training.

RELEVANCE OF MOs TO THE GENERALITY OF TREATMENT EFFECTS

In the applied area, the reinforcer-establishing effect of MOs seems to be well understood, as clinicians may temporarily withhold edibles, tangibles, and even social attention to make them more effective as reinforcers for behaviors being taught (e.g., Taylor et al., 2005). However, these target behaviors will not occur in future or novel circumstances, even if well learned and part of the learner's repertoire, unless relevant MOs are in effect (Fragale et al., 2012; O'Reilly et al., 2012). Fragale and colleagues have shown that after teaching three children diagnosed with autism to mand for preferred items and testing for generalization across settings, the newly acquired mands occurred almost exclusively when items had been restricted prior to the session and seldom occurred when participants could access the items prior to sessions. These results show that even if well established, a behavior may not occur in the future in a new setting if the MO is absent. Thus, it is possible that generalization and maintenance failures are not only a function of novel (generalization) stimuli being dissimilar to those present during training, but also due to different MOs. Thus, when programming for generalization, clinicians must do so not only across different discriminative stimuli (Stokes & Baer, 1977) but also across different MOs (Miguel, 2017). In summary, for a newly acquired response to be generalized and maintained, its relevant MO must also be in effect.

RELEVANCE OF MOs TO APPLIED BEHAVIOR ANALYSIS

Applied behavior analytic research has shown the effects of MOs on a multitude of behaviors across a variety of conditions. MOs have affected the results of preference assessments (Gottschalk, Libby, & Graff, 2000; McAdam et al., 2005) and functional analyses (Fischer, Iwata, & Worsdell, 1997; Worsdell, Iwata, Conners, Kahng, & Thompson, 2000), engagement with activities (Klatt et al., 2000; Vollmer & Iwata, 1991), within-session responding (Roane, Lerman, Kelley, & Van Camp, 1999), social initiations (Taylor et al., 2005), the rate of acquisition of target behaviors (Ivy et al., 2016), and the occurrence of challenging behaviors (O'Reilly et al., 2007).

Gottschalk and colleagues (2000), for instance, compared the results of preference assessments of four children with autism under three conditions. In the control condition, participants had access to four edible items in premeasured portions, 3 times, 24 hr prior to the assessment. In the satiation condition, the same access to premeasured portions was provided, but the participants had free access to one of the stimuli for 10 min prior to the assessment. Finally, in the deprivation condition, participants had the same premeasured portions, but were deprived of one stimulus for 48 hr prior to the assessment. Results showed that across all participants, approach responses were higher during deprivation conditions. These results were replicated with leisure items with both typically developing children and individuals with intellectual disabilities (McAdam et al., 2005) and suggest that results of preference assessments are highly dependent on current MOs.

As an attempt to evaluate the effects of MOs on the results of functional analyses, Worsdell et al. (2000) exposed six individuals with profound intellectual disabilities who engaged in self-injury to an experimental functional analysis (FA), followed by another FA in which the MO and the reinforcer for problem behavior were present or absent. During the EO condition, the experimenter ignored all but problem behavior, while in the AO condition, the experimenter delivered noncontingent reinforcement. These conditions were associated with either the presence or the absence of continuous reinforcement. The authors reported high rates of problem behavior for all participants during the condition in which the EO and reinforcement were present, and almost no responding when both the EO and reinforcement were absent, or when the EO was present and reinforcement was absent. These results are consistent with the conceptualization that for behavior to occur, it must be followed by an *effective* reinforcer, and suggest that MOs may differentially affect the results of FAs.

As previously discussed, in addition to affecting results of commonly used behavior analytic assessments, MOs have been shown to directly affect the rate of acquisition of novel behaviors reinforced with primary, conditioned, or generalized reinforcers (e.g., Ivy et al., 2016; Lang et al., 2009; Moher et al., 2008; O'Reilly et al., 2009), as well as the frequency of behaviors that have already been acquired (e.g., Klatt et al., 2000). Behavior analysts have also directly manipulated MOs to reduce problem behaviors (e.g., Rapp, Cook, McHugh, & Mann, 2017) and teach new skills (Lechago et al., 2010).

Research on MOs falls within the three broad categories previously described by Iwata, Smith, and Michael (1991): demonstrating the effects of MOs on behavior, using MOs to clarify results of assessments, and manipulating MOs to increase or decrease behavior. This ever-growing literature has had much impact on our practice. It allowed behavior analysts to recognize that the three-term contingency is dependent upon a fourth variable that modulates the effectiveness of reinforcement, and hence the evocative strength of discriminative stimuli. A clear understanding of these motivational variables seems critical for interpreting assessment results and designing effective behavior analytic interventions.

As we go about our daily lives, we may clearly identify how MOs influence our own behavior. Revisiting the anecdote about our obsession with Mexican food, we see that food deprivation as a UMO, or, more specifically, not having had Mexican food for some time, increases its value as a reinforcer, and the frequency of previous behaviors that have produced it, such as going to our favorite Mexican restaurant. Food deprivation as a CMO-T establishes the sight of the restaurant as a conditioned reinforcer, increasing any behavior that preceded it (e.g., driving there) and making us happy when we see it. When at the restaurant, the sight of tortilla chips may increase the value of salsa as a reinforcer, as they tend to covary (CMO-S). The spiciness of the salsa establishes its own removal as a reinforcer (CMO-R), which makes us drink water or any other liquid (e.g., too many margaritas). When the chips are gone (CMO-T), we call the waiter to bring us more. And even if we have already eaten, the sight of the restaurant alone (CMO-S) may get us to eat more. Given the ubiquity of motivational variables in our lives, a complete understanding of human behavior demands an analysis of the critical roles of MOs.

SUMMARY

Definition and Characteristics of Motivating Operations

1. A motivating operation (MO) (a) alters the effectiveness of some stimulus as a reinforcer, the value-altering effect; and (b) alters the current frequency of all behavior that has been reinforced by that stimulus, the behavior-altering effect.
